11 Salivary Gland Pathology

SALIVARY GLAND APLASIA/HYPOPLASIA

Salivary gland aplasia or **hypoplasia** is a rare developmental anomaly that can affect one or more of the major salivary glands. The condition may occur alone, although agenesis or hypoplasia of the glands is often a component of one of several syndromes (Box 11.1).

Clinical and Radiographic Features

Salivary gland aplasia/hypoplasia has been reported more frequently in males than females by a 2:1 ratio. Some individuals are affected by agenesis of all four of the largest glands (both parotids and submandibular glands), but others may be missing only one to three of the four glands. In spite of the absence of the glands, the face often has a normal appearance because the sites are filled in by fat or connective tissue. Intraorally, the orifices of the missing glands are absent. Some patients also may exhibit absence of the lacrimal glands or lacrimal puncta.

As would be anticipated, the most significant symptom associated with salivary gland aplasia is severe xerostomia with its attendant problems (see page 470). The tongue may appear leathery, and the patient is at greater risk for developing dental caries and erosion (Fig. 11.1). However, some degree of moisture still may be present because of the continued activity of the minor salivary glands. Absence of the major glands can be confirmed by technetium-99m pertechnetate scintiscan, computed tomography (CT), magnetic resonance imaging (MRI), or ultrasonography.

Lacrimo-auriculo-dento-digital (LADD) syndrome is an autosomal dominant disorder that is caused by a mutation in one the following genes: fibroblast growth factor 10 *(FGF10)*, fibroblast growth factor receptor 2 (*FGFR2*), or fibroblast growth factor receptor 3 (*FGFR3*). It is characterized by aplasia or hypoplasia of the lacrimal and salivary glands, cup-shaped ears, hearing loss, and dental and digital anomalies. Dental features may include hypodontia, microdontia, and mild enamel hypoplasia.

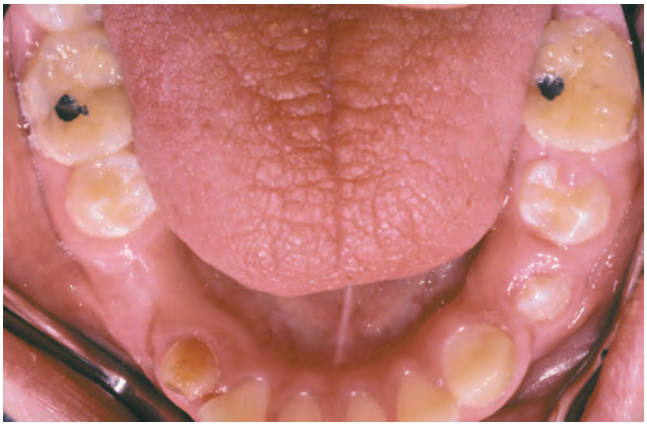
Treatment and Prognosis

Patient management is directed toward compensating for the saliva deficiency, and saliva substitutes are often necessary. If any residual functional salivary gland tissue is present, then sialagogue medications (such as, pilocarpine or cevimeline) may be used to increase saliva production. Salivary flow also may be stimulated via the use of sugarless gum or sour candy. Regular preventive dental care is important to avoid xerostomia-related caries and enamel breakdown.

MUCOCELE (MUCUS EXTRAVASATION PHENOMENON; MUCUS ESCAPE REACTION)

The **mucocele** is a common lesion of the oral mucosa that results from rupture of a salivary gland duct and spillage of mucin into the surrounding soft tissues. This spillage is often the result of local trauma, although there is no known history of trauma in many cases. Unlike the salivary duct cyst (see page 463), the mucocele is not a true cyst because it lacks an epithelial lining. Some authors, however, have included true salivary duct cysts in their reported series of mucoceles, sometimes under the classification of *retention mucocele* or *mucus retention cyst*. Because these two entities exhibit distinctly different clinical and histopathologic features, they are discussed as separate topics in this chapter.

Clinical Features



Mucoceles typically appear as dome-shaped mucosal swellings that can range from 1 or 2 mm to several centimeters in size (Figs. 11.2–11.4). They are most common in children and young adults, perhaps because younger people are more likely to experience trauma that induces mucin spillage. However, mucoceles have been reported in patients of all ages, including infants and older adults. The spilled mucin below the mucosal surface often imparts a bluish translucent hue to the swelling, although deeper mucoceles may be normal in color. The lesion characteristically is fluctuant, but some mucoceles feel firmer to palpation. The reported duration of the lesion can vary from a few days to several years; most patients report that the lesion has been present for several weeks. Many patients relate a history of a recurrent swelling that periodically may rupture and release its fluid contents.

The lower lip is by far the most common site for the mucocele; a recent large study of 1715 cases found that 81.9% occurred at this one site (Table 11.1). Lower lip

• Fig. 11.2 Mucocele. Blue-pigmented nodule on the lower lip.

mucoceles usually are found lateral to the midline. Less common sites include the floor of mouth (ranulas: 5.8%), anterior ventral tongue (from the glands of Blandin-Nuhn: 5.0%), buccal mucosa (4.8%), palate (1.3%), and retromolar pad (0.5%). Mucoceles rarely develop on the upper lip. In the large series summarized in Table 11.1, not a single example was identified from the upper lip. This is in contrast to salivary gland tumors, which are not unusual in the upper lip but are distinctly uncommon in the lower lip.

As noted, the soft palate and retromolar area are uncommon sites for mucoceles. However, one interesting variant, the **superficial mucocele,** does develop in these areas and

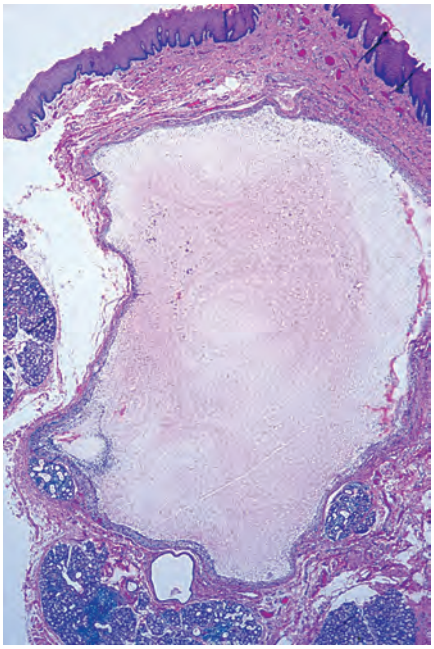
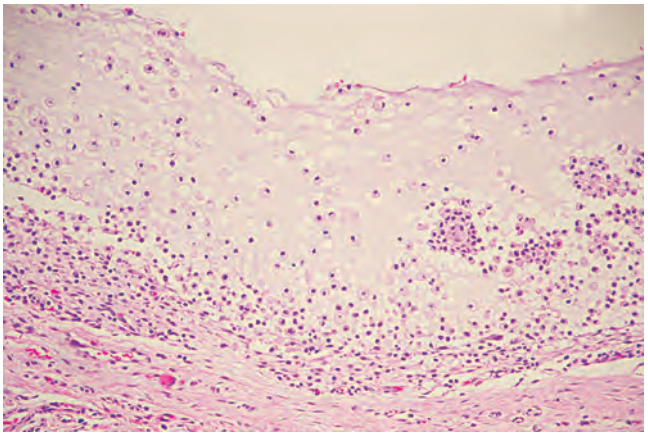
dentlearn.ir

• **Fig. 11.5 Superficial Mucocele.** Vesicle-like lesion on the soft palate.



along the posterior buccal mucosa. Superficial mucoceles present as single or multiple tense vesicles that measure 1–4 mm in diameter (Fig. 11.5). The lesions often burst, leaving shallow, painful ulcers that heal within a few days. Repeated episodes at the same location are not unusual. Some patients relate the development of the lesions to mealtimes. Superficial mucoceles also have been reported to occur in association with lichenoid disorders, such as lichen planus, lichenoid drug eruptions, and chronic graft-versus-host disease (GVHD). The vesicular appearance is created by the superficial nature of the mucin spillage, which causes a separation of the epithelium from the connective tissue. The pathologist must be aware of this lesion and should not mistake it microscopically for a vesiculobullous disorder, especially mucous membrane pemphigoid.

Histopathologic Features

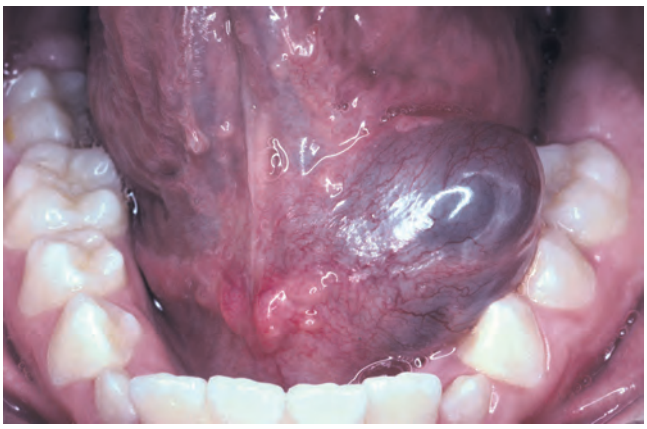


On microscopic examination, the mucocele shows an area of spilled mucin surrounded by a granulation tissue response (Figs. 11.6 and 11.7). The inflammation usually includes numerous foamy histiocytes (macrophages). In some cases, a ruptured salivary duct may be identified feeding into the area. The adjacent minor salivary glands often contain a chronic inflammatory cell infiltrate and dilated ducts.

Treatment and Prognosis

Some mucoceles are short-lived lesions that rupture and heal by themselves. Many lesions, however, are chronic in nature, and local surgical excision is necessary. To minimize the risk of recurrence, the surgeon should remove any adjacent minor salivary glands that may be feeding into the lesion when the area is excised. The excised tissue should be submitted for microscopic examination to confirm the diagnosis and rule out the possibility of a salivary gland tumor. The prognosis is excellent, although occasional mucoceles will recur, necessitating reexcision, especially if the feeding glands are not removed. Mucoceles on the anterior ventral tongue appear to have a higher recurrence rate, which likely is due to the deeper anatomic location of the glands of Blandin-Nuhn.

• **Fig. 11.6 Mucocele.** Mucin-filled cystlike cavity beneath the mucosal surface. Minor salivary glands are present below and lateral to the spilled mucin.



• **Fig. 11.7 Mucocele.** High-power view showing spilled mucin that is associated with granulation tissue containing foamy histiocytes.

◆ RANULA

Ranula is a term used for mucoceles that occur in the floor of the mouth, arising from the sublingual gland. The name is derived from the Latin word *rana,* which means "frog," because the swelling may resemble a frog's translucent underbelly. The term *ranula* also has been used to describe other similar swellings in the floor of the mouth, including true salivary duct cysts, dermoid cysts, and cystic hygromas. However, the term is best used for mucus escape reactions (mucoceles).

The sublingual gland has a complex anatomy. The lesser sublingual gland actually consists of 15–30 smaller glands, each secreting through a short duct of Rivinus to the sublingual plica. Some individuals also have a greater sublingual

dentlearn.ir

• **Fig. 11.8 Ranula.** Blue-pigmented swelling in the left floor of the mouth.

gland with an excretory duct (Bartholin duct) that either joins with Wharton duct or opens next to it at the sublingual caruncle. Unlike the submandibular gland, the sublingual gland produces a continuous flow of mucus even in the absence of neural stimulation, which accounts for its ability to produce a ranula after rupture of one of its multiple ducts.

Clinical Features

The ranula usually appears as a blue, dome-shaped, fluctuant swelling in the floor of the mouth (Fig. 11.8), but deeper lesions may be normal in color. Ranulas are seen most frequently in children and young adults. They tend to be larger than mucoceles in other oral locations, often developing into large masses that fill the floor of the mouth and elevate the tongue. The ranula usually is located lateral to the midline, a feature that may help to distinguish it from a midline dermoid cyst (see page 32). Like other mucoceles, ranulas may rupture and release their mucin contents, only to re-form.

An unusual clinical variant, the **plunging** or **cervical ranula,** occurs when the spilled mucin dissects through the mylohyoid muscle and produces swelling within the neck (Fig. 11.9). A concomitant swelling in the floor of the mouth may or may not be present. If no lesion is produced in the mouth, then the clinical diagnosis of ranula may not be suspected. Imaging studies can be helpful in supporting a diagnosis of plunging ranula and in determining the origin of the lesion. CT, MRI, or ultrasound images of plunging ranulas from the sublingual gland may exhibit a slight extension of the lesion into the sublingual space, known as a "tail sign," although this feature is not always present.

Histopathologic Features

The microscopic appearance of a ranula is similar to that of a mucocele in other locations. The spilled mucin elicits a granulation tissue response that typically contains foamy histiocytes.

• **Fig. 11.9 Plunging Ranula.** Soft swelling in the neck.

Treatment and Prognosis

Treatment of the ranula consists of removal of the feeding sublingual gland and/or marsupialization. Marsupialization (exteriorization) entails removal of the roof of the intraoral lesion, which often can be successful for small, superficial ranulas. However, marsupialization is often unsuccessful for larger ranulas, and most authors emphasize that removal of the offending gland is the most important consideration in preventing a recurrence of the lesion. If the gland is removed, then meticulous dissection of the lining of the lesion may not be necessary for the lesion to resolve, even for the plunging ranula. If the specific portion of the sublingual gland giving rise to the lesion can be identified, then partial excision of the gland may be successful.

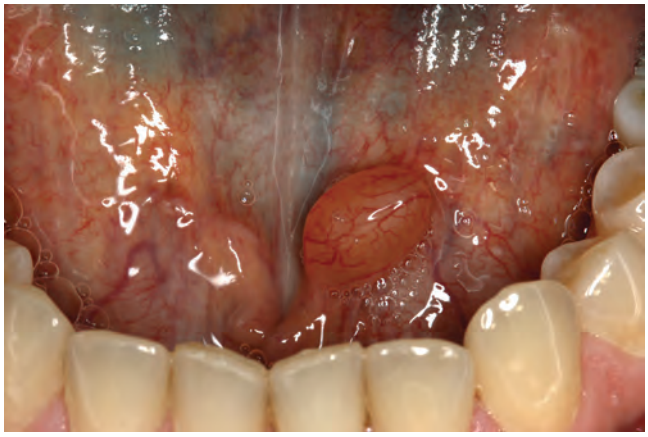
◆ SALIVARY DUCT CYST (MUCUS RETENTION CYST; MUCUS DUCT CYST; SIALOCYST)

The **salivary duct cyst** is an epithelium-lined cavity that arises from salivary gland tissue. Unlike the more common mucocele (see page 460), it is a true developmental cyst that is lined by epithelium that is separate from the adjacent normal salivary ducts. The cause of such cysts is uncertain.

Cystlike dilatation of salivary ducts also may develop secondary to ductal obstruction (e.g., mucus plug), which creates increased intraluminal pressure. Some authors classify such lesions as salivary duct cysts (or *mucus retention cysts*),

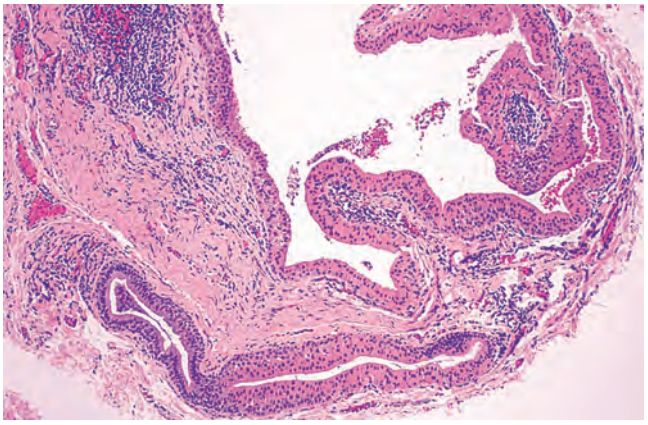
dentlearn.ir

although others believe that these represent salivary ductal ectasia rather than true developmental cysts.



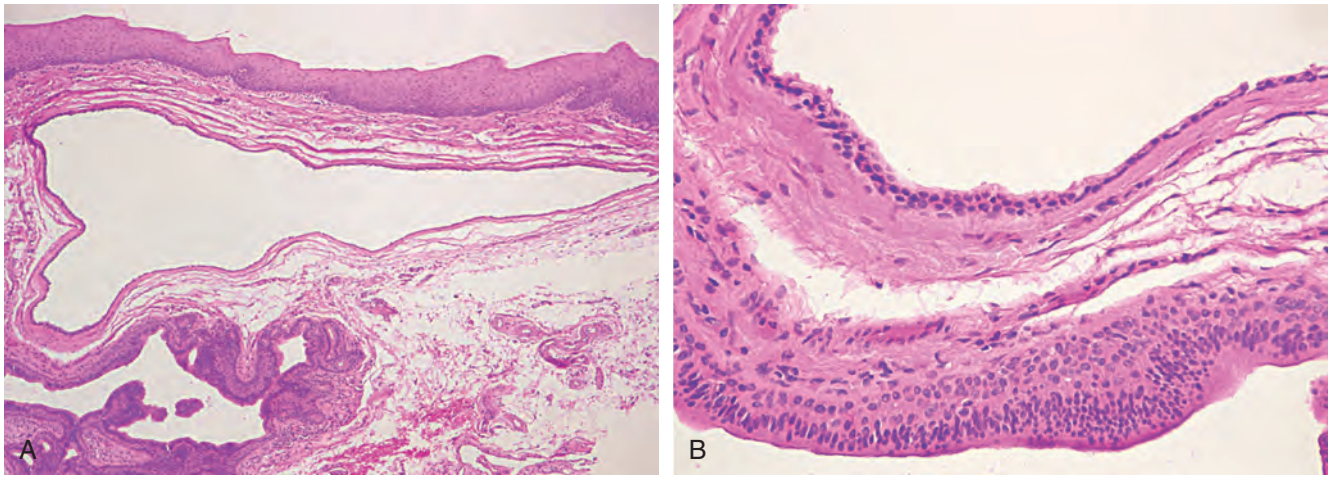
Clinical Features

Salivary duct cysts usually occur in adults and can arise within either the major or minor glands. Cysts of the major glands are most common within the parotid gland, presenting as slowly growing, asymptomatic swellings. Intraoral cysts can occur at any minor gland site, but most frequently they develop in the floor of the mouth, buccal mucosa, and lips (Fig. 11.10). They often look like mucoceles and are characterized by a soft, fluctuant swelling that may appear bluish, depending on the depth of the cyst below the surface. Some cysts may feel relatively firm to palpation. Cysts in the floor of the mouth often arise adjacent to the submandibular duct and sometimes have an amber color.



On rare occasions, patients have been observed to develop prominent ectasia of the excretory ducts of many of the minor salivary glands throughout the mouth. Such lesions have been termed *mucus retention cysts*, although they probably represent multifocal ductal dilatation. The individual lesions often present as painful nodules that demonstrate dilated ductal orifices on the mucosal surface. Mucus or pus may be expressed from these dilated ducts.

Histopathologic Features



The lining of the salivary duct cyst is variable and may consist of cuboidal, columnar, or atrophic squamous epithelium surrounding thin or mucoid secretions in the lumen (Fig. 11.11). Cystlike ductal ectasia secondary to salivary obstruction is characterized by oncocytic metaplasia of the epithelial lining. This epithelium often demonstrates papillary folds into the cystic lumen, somewhat reminiscent of a small Warthin tumor (see page 488) but without the prominent lymphoid stroma (Fig. 11.12). If this proliferation is extensive enough, then these lesions sometimes are diagnosed as **papillary cystadenoma,**

• **Fig. 11.10 Salivary Duct Cyst.** Nodular swelling overlying Wharton duct.

• **Fig. 11.12 Oncocytic Salivary Ductal Ectasia.** This dilated duct is lined by columnar eosinophilic oncocytes that exhibit papillary folds into the ductal lumen. Such lesions may develop secondary to ductal obstruction.

• **Fig. 11.11 Salivary Duct Cyst. A,** Low-power photomicrograph showing a cyst below the mucosal surface. **B,** High-power view of cystic cavity (*top*) lined by thin cuboidal epithelium. Adjacent to the cyst is an excretory salivary gland duct lined by columnar epithelium (*bottom*).

dentlearn.ir

although it seems likely that most are not true neoplasms. The individual lesions of patients with multiple "mucus retention cysts" also show prominent oncocytic metaplasia of the epithelial lining.

Treatment and Prognosis

Isolated salivary duct cysts are treated by conservative surgical excision. For cysts in the major glands, partial or total removal of the gland may be necessary. The lesion should not recur. For patients with multifocal involvement, sialagogue medications may be helpful in stimulating salivary flow, thereby preventing the accumulation of inspissated mucus within the dilated excretory ducts.

◆ SIALOLITHIASIS (SALIVARY CALCULI; SALIVARY STONES)

Sialoliths are calcified structures that develop within the salivary ductal system. Researchers believe that they arise from deposition of calcium salts around a nidus of debris within the duct lumen. This debris may include inspissated mucus, bacteria, ductal epithelial cells, or foreign bodies. The cause of sialoliths is unclear, but their formation can be promoted by chronic sialadenitis and partial obstruction. Their development typically is not related to any systemic derangement in calcium and phosphorus metabolism.

Clinical and Radiographic Features

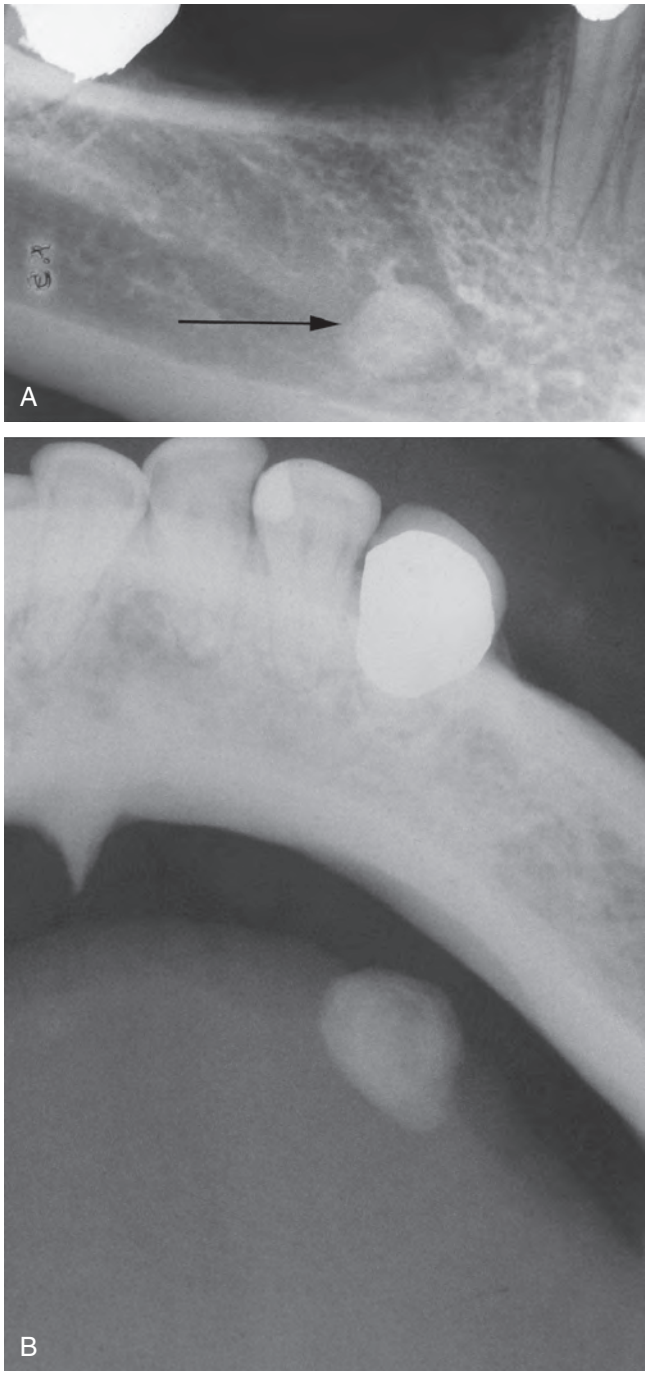
Sialoliths most often develop within the ductal system of the submandibular gland, which accounts for about 80% of cases; the formation of stones within the parotid gland system is distinctly less frequent. The long, tortuous, upward path of the submandibular (Wharton) duct and the thicker, mucoid secretions of this gland may be responsible for its greater tendency to form salivary calculi. Sialoliths also can form within the minor salivary glands, most often within the glands of the upper lip or buccal mucosa. Salivary stones can occur at almost any age, but they are most common in young and middle-aged adults.

Major gland sialoliths most frequently cause episodic pain or swelling of the affected gland, especially at mealtime. The severity of the symptoms varies, depending on the degree of obstruction and the amount of resultant backpressure produced within the gland. If the stone is located toward the terminal portion of the duct, then a hard mass may be palpated beneath the mucosa (Fig. 11.13).

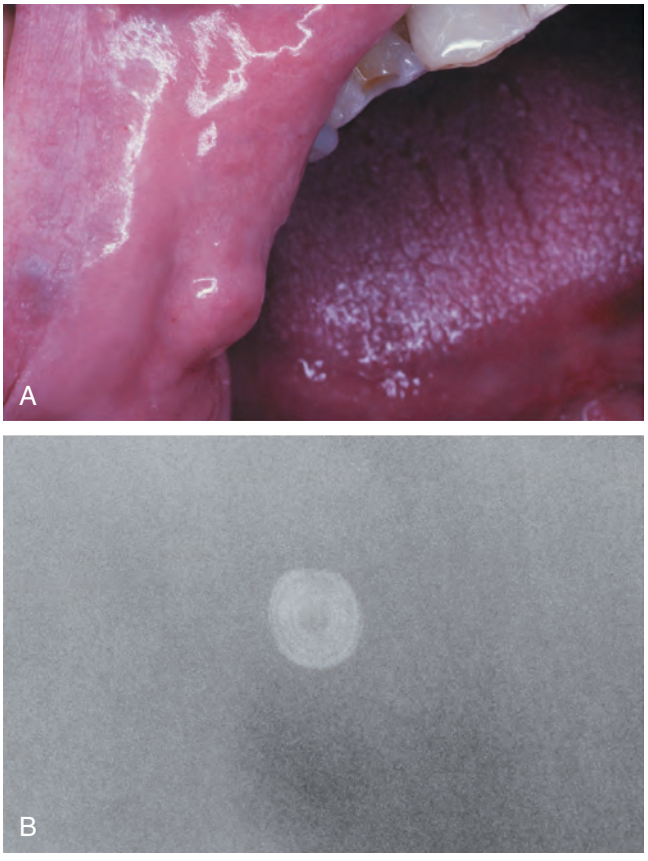
Sialoliths typically appear as radiopaque masses on radiographic examination. However, not all stones are visible on standard radiographs (perhaps because of the degree of calcification of some lesions). They may be discovered anywhere along the length of the duct or within the gland itself (Fig. 11.14). Stones in the terminal portion of the submandibular duct are best demonstrated with an occlusal radiograph. On panoramic or periapical radiographs, the calcification may appear superimposed on the mandible and care must be exercised not to confuse it with an intrabony lesion (Fig. 11.15). Multiple parotid stones radiographically can mimic calcified parotid lymph nodes, such as might occur in tuberculosis. Ultrasound, CT scanning, and sialography may be helpful additional imaging studies for sialoliths. Diagnostic sialendoscopy also can be a valuable tool in the evaluation and diagnosis of ductal obstructions. In this technique, a miniaturized endoscope is inserted into the duct orifice, allowing visualization of the ductal system for any stones, strictures, or adhesions.

Minor gland sialoliths often are asymptomatic but may produce local swelling or tenderness of the affected gland (Fig. 11.16). A small radiopacity often can be demonstrated with a soft tissue radiograph.

• **Fig. 11.13 Sialolithiasis.** Hard mass at the orifice of Wharton duct.

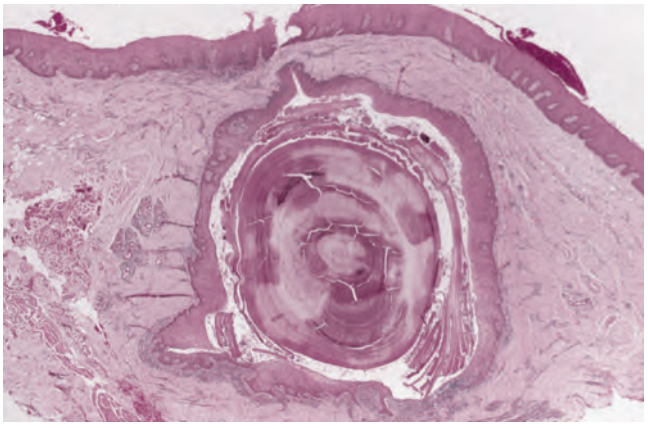


• **Fig. 11.14 Sialolithiasis.** Radiopaque mass located at the left angle of the mandible. (Courtesy of Dr. Roger Bryant.)



Histopathologic Features

On gross examination, sialoliths appear as hard masses that are round, oval, or cylindrical. They are typically yellow, although they may be a white or yellow-brown color. Submandibular stones tend to be larger than those of the parotid or minor glands. Sialoliths are usually solitary, although occasionally two or more stones may be discovered at surgery.



dentlearn.ir

• **Fig. 11.15 Sialolithiasis. A,** Periapical film showing discrete radiopacity (*arrow*) superimposed on the body of the mandible. Care must be taken not to confuse such lesions with intrabony pathosis. **B,** Occlusal radiograph of same patient demonstrating radiopaque stone in Wharton duct.

• **Fig. 11.16 Sialolithiasis. A,** Minor salivary gland sialolith presenting as a hard nodule in the upper lip. **B,** A soft tissue radiograph of the same lesion revealed a laminated calcified mass.

• **Fig. 11.17 Sialolithiasis.** Intraductal calcified mass showing concentric laminations. The duct exhibits squamous metaplasia.

Microscopically, the calcified mass exhibits concentric laminations that may surround a nidus of amorphous debris (Fig. 11.17). If the associated duct also is removed, then it often demonstrates squamous, oncocytic, or mucous cell metaplasia. Periductal inflammation is also evident. The ductal obstruction frequently is associated with an acute or chronic sialadenitis of the feeding gland.

Treatment and Prognosis

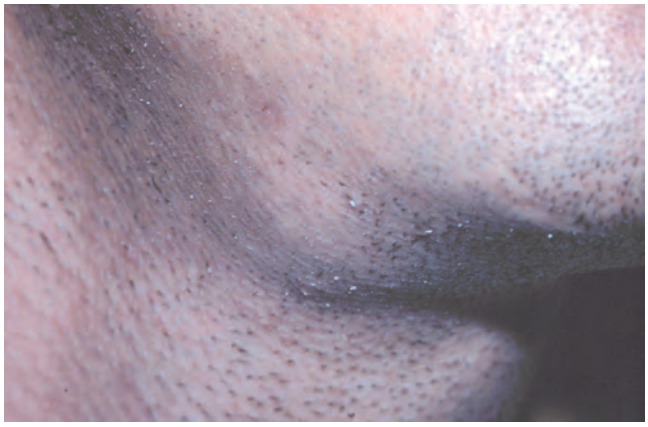
Small sialoliths of the major glands sometimes can be treated conservatively by gentle massage of the gland in an effort to milk the stone toward the duct orifice. Sialagogues (drugs that stimulate salivary flow), moist heat, and increased fluid intake also may promote passage of the stone. Interventional sialendoscopy (with basket retrieval) and lithotripsy are newer techniques that can be effective in the removal of

dentlearn.ir

sialoliths from the major glands. These minimally invasive techniques have low morbidity and may preclude the necessity of gland removal.

Larger sialoliths usually need to be removed surgically, sometimes with the assistance of sialendoscopy. If significant inflammatory damage has occurred within the feeding gland, then the gland may need to be removed. Minor gland sialoliths are best treated by surgical removal, including the associated gland.

SIALADENITIS

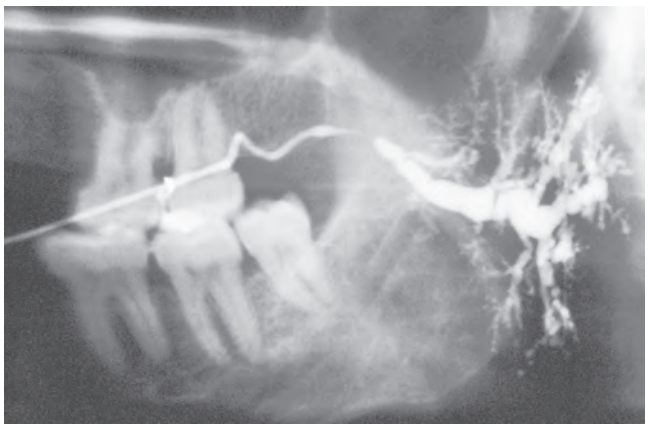


Inflammation of the salivary glands **(sialadenitis)** can arise from various infectious and noninfectious causes. The most common viral infection is mumps (see page 249), although a number of other viruses also can involve the salivary glands, including Coxsackie A, ECHO, choriomeningitis, parainfluenza, human immunodeficiency virus (HIV), and cytomegalovirus (CMV) (in neonates). Most bacterial infections arise as a result of ductal obstruction or decreased salivary flow, allowing retrograde spread of bacteria throughout the ductal system. Blockage of the duct can be caused by sialolithiasis (see page 465), congenital strictures, or compression by an adjacent tumor. Decreased flow can result from dehydration, debilitation, or medications that inhibit secretions.

One of the more common causes of sialadenitis is recent surgery (especially abdominal surgery), after which an acute parotitis *(surgical mumps)* may arise because the patient has been kept without food or fluids (NPO) and has received atropine during the surgical procedure. Other medications that produce xerostomia as a side effect also can predispose patients to such an infection. Most community-acquired cases of acute bacterial sialadenitis are caused by *Staphylococcus aureus* or streptococcal species. Hospital-acquired infections are also most frequently associated with *S. aureus,* but they also may be caused by a variety of other species, including *Eikenella corrodens, Escherichia coli, Fusobacterium, Haemophilus influenzae, Klebsiella, Prevotella, Proteus, and Pseudomonas*. Noninfectious causes of salivary inflammation include Sjögren syndrome (see page 472), sarcoidosis (see page 328), external radiation therapy (see page 280), radioiodine therapy for thyroid disease, and various allergens.

Clinical and Radiographic Features

Acute bacterial sialadenitis is most common in the parotid gland and is bilateral in 10%–25% of cases. The affected gland is swollen and painful, and the overlying skin may be warm and erythematous (Fig. 11.18). An associated low-grade fever and trismus may be present. A purulent discharge often is observed from the duct orifice when the gland is massaged (Fig. 11.19).



Recurrent or persistent ductal obstruction (most commonly caused by sialoliths) can lead to a chronic sialadenitis. Periodic swelling and pain occur within the affected gland, usually developing at mealtime when salivary flow is stimulated. Sialography often demonstrates sialectasia (ductal dilatation) proximal to the area of obstruction (Fig. 11.20). In chronic parotitis, Stensen duct may show a characteristic sialographic pattern known as "sausaging," which reflects a combination of dilatation plus ductal

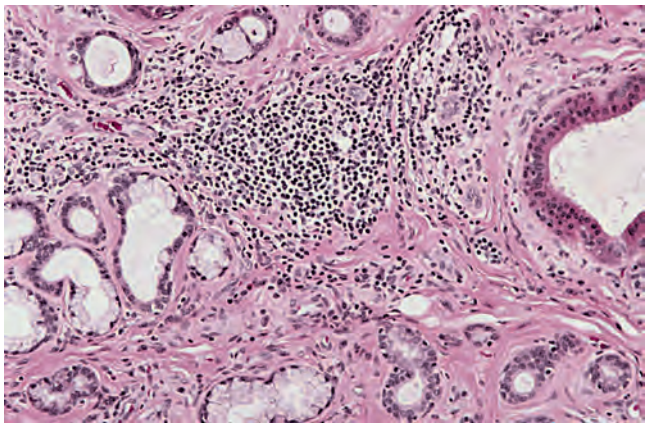
• **Fig. 11.18 Sialadenitis.** Tender swelling of the submandibular gland.

• **Fig. 11.19 Sialadenitis.** A purulent exudate can be seen arising from Stensen duct when the parotid gland is massaged.

• **Fig. 11.20 Chronic Sialadenitis.** Parotid sialogram demonstrating ductal dilatation proximal to an area of obstruction. (Courtesy of Dr. George Blozis.)

dentlearn.ir

strictures from scar formation. Chronic sialadenitis also can occur in the minor glands, possibly as a result of blockage of ductal flow or local trauma.



Juvenile recurrent parotitis is the most common inflammatory salivary disorder of children in the United States and the second most common such disorder worldwide (following mumps). It is characterized by recurring episodes of unilateral or bilateral, non-suppurative parotid swelling, usually beginning between the ages of 3 and 6 years. The exact cause is unknown, although congenital duct malformations, genetic factors, immunologic disorders, and dental malocclusion have been suggested as possible contributing factors. Although multiple recurrences often develop, the condition usually resolves around the time of puberty.

Subacute necrotizing sialadenitis is a form of salivary inflammation that occurs most commonly in teenagers and young adults. The lesion usually involves the minor salivary glands of the hard or soft palate, presenting as a painful nodule that is covered by intact, erythematous mucosa. Unlike necrotizing sialometaplasia (see page 477), the lesion does not ulcerate or slough necrotic tissue. An infectious or allergic cause has been hypothesized.

Histopathologic Features

In patients with acute sialadenitis, accumulation of neutrophils is observed within the ductal system and acini. Chronic sialadenitis is characterized by scattered or patchy infiltration of the salivary parenchyma by lymphocytes and plasma cells. Atrophy of the acini is common, as is ductal dilatation. If associated fibrosis is present, then the term **chronic sclerosing sialadenitis** is used (Fig. 11.21).

Subacute necrotizing sialadenitis is characterized by a heavy mixed inflammatory infiltrate consisting of neutrophils, lymphocytes, histiocytes, and eosinophils. There is loss of most of the acinar cells, and many of the remaining ones exhibit necrosis. The ducts tend to be atrophic and do not show hyperplasia or squamous metaplasia.

• **Fig. 11.21 Chronic Sclerosing Sialadenitis.** Chronic inflammatory infiltrate with associated acinar atrophy, ductal dilatation, and fibrosis.

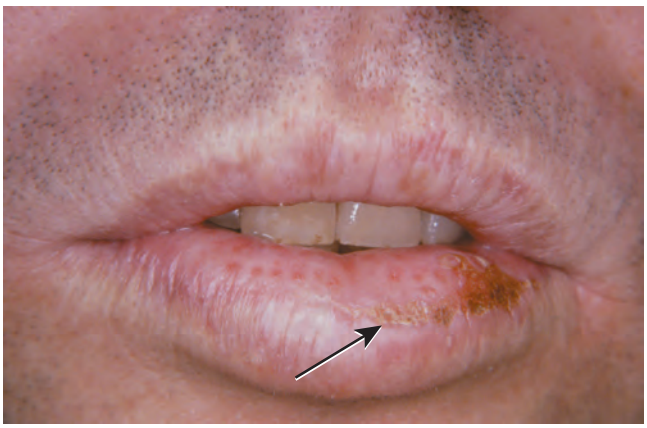
Treatment and Prognosis

Patients with sialadenitis should have a screening panoramic radiograph to investigate for the presence of a sialolith. Additional imaging studies, such as ultrasound, CT, or MRI scans, also may be warranted. If purulence is noted at the duct orifice, then bacterial culture and sensitivity studies should be performed.

The treatment of acute sialadenitis includes appropriate antibiotic therapy and rehydration of the patient to stimulate salivary flow. Surgical drainage may be needed if there is abscess formation. Although this regimen is usually sufficient, a mortality rate as high as 20%–50% has been reported in debilitated patients because of the spread of the infection and sepsis.

The management of chronic sialadenitis depends on the severity of the condition and ranges from conservative therapy to surgical intervention. Initial management often includes antibiotics, analgesics, short-term corticosteroids, sialagogues, and glandular massage. Early cases that develop secondary to ductal blockage may respond to removal of the sialolith or other obstruction. However, if sialectasia is present, then the dilated ducts can lead to stasis of secretions and predispose the gland to further sialolith formation. Sialendoscopy and ductal irrigation often are employed to dilate ductal strictures and to eliminate sialoliths and mucus plugs. If necessary, a period of ductal stenting can also be performed. If conservative methods cannot control chronic sialadenitis, then surgical removal of the affected gland may be necessary.

Sialendoscopy with saline irrigation also has proven to be a useful technique for patients with juvenile recurrent parotitis, often greatly reducing the number of recurring episodes until the disorder resolves at puberty. Subacute necrotizing sialadenitis is a self-limiting condition that usually resolves within 2 weeks of diagnosis without treatment.



◆ CHEILITIS GLANDULARIS

Cheilitis glandularis is a rare inflammatory condition of the minor salivary glands. The cause is uncertain, although several etiologic factors have been suggested, including actinic damage, tobacco, poor hygiene, and heredity.

Clinical Features

Cheilitis glandularis characteristically occurs on the lower lip vermilion, although cases also have been reported to involve the upper lip and palate. Affected individuals experience swelling and eversion of the lower lip as a result of hypertrophy and inflammation of the glands (Fig. 11.22). The openings of the minor salivary ducts are inflamed and dilated, and pressure on the glands may produce mucopurulent secretions from the ductal openings. The condition most often has been reported in middle-aged and older men, although cases also have been described in women and children. However, some of the childhood cases may represent other entities,

dentlearn.ir

• **Fig. 11.22 Cheilitis Glandularis.** Prominent lower lip with inflamed openings of the minor salivary gland ducts. An early squamous cell carcinoma has developed on the patient's left side just lateral to the midline (*arrow*). (Courtesy of Dr. George Blozis.)

such as exfoliative cheilitis (see page 294). Examples also have been described in albino patients, presumably secondary to sun sensitivity.

Historically, cheilitis glandularis has been classified into three types, based on the severity of the disease:

1. Simple
2. Superficial suppurative (Baelz disease)
3. Deep suppurative (cheilitis glandularis apostematosa)

The latter two types represent progressive stages of the disease with bacterial involvement; they are characterized by increasing inflammation, suppuration, ulceration, and swelling of the lip.

Histopathologic Features

The microscopic findings of cheilitis glandularis may include chronic sialadenitis, ductal dilatation with mucin accumulation, and oncocytic ductal metaplasia. Concomitant dysplastic changes may be observed in the overlying surface epithelium in some cases.

Treatment and Prognosis

The treatment of choice for most cases of persistent cheilitis glandularis associated with actinic damage is vermilionectomy (lip shave), which usually produces a satisfactory cosmetic result. It has been noted that some cases have been associated with the development of squamous cell carcinoma of the overlying epithelium of the lip. Because actinic damage has been implicated in many cases of cheilitis glandularis, it is likely that this same solar radiation is responsible for the malignant degeneration.

◆ SIALORRHEA (PTYALISM)

Sialorrhea, or excessive salivation, is an uncommon condition that has various causes. Minor sialorrhea may result from local irritations, such as aphthous ulcers or ill-fitting dentures. Patients with new dentures often experience excess saliva production until they become accustomed to the prosthesis. Episodic hypersecretion of saliva, or "water brash," may occur as a protective buffering system to neutralize stomach acid in individuals with gastroesophageal reflux disease. Excessive salivation rarely develops in pregnant women (*ptyalism gravidarum*), sometimes in association with hyperemesis of pregnancy. Sialorrhea is a well-known clinical feature of rabies and heavy-metal poisoning (see page 304). It also may occur as a consequence of certain medications, such as antipsychotic agents, especially clozapine, and cholinergic agonists used to treat dementia of the Alzheimer type and myasthenia gravis.

Drooling can be a problem for patients who are intellectually disabled, who have undergone surgical resection of the mandible, or who have various neurologic disorders such as cerebral palsy, Parkinson disease, amyotrophic lateral sclerosis (ALS), or stroke. In these instances, the drooling is probably not caused by over-production of saliva but by poor neuromuscular control.

In addition, there is a second group of patients who report complaints of drooling; however, no obvious clinical evidence of excessive saliva production is observed, and they do not have any of the recognized causes for sialorrhea. Personality analysis has suggested that the complaint of drooling in such otherwise healthy patients does not have an organic basis but may be associated with high levels of neuroticism and a tendency to dissimulate.

Clinical Features

Excess saliva production typically produces drooling and choking, which may cause social embarrassment. In children with intellectual disability or cerebral palsy, uncontrolled salivary flow may lead to macerated sores around the mouth, chin, and neck that can become secondarily infected. The constant soiling of clothes and bed linens can be a significant problem for the parents and caretakers of these patients.

Treatment and Prognosis

Some causes of sialorrhea are transitory or mild, and no treatment is needed. For individuals with increased salivation associated with gastroesophageal reflux disease, medical management of their reflux problem may be beneficial.

For persistent severe drooling, therapeutic intervention may be indicated. Speech therapy can be used to improve neuromuscular control, but patient cooperation is necessary. Anticholinergic medications can decrease saliva production but may produce unacceptable side effects. Transdermal scopolamine has been tried with some success, but it should not be used in children younger than age 10. Intraglandular injection of botulinum toxin (type A or B) has been shown to be successful in reducing salivary secretions, with duration of action that varies from 6 weeks to 6 months. Salivary ablation also has been accomplished via image-guided injection of sodium tetradecyl sulfate and ethanol into the glands.

dentlearn.ir

Several surgical techniques have been used successfully to control severe drooling in individuals with poor neuromuscular control:

- Relocation of the submandibular ducts to the base of the tongue or tonsillar fossa (sometimes along with excision of the sublingual glands)
- Relocation of the parotid ducts
- Submandibular gland excision plus parotid duct ligation
- Ligation of the parotid and submandibular ducts

XEROSTOMIA

Xerostomia refers to a subjective sensation of a dry mouth; it is frequently, but not always, associated with salivary gland hypofunction. A number of factors may play a role in the cause of xerostomia, and these are listed in Box 11.2.

BOX 11.2 Causes of Xerostomia

Developmental/Hereditary Origin

Salivary gland aplasia
Ectodermal dysplasia

Water/Metabolite Loss

Dehydration
Hemorrhage
Vomiting/diarrhea

Iatrogenic Origin

Medications
Radiation therapy to the head and neck
Chemotherapy

Infectious Diseases

Human immunodeficiency virus (HIV) infection
Hepatitis C infection
Cytomegalovirus infection

Autoimmune Disorders

Sjögren syndrome
Rheumatoid arthritis
Systemic lupus erythematosus
Systemic sclerosis
Primary biliary cirrhosis

Other Systemic Diseases

Diabetes mellitus
Diabetes insipidus
Sarcoidosis
Amyloidosis
    End-stage renal disease
Graft-versus-host disease (GVHD)
Psychogenic disorders

Local Factors

Decreased mastication
Smoking
Mouth breathing

Xerostomia is a common problem that has been reported in 25% of older adults. In the past, complaints of dry mouth in older patients often were ascribed to the predictable result of aging. However, it is now generally thought that any reductions in salivary function associated with age are modest and probably are not associated with any significant reduction in salivary function. Instead, xerostomia in older adults is more likely to be the result of other factors, especially medications. More than 500 drugs have been reported to produce xerostomia as a side effect, including 63% of the 200 most frequently prescribed medicines in the United States. A list of the most common and significant drugs associated with xerostomia is provided in Table 11.2. Not only are specific drugs known to produce dry mouth, but the prevalence of xerostomia also increases in relation to the total number of drugs that a person takes, regardless of whether the individual medications are xerogenic or not.

Clinical Features

Examination of the patient typically demonstrates a reduction in salivary secretions, and the residual saliva appears either foamy or thick and "ropey." The mucosa appears

TABLE 11.2 Medications That May Produce Xerostomia

Class of Drug	Example
Antihistamine agents	Diphenhydramine Chlorpheniramine
Decongestant agents	Pseudoephedrine Loratadine
Antidepressant agents	Amitriptyline Citalopram Duloxetine Fluoxetine Paroxetine Sertraline Bupropion
Antipsychotic agents	Phenothiazine derivatives Haloperidol Quetiapine
Sedatives and anxiolytic agents	Diazepam Lorazepam Alprazolam
Antihypertensive agents	Reserpine Methyldopa Chlorothiazide Furosemide Metoprolol Calcium channel blockers
Anticholinergic/antimuscarinic agents	Atropine Scopolamine Oxybutynin Solifenacin Tolterodine

dentlearn.ir

dry, and the clinician may notice that the examining gloves stick to the mucosal surfaces. The dorsal tongue often is fissured with atrophy of the filiform papillae (see Fig. 11.1). The patient may complain of difficulty with mastication and swallowing, and they may even indicate that food adheres to the oral membranes during eating. The clinical findings, however, do not always correspond to the patient's symptoms. Some patients who complain of dry mouth may appear to have adequate salivary flow and oral moistness. For example, patients with burning mouth syndrome sometimes will describe dry mouth symptoms, despite having an apparently adequate flow of saliva upon examination. Such complaints may be related to the oral sensory neuropathy that underlies this condition (see page 868). Conversely, some patients who clinically appear to have a dry mouth have no complaints. The degree of saliva production can be assessed by measuring both resting and stimulated salivary flow.

There is an increased prevalence of oral candidiasis in patients with xerostomia because of the reduction in the cleansing and antimicrobial activity normally provided by saliva. In addition, these patients are more prone to dental decay, especially cervical and root caries. This problem has been associated more often with radiation therapy, and it is sometimes called *radiation-induced caries* but more appropriately should be called *xerostomia-related caries* (see page 282).

Treatment and Prognosis

The treatment of xerostomia is difficult and often unsatisfactory. Artificial salivas, moisturizing sprays, or gels may help make the patient more comfortable, as may continuous sips of water throughout the day. In addition, sugarless candy can be used in an effort to stimulate salivary flow. In recent years, use of miniaturized intraoral electrostimulating devices has been reported to be successful in improving dry mouth symptoms. If the dryness is secondary to the patient's medication, then discontinuation or dose modification in consultation with the patient's physician may be considered; a substitute drug also can be tried.

Systemic pilocarpine is a parasympathomimetic agonist that can be used as a sialagogue. At doses of 5–10 mg, three to four times daily, it can be an effective promoter of salivary secretion. Excess sweating is a common side effect, but more serious problems, such as increased heart rate and blood pressure, are uncommon. Cevimeline hydrochloride, a cholinergic agonist with affinity for muscarinic M_3 receptors, also has been proven to be an effective sialagogue. Both pilocarpine and cevimeline are contraindicated in patients with narrow-angle glaucoma.

Because of the increased potential for dental caries in patients with xerostomia, frequent dental visits are recommended. Office and daily home fluoride applications can be used to help prevent decay, and chlorhexidine mouth rinses minimize plaque buildup.

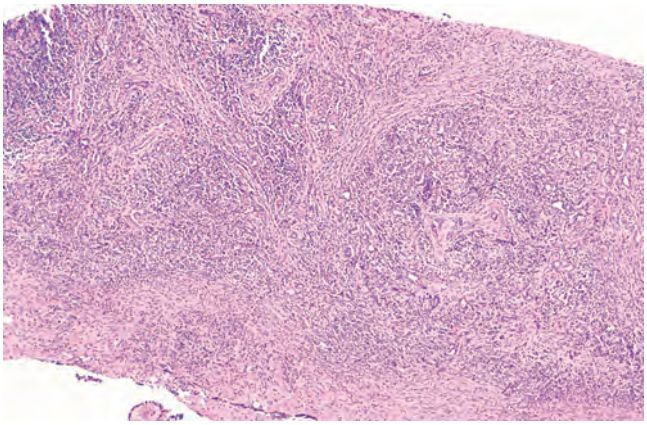
◆ IGG4-RELATED DISEASE

In the late 1800s, Johann von Mikulicz-Radecki described a patient with an unusual bilateral painless swelling of the lacrimal glands and all of the salivary glands, which was caused by an intense chronic inflammatory infiltrate. This clinical presentation became known as **Mikulicz disease.** Similar cases of parotid and lacrimal enlargement caused by other diseases (e.g., tuberculosis, sarcoidosis, and lymphoma) were considered to be different from Mikulicz disease and were termed **Mikulicz syndrome.** However, these two terms have become so confusing and ambiguous that they should no longer be used.

Although the true nature of his original patient's condition is uncertain, some examples of so-called Mikulicz disease likely have been benign lymphoepithelial lesions associated with Sjögren syndrome (see page 472). However, it is thought that other examples would be classified today as **IgG4-related disease,** a recently described fibroinflammatory disorder.

IgG4-related disease was first recognized as a sclerosing inflammatory process of the pancreas under the designation *autoimmune pancreatitis*. This condition later was linked to elevated serum levels of IgG4, as well as the presence of IgG4-positive plasma cells within pancreatic tissues. The systemic nature of IgG4-related disease was established when it was recognized that a variety of inflammatory lesions in other organs, including the salivary and lacrimal glands, represent the same disease process.

The pathogenesis of IgG4-related disease is uncertain, although both type 2 helper T-lymphocytes and B lymphocytes have been suggested to be involved. IgG4 actually is regarded as an anti-inflammatory and anti-allergic molecule, and its elevation likely represents a bystander phenomenon rather than a causative factor. Normally, IgG4 comprises less than 5% of the body's total IgG. In this condition, however, serum concentrations of polyclonal IgG4 can measure up to 25 times greater than normal levels, although 20%–40% of patients will show IgG4 levels within normal limits. Allergic disorders such as asthma, allergic rhinitis, and atopic dermatitis are common.



Clinical Features

IgG4-related disease typically occurs in middle-aged and older adults, with a mean age of approximately 60 years. Men are affected equally or slightly more often than women, although reports from Japan have shown a female predilection. Following the pancreas, the head and neck region is the second most common site affected by this condition. Orbital involvement may be characterized by swollen eyelids, lacrimal inflammation, proptosis, pain, and diplopia. Optic nerve involvement can lead to permanent visual loss. IgG4-related sialadenitis occurs most frequently in the submandibular gland and only rarely involves the parotid gland and minor salivary glands (Fig. 11.23). Patients present with

dentlearn.ir

• **Fig. 11.23 IgG4-related Disease.** Bilateral enlargement of the submandibular glands. (Courtesy of Dr. Benjamin Martinez.)

• **Fig. 11.24 IgG4-related Disease.** Diffuse lymphoplasmacytic inflammation in the submandibular gland with associated interlobular fibrosis. (Courtesy of Dr. Benjamin Martinez.)

unilateral or bilateral submandibular gland swelling ranging from 1.5 to 5 cm in diameter, which often mimics a neoplastic process.

Because IgG4-related disease can affect almost any tissue or organ within the body, the severity and course of the disorder depend on the specific site of involvement. Pancreatitis can lead to obstructive jaundice, weight loss, and abdominal discomfort. Sclerosing cholangitis can result in hepatic failure. Other complications include abdominal aortitis with aneurysm formation, inflammatory pseudotumors of the kidney, thyroid inflammation (Riedel thyroiditis), and lymphadenopathy.

Histopathologic Features

Microscopic examination of an affected submandibular gland reveals chronic sclerosing sialadenitis, which is characterized by a heavy lymphoplasmacytic infiltrate, hyperplastic lymphoid follicles, and acinar atrophy. Immunohistochemistry should reveal increased numbers of IgG4-positive plasma cells (greater than 30–50 per high-power field), plus the ratio of IgG4-positive plasma cells to total IgG-positive plasma cells should be greater than 40%. Prominent interlobular fibrosis results in a storiform pattern when the gland is viewed at low power (Fig. 11.24). Another common finding is obliterative phlebitis, which can be highlighted with an elastic stain. This overall pattern has sometimes been termed a **Küttner tumor.** Labial salivary gland biopsy has been suggested as a minimally invasive procedure for the diagnosis of IgG4-related sialadenitis; however, its sensitivity for the diagnosis is considered very low.

Treatment and Prognosis

IgG4-related disease often requires immediate, aggressive treatment with systemic corticosteroids to prevent significant organ damage and failure. Glucocorticoid-sparing agents, such as azathioprine, mycophenolate mofetil, and methotrexate, also can be used. Most patients show a rapid response to immunosuppressive therapy and have a favorable prognosis. For patients with recurrent disease, B-cell depletion with rituximab can be effective. Submandibular gland lesions or highly fibrotic orbital pseudotumors sometimes are treated by surgical resection.

◆ SJÖGREN SYNDROME

Sjögren syndrome is a chronic, systemic autoimmune disorder that principally involves the salivary and lacrimal glands, resulting in xerostomia (dry mouth) and xerophthalmia (dry eyes). The effects on the eye often are called **keratoconjunctivitis sicca** (*sicca* means "dry"), and the clinical presentation of both xerostomia and xerophthalmia is also sometimes called the *sicca syndrome.* Traditionally, two forms of the disease are recognized:

1. *Primary* Sjögren syndrome (sicca syndrome alone; no other autoimmune disorder is present)
2. *Secondary* Sjögren syndrome (the patient manifests sicca syndrome in addition to another associated autoimmune disease)

The cause of Sjögren syndrome is unknown. Although it is not a hereditary disease *per se,* there is strong evidence of a genetic influence. Examples of Sjögren syndrome have been reported in twins or in two or more members of the same family. Relatives of affected patients have an increased frequency of other autoimmune diseases. A variety of candidate genes have been implicated in the pathogenesis, including those related to certain histocompatibility antigens (HLAs), interferon response, and B-lymphocyte function. Researchers have suggested that viruses, such as Epstein-Barr virus (EBV) or human T-cell lymphotropic virus, may play a pathogenetic role in Sjögren syndrome, but evidence for this is still speculative.

dentlearn.ir

Clinical and Radiographic Features

Sjögren syndrome is considered to be the second most common autoimmune disorder, following rheumatoid arthritis. Although the exact prevalence depends on the clinical criteria used, current estimates place the population prevalence at 1% (0.1%–4.8%), with a 9:1 female-to-male ratio. It is seen predominantly in middle-aged adults, but rare examples have been described in children. The classification criteria adopted in 2016 by the American College of Rheumatology and European League Against Rheumatism are presented in Box 11.3.

When the condition is associated with another connective tissue disease, it is called *secondary Sjögren syndrome*. It can be associated with almost any other autoimmune disease, but the most common associated disorder is rheumatoid arthritis. About 15% of patients with rheumatoid arthritis have Sjögren syndrome. In addition, secondary Sjögren syndrome may develop in 30% of patients with systemic lupus erythematosus (SLE).

The principal oral symptom is xerostomia, which is caused by decreased salivary secretions; however, the severity of this dryness can vary widely from patient to patient. The saliva may appear frothy, with a lack of the usual pooling saliva in the floor of the mouth. Affected patients may complain of difficulty in swallowing, altered taste, or difficulty in wearing dentures. The tongue often becomes fissured and exhibits atrophy of the papillae (Fig. 11.25). The oral mucosa may be red and tender, usually as a result of secondary candidiasis. Related denture sore mouth and angular cheilitis are common. The lack of salivary cleansing action predisposes the patient to dental decay, especially cervical caries.

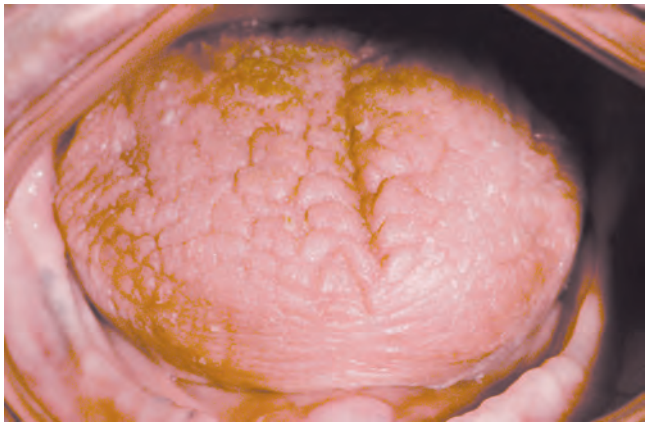
From one-third to one-half of patients have diffuse, firm enlargement of the major salivary glands during the course of their disease (Fig. 11.26). This swelling is usually bilateral, may be nonpainful or slightly tender, and may be intermittent or persistent in nature. The greater the severity of the disease, the greater the likelihood of this salivary enlargement. In addition, the reduced salivary flow places these individuals at increased risk for retrograde bacterial sialadenitis.

Although it is not diagnostic, sialographic examination often reveals punctate sialectasia and lack of normal arborization of the ductal system, typically demonstrating a "fruit-laden, branchless tree" pattern (Fig. 11.27). Scintigraphy with radioactive technetium-99m pertechnetate

• BOX 11.3 American College of Rheumatology/European League Against Rheumatism Classification Criteria for Primary Sjögren Syndrome

The classification of primary **Sjögren syndrome** applies to an individual who meets one or more *inclusion criteria*, does not have any of the conditions listed as *exclusion criteria*, and has total score of ≥4 when the weights from the following criteria items are added:

Item	Weight/Score
Labial salivary gland with focal lymphocytic sialadenitis and focus score of ≥1 foci/4 mm^2	3
Anti-SSA/Ro-positive	3
Ocular staining score ≥5 (or van Bijsterveld score ≥4) in at least one eye^^^	1
Schirmer test ≤5 mm/5 minutes in at least one eye^^^	1
Unstimulated whole saliva flow rate ≤1 mL/minute (as described by Navazesh and Kumar)^^^	1



Inclusion criteria—patient has at least one symptom of ocular or oral dryness, defined as a positive response to at least one of the following questions:
(1) Have you had daily, persistent, troublesome dry eyes for more than 3 months?
(2) Do you have a recurrent sensation of sand or gravel in the eyes?
(3) Do you use tear substitutes more than three times a day?
(4) Have you had a daily feeling of dry mouth for more than 3 months?
(5) Do you frequently drink liquids to aid in swallowing dry food?
-or-
A patient in whom there is suspicion of Sjögren syndrome (SS) from the European League Against Rheumatism SS Disease Activity Index questionnaire (at least one domain with a positive item).

Exclusion criteria—patient with a prior diagnosis of any of the following conditions, which would exclude diagnosis of SS and participation in SS studies or therapeutic trials because of overlapping clinical features or interference with criteria tests:
(1) History of head and neck radiation treatment
(2) Active hepatitis C infection (with confirmation by PCR)
(3) Acquired immunodeficiency syndrome (AIDS)
(4) Sarcoidosis
(5) Amyloidosis
(6) Graft-versus-host disease
(7) IgG4-related disease

^^^Patients who are normally taking anticholinergic drugs should be evaluated for objective signs of salivary hypofunction and ocular dryness after a sufficient interval without these medications in order for these components to be a valid measure of oral and ocular dryness.

Source: Shiboski CH, Shiboski SC, Seror R, et al: 2016 American College of Rheumatology/European League Against Rheumatism classification criteria for primary Sjögren's syndrome. A consensus and data-driven methodology involving three international patient cohorts, Ann Rheum Dis 76:9–16, 2017.

dentlearn.ir

characteristically shows decreased uptake and delayed emptying of the isotope. Ultrasonography may reveal multiple hypoechoic or anechoic areas in the parotid and submandibular glands.

The term **keratoconjunctivitis sicca** describes not only the reduced tear production by the lacrimal glands but also the pathologic effect on the epithelial cells of the ocular surface. As in xerostomia, the severity of xerophthalmia can vary widely from one patient to the next. The lacrimal inflammation causes a decrease of the aqueous layer of the tear film; however, mucin production is normal and may result in a

• **Fig. 11.27 Sjögren Syndrome.** Parotid sialogram demonstrating atrophy and punctate sialectasia ("fruit-laden, branchless tree"). (Courtesy of Dr. George Blozis.)

mucoid discharge. Patients often complain of a scratchy, gritty sensation or the perceived presence of a foreign body in the eye. Defects of the ocular surface epithelium develop, which may result in blurred vision and, sometimes, an aching pain. The ocular manifestations are least severe in the morning on wakening and become more pronounced as the day progresses.

A simple means to confirm the decreased tear secretion is the Schirmer test. A standardized strip of sterile filter paper is placed over the margin of the lower eyelid, so that the tabbed end rests just inside the lower lid. By measuring the length of wetting of the filter paper, tear production can be assessed. Values less than 5 mm (after a 5-minute period) are considered abnormal. In addition, the possibility of damage to the corneal and conjunctival surfaces can be assessed by slit lamp examination after rose bengal and lissamine green staining.

Sjögren syndrome is a systemic disease, and the inflammatory process also can affect various other body tissues. The skin is often dry, as are the nasal and vaginal mucosae. Fatigue is fairly common, and depression sometimes can occur. Other possible associated problems include lymphadenopathy, primary biliary cholangitis, Raynaud phenomenon, interstitial nephritis, interstitial lung fibrosis, vasculitis, and peripheral neuropathies (see Box 11.4).

Laboratory Values

In patients with Sjögren syndrome, the erythrocyte sedimentation rate often is high and serum immunoglobulin (Ig) levels, especially IgG, typically are elevated. A variety of autoantibodies can be produced, and although none of these is specifically diagnostic, their presence can be another helpful clue to the diagnosis. A positive rheumatoid factor (RF) is found in approximately 60% of cases, regardless of whether the patient has rheumatoid arthritis. Antinuclear antibodies (ANAs) are also present in 75%–85% of patients. Two particular nuclear autoantibodies—anti-SS-A (anti-Ro) and anti-SS-B (anti-La)—may be found, especially in patients

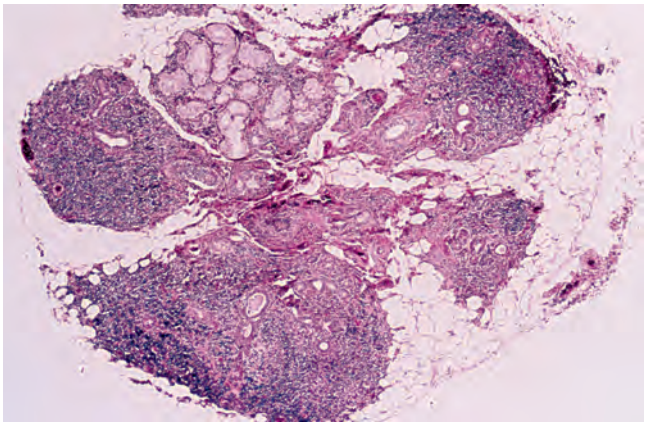
with primary Sjögren syndrome. Anti-SS-A antibodies have been detected in approximately 50%–76% of patients, whereas anti-SS-B antibodies have been discovered in 30%–60% of these individuals.

Histopathologic Features

The basic microscopic finding in Sjögren syndrome is a lymphocytic infiltration of the salivary glands, which leads to destruction of the acinar units. More advanced lesions result in a pattern known as a **benign lymphoepithelial lesion (myoepithelial sialadenitis).** Although the acini are destroyed, the ductal epithelium persists. The ductal cells and surrounding myoepithelial cells become hyperplastic, forming highly characteristic groups of cells, known as *epimyoepithelial islands,* throughout the lymphoid proliferation (Fig. 11.28). Germinal centers may or may not be seen. Lymphocytic infiltration of the minor glands also occurs, although epimyoepithelial islands are rarely seen in this location.

Biopsy of the minor salivary glands of the lower lip sometimes is used as a diagnostic test for Sjögren syndrome. A 1.5- to 2.0-cm incision is made on clinically normal lower labial mucosa, parallel to the vermilion border and lateral to the midline, allowing the harvest of five or more accessory glands. These glands then can be examined histopathologically for the presence of focal chronic inflammatory aggregates composed of 50 or more lymphocytes and plasma cells. The aggregates should be adjacent to normal-appearing acini and should be found consistently in most of the glands in the specimen. The following formula has been suggested:



• **Fig. 11.28 Benign Lymphoepithelial Lesion in Sjögren Syndrome.** Lymphocytic infiltrate of the parotid gland with an associated epimyoepithelial island.

$$\text{Focus score} = \frac{\text{Number of inflammatory aggregates} \times 4}{\text{Number of mm}^2 \text{ of salivary gland parenchyma}}$$

The focus score calculates the number of inflammatory aggregates per 4-mm^2 area of salivary gland tissue. A focus score $\geq$1 (i.e., one or more foci of 50 or more cells per 4-mm^2 area of glandular tissue) is considered supportive of the diagnosis of Sjögren syndrome (Fig. 11.29). The greater the number of foci (up to 12 or confluent foci) is, the greater is the correlation with this diagnosis. The focal nature of this chronic inflammation among otherwise normal acini is a highly suggestive pattern; in contrast, the finding of scattered inflammation with ductal dilatation and fibrosis (chronic sclerosing sialadenitis) does not support the diagnosis of Sjögren syndrome.

Although labial salivary gland biopsy has become a widely used test in the diagnosis of Sjögren syndrome, it is not 100% reliable. Some patients diagnosed with Sjögren syndrome will show no significant labial gland inflammation; conversely, examination of labial glands removed incidentally from non-Sjögren patients sometimes will show focal lymphocytic infiltrates. Sjögren syndrome patients who smoke have been shown to have a significantly lower frequency of abnormal lymphocytic foci scores in their labial gland specimens. It also is important that a pathologist experienced in the analysis of these specimens examines the labial gland biopsies. One study showed that slightly more than half of labial gland specimens required a revised diagnosis after being reviewed by a second pathologist.

dentlearn.ir

• **Fig. 11.29 Sjögren Syndrome.** Labial gland biopsy showing multiple lymphocytic foci.

Other authors have advocated incisional biopsy of the parotid gland through a posterior/inferior auricular approach instead of a labial salivary gland biopsy. One study has shown this technique to be more sensitive in demonstrating inflammatory changes that support the diagnosis of Sjögren syndrome; however, other authors think that this technique confers no increased benefit over labial gland biopsy. Parotid biopsy may enable the clinician to evaluate an enlarged gland for the development of lymphoma and rule out the possibility of sialadenosis or sarcoidosis.

Treatment and Prognosis

The treatment of the patient with Sjögren syndrome is mostly supportive. The dry eyes are best managed by periodic use of artificial tears. Thicker ocular gels or ointments may be utilized at bedtime for longer lasting relief. For more severe eye disease, short-term topical corticosteroids or 0.05% cyclosporine can be prescribed to decrease ocular inflammation. In addition, the FDA recently has approved topical lifitegrast for treatment of dry eye symptoms.

Artificial salivas are available for the treatment of xerostomia; sugarless candy or gum can help to keep the mouth moist. Sialagogue medications, such as pilocarpine and cevimeline, can be useful to stimulate salivary flow if enough functional salivary tissue still remains. Medications known to diminish secretions should be avoided, if at all possible. Because of the increased risk of dental caries, daily fluoride applications may be indicated in dentulous patients. Antifungal therapy often is needed to treat secondary candidiasis.

Patients with Sjögren syndrome have a lifetime risk for lymphoma of 5%–10%, which is estimated to be about 15–20 times greater than the general population. These tumors may arise initially within the salivary glands or within lymph nodes. With the advent of modern molecular pathology techniques to detect B-cell monoclonality (e.g., *in situ* hybridization, polymerase chain reaction [PCR]), many salivary gland infiltrates formerly thought to represent benign lymphoepithelial lesions are now being diagnosed as lymphomas. These tumors are predominantly low-grade non-Hodgkin B-cell lymphomas of the mucosa-associated lymphoid tissue (i.e., **MALT lymphomas, extranodal marginal zone B-cell lymphomas**), although occasionally, high-grade lymphomas can develop that demonstrate more aggressive behavior. Prognostic risk factors for lymphoma development include persistent parotid gland enlargement, lymphadenopathy, splenomegaly, neutropenia, low C4 complement levels, cryoglobulinemia, and palpable purpura. The detection of immunoglobulin gene rearrangements in labial salivary gland biopsies may prove to be a useful marker for predicting the development of lymphoma.

◆ SIALADENOSIS (SIALOSIS)

Sialadenosis is an unusual non-inflammatory disorder characterized by salivary gland enlargement, particularly involving the parotid glands. The condition frequently is associated with an underlying systemic problem, which may be endocrine, nutritional, or neurogenic in origin (Box 11.5). The best known of these conditions include diabetes mellitus, general malnutrition, alcoholism, and bulimia.

These conditions are believed to result in dysregulation of the autonomic innervation of the salivary acini, causing an aberrant intracellular secretory cycle. This leads to excessive accumulation of secretory granules, with marked enlargement of the acinar cells. In addition, reduced innervation of myoepithelial cells may lead to atrophy of the supporting myofilaments around the acinar cells.

Clinical and Radiographic Features

Sialadenosis usually appears as a slowly evolving swelling of the parotid glands, which may or may not be painful (Fig. 11.30). The condition is usually bilateral, but it also

dentlearn.ir

• **Fig. 11.30 Sialadenosis.** Enlargement of the parotid and submandibular glands secondary to alcoholism. (Courtesy of Dr. George Blozis.)

can be unilateral. In some patients, the submandibular glands may be affected, but involvement of minor salivary glands is distinctly rare. Decreased salivary secretion may occur. Sialography demonstrates a "leafless tree" pattern, which is thought to be caused by compression of the finer ducts by hypertrophic acinar cells.

Histopathologic Features

Microscopic examination reveals hypertrophy of the acinar cells, sometimes two to three times greater than normal size. The nuclei are displaced to the cell base, and the cytoplasm is engorged with zymogen granules. In cases associated with long-standing diabetes or alcoholism, there may be acinar atrophy and fatty infiltration. Significant inflammation is not observed.

Treatment and Prognosis

The clinical management of sialadenosis is often unsatisfactory because it is closely related to the control of the underlying cause. Mild examples may cause few problems. If the swelling becomes a cosmetic concern, then partial parotidectomy can be performed. Pilocarpine has been reported to be beneficial in reducing salivary gland enlargement in bulimic patients.

◆ ADENOMATOID HYPERPLASIA OF THE MINOR SALIVARY GLANDS

Clinical Features

Adenomatoid hyperplasia is a rare lesion of the minor salivary glands characterized by localized swelling that mimics a neoplasm. This pseudotumor most often occurs on the hard or soft palate, although it also has been reported in other oral minor salivary gland sites. The pathogenesis of adenomatoid hyperplasia is uncertain, but it has been speculated that local trauma may play a role. It is most common in the fourth to sixth decades of life. Most examples present as sessile, painless masses that may be soft or firm to palpation. They usually are normal in color, although a few lesions are red or bluish.

Histopathologic Features

Microscopic examination demonstrates lobular aggregates of relatively normal-appearing mucous acini that are greater in number than normally would be found in the area. These glands also sometimes appear to be increased in size. In some instances, the glands are situated close to the mucosal surface. Chronic inflammation occasionally is seen, but it usually is mild and localized.

Treatment and Prognosis

Because the clinical presentation of adenomatoid hyperplasia mimics a tumor, biopsy is necessary to establish the diagnosis. Once the diagnosis has been established, no further treatment is indicated and the lesion should not recur.

The pathologist should be wary of making a diagnosis of adenomatoid hyperplasia without good clinical correlation. On occasion, attempted biopsy of a true salivary gland tumor may harvest only adjacent normal salivary tissue, which might be misinterpreted as adenomatoid hyperplasia. Good communication between the clinician and pathologist is important.

◆ NECROTIZING SIALOMETAPLASIA

Necrotizing sialometaplasia is an uncommon, locally destructive inflammatory condition of the salivary glands. Although the cause is uncertain, most authors believe it is the result of ischemia of the salivary tissue that leads to local infarction. The importance of this lesion rests in the fact that it mimics a malignant process, both clinically and microscopically.

A number of potential predisposing factors have been suggested, including the following:

- Traumatic injuries
- Dental injections
- Ill-fitting dentures
- Upper respiratory infections

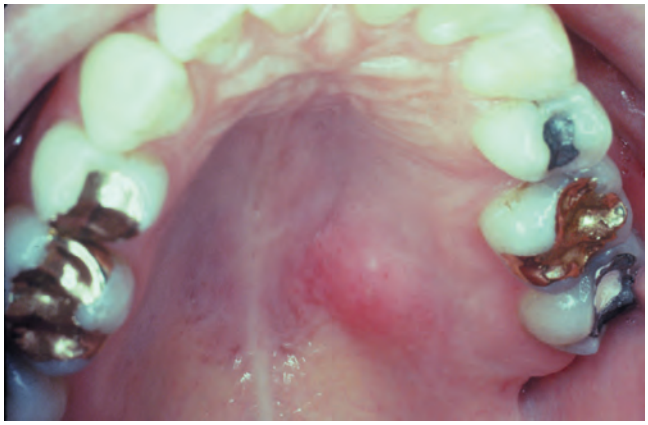
dentlearn.ir

- Adjacent tumors
- Previous surgery
- Eating disorders with binge-purging

Researchers have suggested that these factors may play a role in compromising the blood supply to the involved glands, resulting in ischemic necrosis. However, many cases occur without any known predisposing factors.

Clinical Features

Necrotizing sialometaplasia most frequently develops in the palatal salivary glands; more than 75% of all cases occur on the posterior palate. The hard palate is affected more often than the soft palate. About two-thirds of palatal cases are unilateral, with the rest being bilateral or midline in location. Necrotizing sialometaplasia also has been reported in other minor salivary gland sites and, occasionally, in the parotid gland. The submandibular and sublingual glands are rarely affected. Although it can occur at almost any age, necrotizing sialometaplasia is most common in adults; the mean age of onset is 46 years. Males are affected nearly twice as often as females.

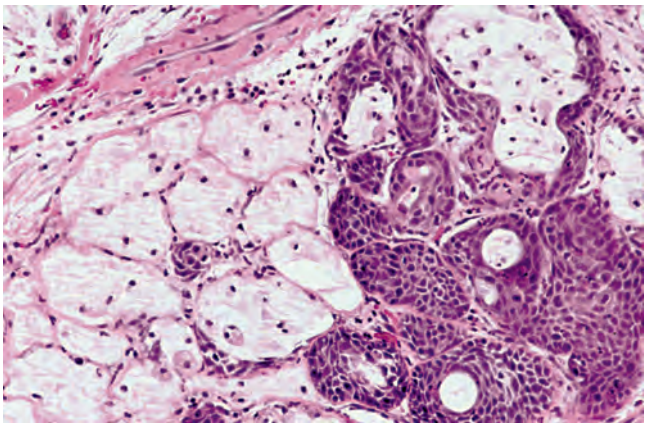


The condition appears initially as a nonulcerated swelling, often associated with pain or paresthesia (Fig. 11.31). Within 2–3 weeks, necrotic tissue sloughs out, leaving a craterlike ulcer that can range from less than 1 cm to more than 5 cm in diameter (Fig. 11.32). The patient may report that "a part of my palate fell out." At this point, the pain often subsides. In rare instances, there can be destruction of the underlying palatal bone.

Histopathologic Features

The microscopic appearance of necrotizing sialometaplasia is characterized by acinar necrosis in early lesions, followed by associated squamous metaplasia of the salivary ducts (Fig. 11.33). Although the mucous acinar cells are necrotic, the overall lobular architecture of the involved glands is still preserved—a helpful histopathologic clue. There may be liberation of mucin, with an associated inflammatory response. The squamous metaplasia of the salivary ducts can be striking and produce a pattern that is easily misdiagnosed as squamous cell carcinoma or mucoepidermoid carcinoma. The frequent association of pseudoepitheliomatous hyperplasia of the overlying epithelium may further compound this mistaken impression. In most cases, however, the squamous proliferation has a bland cytologic appearance. In examples that are difficult to distinguish from carcinoma, low immunoreactivity for p53 protein and Ki-67 may help to support a diagnosis of necrotizing sialometaplasia.

Treatment and Prognosis



Because of the worrisome clinical presentation of necrotizing sialometaplasia, biopsy usually is indicated to rule out the possibility of malignant disease. Once the diagnosis has been established, no specific treatment is indicated or necessary. The lesion typically resolves on its own accord, with an average healing time of 5–6 weeks.

• **Fig. 11.31 Necrotizing Sialometaplasia.** Early lesion demonstrating swelling of the posterior lateral hard palate. (From Allen CM, Camisa C: Diseases of the mouth and lips. In Sams WM, Lynch P, editors: *Principles of dermatology,* New York, 1990, Churchill Livingstone.)

• **Fig. 11.32 Necrotizing Sialometaplasia.** Later-stage lesion showing craterlike defect of the posterior palate.

• **Fig. 11.33 Necrotizing Sialometaplasia.** Necrotic mucous acini (*left*) and adjacent ductal squamous metaplasia (*right*).

dentlearn.ir

On rare occasions, necrotizing sialometaplasia has been described occurring adjacent to salivary gland tumors. Therefore, care should be taken to ensure that such glandular necrosis is not masking the presence of an adjacent true neoplasm.

SALIVARY GLAND TUMORS

◆ GENERAL CONSIDERATIONS

Tumors of the salivary glands constitute an important area in the field of oral and maxillofacial pathology. Although such tumors are uncommon, they are by no means rare. The annual incidence of salivary gland tumors around the world ranges from about 1.0 to 6.5 cases per 100,000 people. Although soft tissue neoplasms (e.g., hemangioma), lymphoma, and metastatic tumors can occur within the salivary glands, the discussion in this chapter is limited to primary epithelial neoplasms.

An often-bewildering array of salivary tumors has been identified and categorized. In addition, the classification scheme is a dynamic one that changes as clinicians learn more about these lesions. Box 11.6 includes most of the currently recognized tumors. Some of the tumors on this list are not specifically discussed because their rarity places them outside the scope of this text.

A number of investigators have published their findings on salivary gland neoplasia, but a comparison of these studies is often difficult. Some studies have been limited to only the major glands or have not included all the minor salivary gland sites. In addition, the ever-evolving classification system makes an evaluation of some older studies difficult, especially when researchers attempt to compare them with more recent analyses. Notwithstanding these difficulties, it is still helpful to compare these studies because they provide a good overview of salivary neoplasia in general. An evaluation of various studies shows fairly consistent trends (with minor variations) with regard to salivary gland tumors.

Tables 11.3 and 11.4 summarize five large series of primary epithelial salivary gland tumors, analyzed by sites of occurrence and frequency of malignancy, respectively. Some variations between studies may represent differences in diagnostic criteria, geographic differences, or referral bias in the cases seen. (Some centers may tend to see more malignant tumors on referral from other sources.)

The most common site for salivary gland tumors is the parotid gland, accounting for 61%–80% of all cases. Fortunately, a relatively low percentage of parotid tumors are malignant, ranging from 15% to 32%. Overall, it can be stated that two-thirds to three-quarters of all salivary tumors occur in the parotid gland, and two-thirds to three-quarters of these parotid tumors are benign.

Table 11.5 summarizes four large series of parotid neoplasms. The pleomorphic adenoma is overwhelmingly the most common tumor (45%–63% of all cases in the parotid gland). Warthin tumors are also fairly common; they account for 8%–22% of cases. A variety of malignant tumors occur, with the mucoepidermoid carcinoma appearing to be the most frequent overall. Although previous studies suggested that the United Kingdom may have a lower frequency of this tumor, a more recent series showed prevalence numbers equivalent to other countries.

Approximately 10% of all salivary tumors occur in the submandibular gland, but the frequency of malignancy in this gland is much greater than that of the parotid gland, ranging from 26% to 45%. However, as shown in Table 11.6, the pleomorphic adenoma is still the most common tumor and makes up 53%–72% of all neoplasms. Unlike its occurrence in the parotid gland, the Warthin

• BOX 11.6 Classification of Salivary Gland Tumors

Benign

*Includes all "other monomorphic adenomas."

tumor is unusual in the submandibular gland, making up about 1% of all tumors. Adenoid cystic carcinoma is the most common malignancy, ranging from 11% to 17% of all cases.

Tumors of the sublingual gland are rare, comprising about 1% of all salivary neoplasms. However, 70%–97% of sublingual tumors are malignant.

Tumors of the various smaller minor salivary glands make up 9%–28% of all tumors, which makes this group the second most common site for salivary neoplasia. Table 11.7 summarizes the findings of five large surveys of minor gland tumors. Unfortunately, relatively high proportions (38%–54%) of these have been malignant in most studies. Excluding rare sublingual tumors, it can be stated that the smaller the gland is, the greater is the likelihood of malignancy for a salivary gland tumor.

As observed in the major glands, the pleomorphic adenoma is the most common minor gland tumor and accounts for about 33%–41% of all cases. Mucoepidermoid carcinoma is the most frequent malignancy of minor gland origin, comprising 13%–23% of all tumors. Adenoid cystic carcinoma and polymorphous adenocarcinoma are also recognized as relatively common malignant tumors arising from the minor salivary glands.

The palate is the most frequent site for minor salivary gland tumors, with 42%– 57% of all cases found there (Table 11.8). Most of these occur on the posterior lateral hard or soft palate, which have the greatest concentration of glands. Table 11.9 shows the relative prevalence of various tumors on the palate. The lips are the second most common location for minor gland tumors (15%–24% of cases), followed by the buccal mucosa (12%–15% of cases). Labial tumors are significantly more common in the upper lip, which accounts for 74%–87% of all lip tumors (Table 11.10). Although mucoceles are commonly found on the lower lip, this is a surprisingly rare site for salivary gland tumors.

Significant differences in the percentage of malignancies and the relative frequency of various tumors can be noted for different minor salivary gland sites. As shown in Table 11.11, 41%– 51% of palatal tumors and 30%–59% of buccal mucosa tumors are malignant, similar to the overall prevalence of malignancy in all minor salivary gland sites combined. In the upper lip, however, only 9%–25% of

da Silva et al. (2018)	1114	57%	15%	13%	4%	2%	3%	6%

tumors are malignant because of the high prevalence of the canalicular adenoma, which has a special affinity for this location. In contrast, although lower lip tumors are uncommon, 43%– 86% are malignant (mostly mucoepidermoid carcinomas). Up to 95% of retromolar tumors are malignant, also because of a predominance of mucoepidermoid carcinomas. Unfortunately, most tumors in the floor of the mouth and tongue are also malignant.

Salivary tumor pathology has been revolutionized over the past decade by the identification of a variety of genetic mutations in these neoplasms. Not only do such genetic abnormalities help us to understand the pathogenesis of these tumors, the specificity of such mutations often plays a critical role in helping to establish the final diagnosis and subsequent treatment. Table 11.12 lists a number of genetic abnormalities that have been associated with various salivary tumors.

◆ PLEOMORPHIC ADENOMA (BENIGN MIXED TUMOR)

The **pleomorphic adenoma,** or **benign mixed tumor,** is easily the most common salivary neoplasm. It accounts for 45%– 63% of parotid tumors, 53%–72% of submandibular tumors, and 33%–41% of minor gland tumors.

Pleomorphic adenomas are epithelial tumors characterized by a mixture of ductal cells, myoepithelium-like cells, and mesenchymal metaplasia. A remarkable microscopic diversity can exist from one tumor to the next, as well as in different areas of the same tumor. The terms *pleomorphic adenoma* and *mixed tumor* both represent attempts to describe this tumor's unusual histopathologic features, but neither term is entirely accurate. Although the basic tumor pattern is highly variable, rarely are the individual cells actually pleomorphic. (However, focal minor atypia is acceptable.) Likewise, although the tumor often has a prominent mesenchyme-appearing "stromal" component, it is not truly a mixed neoplasm that is derived from more than one germ layer. Cytogenetic analysis has shown translocations in approximately 70% of pleomorphic adenomas, primarily involving *pleomorphic adenoma gene 1 (PLAG1)* or the *high-mobility group AT-hook 2 gene (HMGA2).*

Clinical and Radiographic Features

Regardless of the site of origin, the pleomorphic adenoma typically appears as a painless, slowly growing, firm mass (Figs. 11.34–11.36). The patient may be aware of the lesion for many months or years before seeking a diagnosis. The

tumor can occur at any age but is most common in young and middle-aged adults between the ages of 30 and 60. Pleomorphic adenoma is also the most common primary salivary gland tumor to develop during childhood. There is a slight female predilection.

Most pleomorphic adenomas of the parotid gland occur in the superficial lobe and present as a swelling overlying the mandibular ramus in front of the ear. Facial nerve palsy and pain are rare. Initially, the tumor is movable but becomes less mobile as it grows larger. If neglected, then the lesion can grow to grotesque proportions. About 10% of parotid mixed tumors develop within the deep lobe of the gland beneath the facial nerve (Fig. 11.37). Sometimes these lesions grow in a medial direction between the ascending ramus and stylomandibular ligament, resulting in a dumbbell-shaped tumor that appears as a mass of the lateral pharyngeal wall or soft palate. On rare occasions, bilateral pleomorphic adenomas of the parotid glands have been reported, developing in either a synchronous or metachronous fashion.

The palate is the most common site for minor gland mixed tumors, accounting for approximately 50%–65% of intraoral examples. This is followed by the upper lip (19%–27%) and buccal mucosa (13%– 17%). Palatal tumors almost always are found on the posterior lateral aspect of the palate, presenting as smooth-surfaced, dome-shaped masses (Fig. 11.38). If the tumor is traumatized, then secondary ulceration may occur. Because of the tightly bound nature of the hard palate mucosa, tumors in this location are not movable, although those in the lip or buccal mucosa frequently are mobile (Fig. 11.39).

Histopathologic Features

The pleomorphic adenoma is typically a well-circumscribed, encapsulated tumor (Fig. 11.40). However, the capsule may be incomplete or show infiltration by tumor cells. This lack of complete encapsulation is more common for minor gland

• **Fig. 11.37 Pleomorphic Adenoma. A**, Large tumor from the deep lobe of the parotid gland, which has resulted in a firm mass of the lateral soft palate. **B**, Contrast-enhanced axial magnetic resonance image (MRI) of a tumor of the deep lobe of the parotid gland. (Courtesy of Dr. Terry Day.)

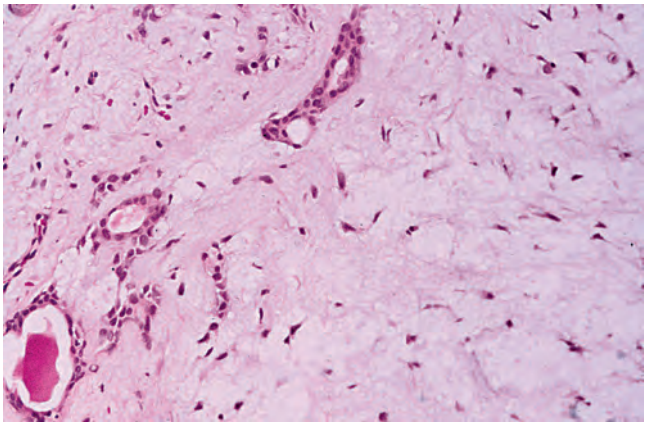
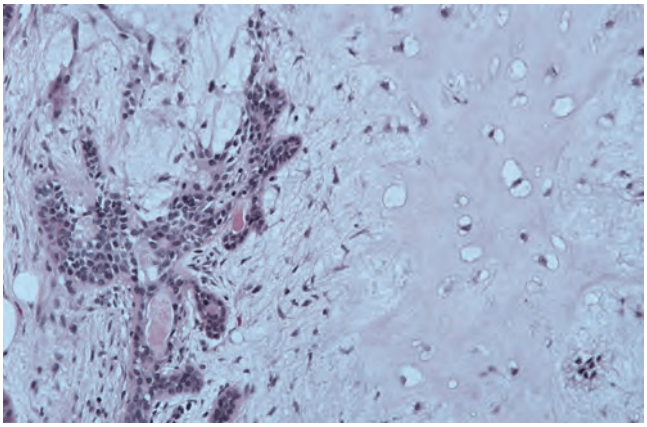
• **Fig. 11.40 Pleomorphic Adenoma.** Low-power view showing a well-circumscribed, encapsulated tumor mass. Even at this power, the variable microscopic pattern of the tumor is evident.



the mesenchyme-like component is highly variable among different tumors. Some tumors may consist almost entirely of background "stroma." Others are highly cellular with little background alteration.

The epithelium often forms ducts and cystic structures or may occur as islands or sheets of cells. Keratinizing squamous cells and mucus-producing cells also can be seen. Myoepithelial cells often make up a large percentage of the tumor cells and have a variable morphology, sometimes appearing angular or spindled. Some myoepithelial cells are rounded and demonstrate an eccentric nucleus and eosinophilic hyalinized cytoplasm, thus resembling plasma cells (Fig. 11.41). These characteristic plasmacytoid myoepithelial cells are more prominent in tumors arising in the minor glands.



The highly characteristic "stromal" changes are believed to be produced by the myoepithelial cells. Extensive accumulation of mucoid material may occur between the tumor cells, resulting in a myxomatous background (Fig. 11.42). Vacuolar degeneration of cells in these areas can produce a chondroid appearance (Fig. 11.43). In many tumors, the

• **Fig. 11.41 Pleomorphic Adenoma.** Plasmacytoid myoepithelial cells.

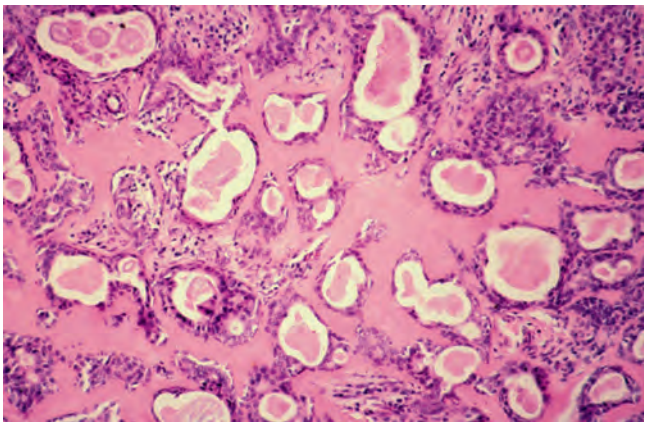
• **Fig. 11.42 Pleomorphic Adenoma.** Ductal structures *(left)* with associated myxomatous background *(right)*.

• **Fig. 11.43 Pleomorphic Adenoma.** Chondroid material *(right)* with adjacent ductal epithelium and myoepithelial cells.

stroma exhibits areas of an eosinophilic, hyalinized change (Fig. 11.44). At times, fat or osteoid also is seen.

Occasionally, salivary tumors are seen that are composed almost entirely of myoepithelial cells with no ductal elements. Such tumors often are called **myoepitheliomas,**

dentlearn.ir



although they probably represent one end of the spectrum of mixed tumors.

Treatment and Prognosis

Pleomorphic adenomas are best treated by surgical excision. For lesions in the superficial lobe of the parotid gland, superficial parotidectomy with identification and preservation of the facial nerve traditionally has been recommended, although some surgeons may opt for less aggressive partial superficial parotidectomy or extracapsular dissection. However, local enucleation should be avoided because the entire tumor may not be removed or the capsule may be violated, resulting in seeding of the tumor bed. For tumors of the deep lobe of the parotid, total parotidectomy is usually necessary, also with preservation of the facial nerve, if possible. Submandibular tumors are best treated by total removal of the gland with the tumor. Tumors of the hard palate usually are excised down to periosteum, including the overlying mucosa. In other oral sites the lesion often enucleates easily through the incision site.

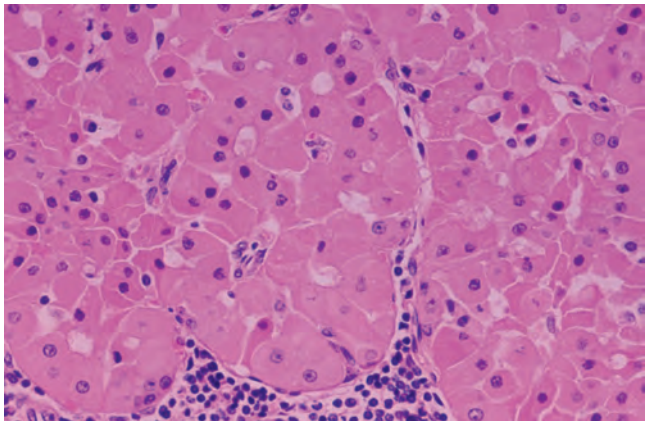
With adequate surgery the prognosis is excellent, with a cure rate of more than 95%. The risk of recurrence appears to be lower for tumors of the minor glands. Conservative enucleation of parotid tumors often results in recurrence, with management of these cases made difficult as a result of multifocal seeding of the primary tumor bed. In such cases, multiple recurrences are not unusual and may necessitate adjuvant radiation therapy. Tumors with a predominantly myxoid appearance are more susceptible to recur than those with other microscopic patterns.

Malignant degeneration is a potential complication, resulting in a **carcinoma ex pleomorphic adenoma** (see page 499). The risk of malignant transformation is probably small, but it may occur in as many as 3%–4% of all cases. This risk increases with the duration of the tumor.

• **Fig. 11.44 Pleomorphic Adenoma.** Many of the ducts and myoepithelial cells are surrounded by a hyalinized, eosinophilic background alteration.

◆ ONCOCYTOMA (OXYPHILIC ADENOMA)

The **oncocytoma** is a benign salivary gland tumor composed of large epithelial cells known as **oncocytes.** The prefix *onco-* is derived from the Greek word *onkoustai,* which means *to swell.* The swollen granular cytoplasm of oncocytes is due to excessive accumulation of mitochondria. Focal oncocytic metaplasia of salivary ductal and acinar cells is a common finding that is related to patient age; oncocytes are uncommon in persons younger than 50, but they can be found in almost all individuals by age 70. In addition to salivary glands, oncocytes have been identified in a number of other organs, especially the thyroid, parathyroid, and kidney. The oncocytoma is a rare neoplasm, representing approximately 1% of all salivary tumors.



Clinical Features

The oncocytoma is predominantly a tumor of older adults, with peak prevalence in the sixth to eighth decades of life. No significant sex predilection has been observed. Oncocytomas occur primarily in the major salivary glands, especially the parotid gland, which accounts for about 85%–90% of all cases. Oncocytomas of the minor salivary glands are exceedingly rare.

The tumor appears as a firm, slowly growing, painless mass that rarely exceeds 4 cm in diameter. Parotid oncocytomas usually are found in the superficial lobe and are clinically indistinguishable from other benign tumors. On occasion, bilateral tumors can occur, although these may represent examples of **oncocytosis (multinodular oncocytic hyperplasia)** (see next topic).

Histopathologic Features

The oncocytoma is usually a well-circumscribed tumor that is composed of sheets of large polyhedral cells (oncocytes), with abundant granular, eosinophilic cytoplasm (Fig. 11.45). Sometimes these cells form an alveolar or glandular pattern.

• **Fig. 11.45 Oncocytoma.** Sheet of large, eosinophilic oncocytes.

dentlearn.ir

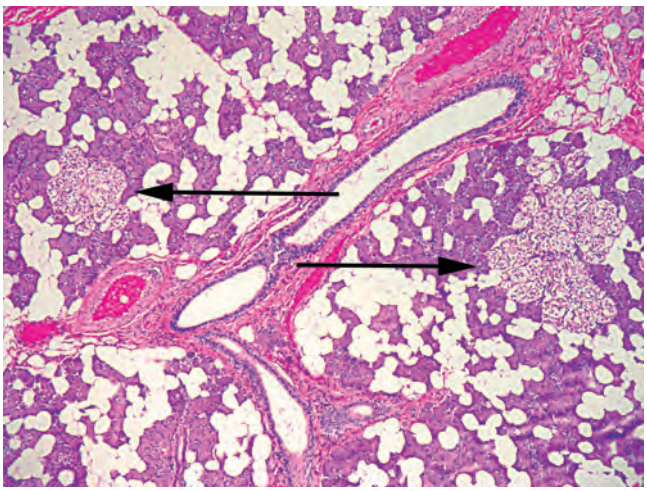
The cells have centrally located nuclei that can vary from small and hyperchromatic to large and vesicular. Little stroma is present, usually in the form of thin fibrovascular septa. An associated lymphocytic infiltrate may be noted.

The granularity of the cells corresponds to an overabundance of mitochondria, which can be demonstrated by electron microscopy. These granules also can be identified on light microscopic examination with a phosphotungstic acid hematoxylin (PTAH) stain. The cells also contain glycogen, as evidenced by their positive staining with the periodic acid-Schiff (PAS) technique but by negative PAS staining after digestion with diastase.

Oncocytomas may contain variable numbers of cells with a clear cytoplasm. In rare instances, these clear cells may compose most of the lesion and create difficulty in distinguishing the tumor from low-grade salivary clear cell adenocarcinoma or metastatic renal cell carcinoma.

Treatment and Prognosis

Oncocytomas are best treated by surgical excision. In the parotid gland, this usually entails partial parotidectomy (lobectomy) to avoid violation of the tumor capsule. The facial nerve should be preserved whenever possible. For tumors in the submandibular gland, treatment consists of total removal of the gland. Oncocytomas of the oral minor salivary glands should be removed with a small margin of normal surrounding tissue.



The prognosis after removal is good, with a low rate of recurrence. However, oncocytomas of the sinonasal glands can be locally aggressive and have been considered to be low-grade malignancies. Rare examples of histopathologically malignant oncocytomas **(oncocytic carcinoma)** also have been reported. Unfortunately, these carcinomas have a relatively poor prognosis.

◆ ONCOCYTOSIS (MULTINODULAR ONCOCYTIC HYPERPLASIA)

Oncocytic metaplasia is the transformation of ductal and acinar cells to oncocytes. Such cells are uncommon before the age of 50; however, as people get older, occasional oncocytes are common findings in the salivary glands. Focal oncocytic metaplasia also may be a feature of other salivary gland tumors. **Oncocytosis** refers to both the proliferation and the accumulation of oncocytes within salivary gland tissue. It may mimic a tumor, both clinically and microscopically, but it also is considered to be a metaplastic process rather than a neoplastic one.

Clinical Features

Oncocytosis is found primarily in the parotid gland; however, in rare instances, it may involve the submandibular or minor salivary glands. It can be an incidental finding in otherwise normal salivary gland tissue, but it may be extensive enough to produce clinical swelling. Usually the proliferation is multifocal and nodular, but sometimes the entire gland can be replaced by oncocytes **(diffuse hyperplastic oncocytosis).** As with other oncocytic proliferations, oncocytosis occurs most frequently in older adults.

• **Fig. 11.46 Oncocytosis.** Multifocal collections of clear oncocytes *(arrows)* in the parotid gland.

Histopathologic Features

Microscopic examination usually reveals focal nodular collections of oncocytes within the salivary gland tissue. These enlarged cells are polyhedral and demonstrate abundant granular, eosinophilic cytoplasm as a result of the proliferation of mitochondria. On occasion, these cells may have a clear cytoplasm from the accumulation of glycogen (Fig. 11.46). The multifocal nature of the proliferation may be confused with that of a metastatic tumor, especially when the oncocytes are clear in appearance.

Treatment and Prognosis

Oncocytosis is a benign condition and often is discovered only as an incidental finding. No further treatment is necessary, and the prognosis is excellent.

◆ WARTHIN TUMOR (PAPILLARY CYSTADENOMA LYMPHOMATOSUM)

Warthin tumor is a benign neoplasm that occurs almost exclusively in the parotid gland. Although it is less common than the pleomorphic adenoma, it represents the second most common benign parotid tumor, accounting for 7.7%–22.4% of all parotid neoplasms in large surveys (Table 11.5). However, several papers from central Europe have reported an increased incidence of Warthin tumor in recent years, surpassing that of pleomorphic adenoma in this region. The name **adenolymphoma** also has been used for this tumor, but this term should be avoided because it overemphasizes the lymphoid component and may give the

dentlearn.ir

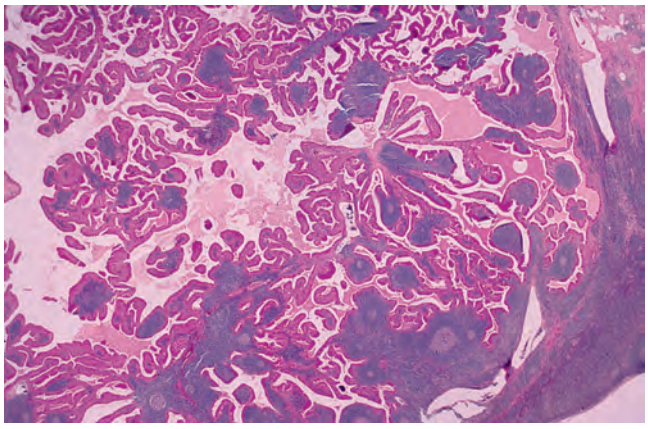
mistaken impression that the lesion is a type of lymphoma. Analyses of the epithelial and lymphoid components of the Warthin tumor usually have shown both to be polyclonal; this suggests that this lesion may not represent a neoplasm but would be better classified as a tumorlike process. Only 10% of tumors show genetic alterations.

The pathogenesis of Warthin tumor is uncertain. The traditional hypothesis suggests that it arises from heterotopic salivary gland tissue found within parotid lymph nodes. However, researchers have also suggested that these tumors may develop from a proliferation of salivary gland ductal epithelium that is associated with secondary formation of lymphoid tissue. A number of studies have demonstrated a strong association between the development of this tumor and smoking. Smokers have an eightfold greater risk for Warthin tumor than do nonsmokers. Obesity recently has been shown to be another potential risk factor.

Clinical Features

The Warthin tumor usually appears as a slowly growing, painless, nodular mass of the parotid gland (Fig. 11.47). It may be firm or fluctuant to palpation. The tumor most frequently occurs in the tail of the parotid near the angle of the mandible, and it may be noted for many months before the patient seeks a diagnosis. One unique feature is the tendency of Warthin tumor to occur bilaterally, which has been noted in 5%–17% of reported cases. Most of these bilateral tumors do not occur simultaneously but are metachronous (occurring at different times).

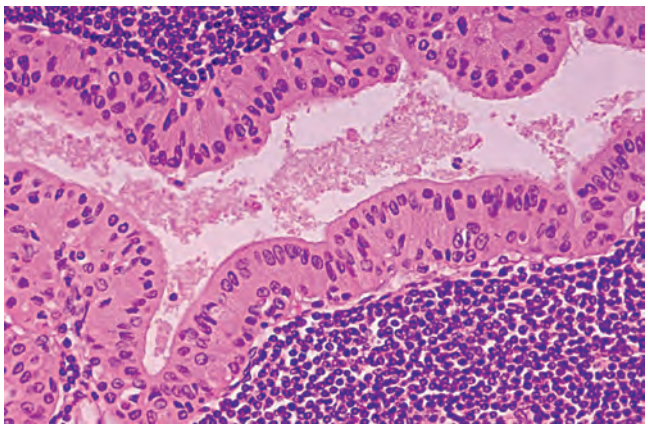
• **Fig. 11.47 Warthin Tumor.** Mass in the tail of the parotid gland. (Courtesy of Dr. George Blozis.)



In rare instances, the Warthin tumor has been reported within the submandibular gland or minor salivary glands. However, because the lymphoid component is often less pronounced in these extraparotid sites, the pathologist should exercise caution to avoid overdiagnosis of a lesion better classified as a papillary cystadenoma or a salivary duct cyst with oncocytic ductal metaplasia.

Warthin tumor most often occurs in older adults, with peak prevalence in the sixth and seventh decades of life. The observed frequency of this tumor is much lower in blacks than in whites. Most studies show a decided male predilection, with some early studies demonstrating a male-to-female ratio up to 10:1. However, more recent investigations show a more balanced sex ratio. Because Warthin tumors have been associated with cigarette smoking, this changing sex ratio may be a reflection of a more equal prevalence of smoking in women over the past few decades. This association with smoking also may help explain the frequent bilaterality of the tumor, because any tumorigenic effects of smoking would be manifested in both parotids.

Histopathologic Features



The Warthin tumor has one of the most distinctive histopathologic patterns of any tumor in the body. Although the term **papillary cystadenoma lymphomatosum** is cumbersome, it accurately describes the salient microscopic features.

The tumor is composed of a mixture of ductal epithelium and a lymphoid stroma (Figs. 11.48 and 11.49). The epithelium is oncocytic in nature, forming uniform rows of cells surrounding cystic spaces. The cells have abundant, finely granular eosinophilic cytoplasm and are arranged in two layers. The inner luminal layer consists of tall columnar cells with centrally placed, palisaded, and slightly hyperchromatic nuclei. Beneath this is a second layer of cuboidal or polygonal cells with more vesicular nuclei. The lining epithelium demonstrates multiple papillary infoldings that protrude into the cystic spaces. Focal areas of squamous metaplasia or mucous cell prosoplasia may be seen. The epithelium is supported by

• **Fig. 11.48 Warthin Tumor.** Low-power view showing a papillary cystic tumor with a lymphoid stroma.

dentlearn.ir

• **Fig. 11.49 Warthin Tumor.** High-power view of epithelial lining showing double row of oncocytes with adjacent lymphoid stroma.

a lymphoid stroma that frequently shows germinal center formation.

Treatment and Prognosis

Surgical removal is the treatment of choice for most patients with Warthin tumor. The procedure usually is easily accomplished because of the superficial location of the tumor. Some surgeons prefer local resection with minimal surrounding tissue; others opt for superficial parotidectomy to avoid violating the tumor capsule and because a tentative diagnosis may not be known preoperatively. If a confident diagnosis of Warthin tumor can be made by fine-needle aspiration cytology of a non-suspicious parotid growth, some clinicians will elect to manage the patient conservatively with regular follow-up visits rather than surgery.

A 2%–6% recurrence rate has been reported following surgery. Many authors, however, believe that the tumor is frequently multicentric in nature; therefore, it is difficult to determine whether these are true recurrences or secondary tumor sites. Malignant Warthin tumors **(carcinoma ex papillary cystadenoma lymphomatosum)** have been reported but are exceedingly rare.

◆ MONOMORPHIC ADENOMA

The term **monomorphic adenoma** originally was used to describe a group of benign salivary gland tumors demonstrating a more uniform histopathologic pattern than the common pleomorphic adenoma. In some classification schemes, a variety of tumors were included under the broad heading of monomorphic adenoma, including Warthin tumor, oncocytoma, basal cell adenoma, and canalicular adenoma. Other authors have used this term more specifically as a synonym just for the basal cell adenoma or canalicular adenoma. Because of its ambiguous nature, the term *monomorphic adenoma* probably should be avoided, and each of the tumors mentioned should be referred to by its more specific name.

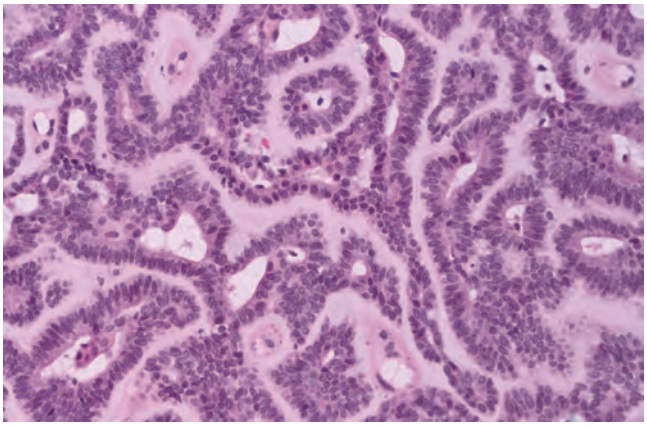
• **Fig. 11.50 Canalicular Adenoma.** Mass in the upper lip. (Courtesy of Dr. John Fantasia.)

◆ CANALICULAR ADENOMA

The **canalicular adenoma** is an uncommon tumor that occurs almost exclusively in the minor salivary glands. Because of its uniform microscopic pattern, the canalicular adenoma also has been called a *monomorphic adenoma.* However, because this term also has been applied to other tumors, its use probably should be discontinued. Likewise, the term **basal cell adenoma** sometimes has been used synonymously for this tumor but should be avoided because it refers to a separate tumor with different clinical features (see next topic). Based on its immunohistochemical profile, the canalicular adenoma may arise from intercalated duct luminal cells.

Clinical Features

The canalicular adenoma shows a striking predilection for the upper lip, with 66%–78% occurring in this location. It represents the first or second most common tumor (along with pleomorphic adenoma) of the upper lip. The buccal mucosa is the second most common site. Occurrence in other minor salivary glands is uncommon, and canalicular adenomas of the parotid gland are rare.



The tumor nearly always occurs in older adults, with peak prevalence in the seventh decade of life. There is a definite female predominance, ranging from 1.5 to 1.8 females for each male.

The canalicular adenoma appears as a slowly growing, painless mass that usually ranges from several millimeters to 2 cm (Fig. 11.50). It may be firm or somewhat fluctuant to palpation. The overlying mucosa may be normal in color or bluish and can be mistaken for a mucocele. However, mucoceles of the upper lip are rare. In some instances, the lesion has been noted to be multifocal, with multiple separate tumors discovered in the upper lip or buccal mucosa.

Histopathologic Features

The microscopic pattern of canalicular adenoma is monomorphic in nature. This pattern is characterized by single-layered cords of columnar or cuboidal epithelial cells with

dentlearn.ir

• **Fig. 11.51 Canalicular Adenoma.** Uniform columnar cells forming canal-like ductal structures.

deeply basophilic nuclei (Fig. 11.51). In some areas, adjacent parallel rows of cells may be seen, resulting in a bilayered appearance of the tumor cords. These cells enclose ductal structures, sometimes in the form of long canals. Larger cystic spaces often are created, and the epithelium may demonstrate papillary projections into the cystic lumina. Small groups of metaplastic cells, known as squamous balls or morules, sometimes are found in the cystic spaces. The tumor cells are supported by a loose connective tissue stroma with prominent vascularity. Unlike the appearance in pleomorphic adenomas, stromal alterations, such as chondroid metaplasia, do not occur. A thin, fibrous capsule often surrounds the tumor, although satellite islands are observed in the surrounding salivary gland tissue in approximately 13%–24% of cases, which explains the tendency for multifocal tumors.

Treatment and Prognosis

The canalicular adenoma is best treated by local surgical excision. Recurrence is uncommon and actually may represent cases that are multifocal in nature.

◆ BASAL CELL ADENOMA

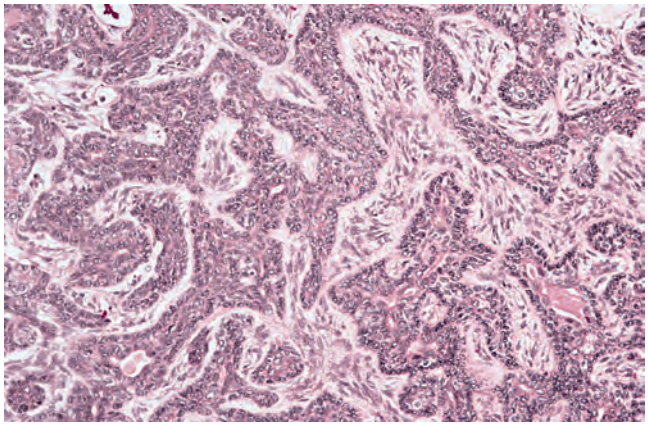
The **basal cell adenoma** is a benign salivary tumor that derives its name from the basaloid appearance of the tumor cells. It is an uncommon neoplasm that represents only 1%–4% of all salivary tumors. Because of its uniform histopathologic appearance, it often has been classified as one of the monomorphic adenomas. However, as mentioned previously, this term probably should be avoided because of its imprecise and frequently confusing definition. In addition, ultrastructural and immunohistochemical studies have shown that basal cell adenomas are not necessarily composed of only one cell type but sometimes of a combination of salivary ductal epithelium and myoepithelial cells. The basal cell adenoma shows some histopathologic similarity to the canalicular adenoma; in the past, these two terms sometimes were used synonymously. However, histopathologic and clinical differences warrant that they be considered as distinct entities.

Clinical Features

Unlike the canalicular adenoma, the basal cell adenoma is primarily a tumor of the parotid gland, with around 75% of all cases occurring there. However, the minor glands represent the second most common site, specifically the glands of the upper lip and buccal mucosa. The tumor can occur at any age but is most common in middle-aged and older adults, with peak prevalence in the seventh decade of life. The tumor appears to be more common in women, with some studies showing as high as a 2:1 female-to-male ratio.

Clinically, the basal cell adenoma appears as a slowly growing, freely movable mass similar to a pleomorphic adenoma. Most tumors are less than 3 cm in diameter. Parotid tumors usually are located within the superficial lobe of the gland.

One subtype, the **membranous basal cell adenoma,** deserves separate mention. This form of the tumor appears to be hereditary, often occurring in combination with skin appendage tumors, such as **dermal cylindromas** and **trichoepitheliomas** (**Brooke-Spiegler syndrome**). Multiple bilateral tumors may develop within the parotids. Because these tumors often bear a histopathologic resemblance to the skin tumors, they also have been called **dermal analogue tumors.**



Histopathologic Features

The basal cell adenoma is usually encapsulated or well circumscribed. The most common subtype is the solid variant, which consists of multiple islands and cords of epithelial cells that are supported by a small amount of fibrous stroma. The peripheral cells of these islands are palisaded and cuboidal to columnar in shape, similar to the microscopic appearance of basal cell carcinoma. These peripheral cells are frequently hyperchromatic; the central cells of the islands tend to have paler staining nuclei. The central cells occasionally form eddies or keratin pearls.

The trabecular subtype demonstrates narrow cordlike epithelial strands (Fig. 11.52). The tubular subtype is characterized by the formation of small, round, ductlike structures. Some basal cell adenomas demonstrate zones with a cribriform pattern that can mimic adenoid cystic carcinoma. Frequently, a mixture of histopathologic subtypes is seen. Immunohistochemical expression of nuclear β-catenin in the basal cell adenoma can help to distinguish this tumor from adenoid cystic carcinoma. One recent study found that 60% of basal cell adenomas harbored mutations of the *CTNNB1* gene.

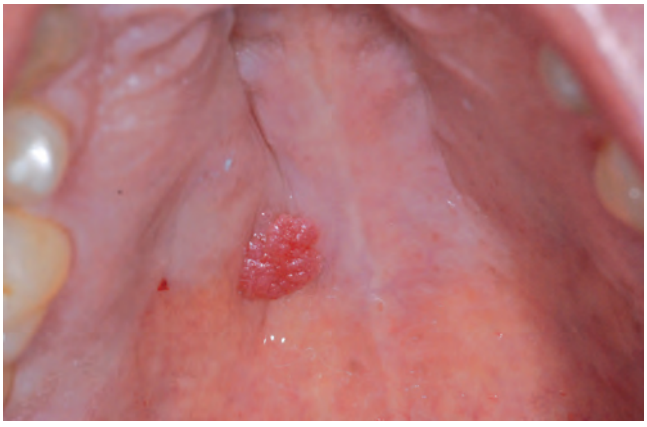
The membranous basal cell adenoma exhibits multiple large lobular islands of tumor that are molded together in a jigsaw puzzle fashion. These islands are surrounded by a thick layer of hyaline material, which represents reduplicated

dentlearn.ir

• **Fig. 11.52 Basal Cell Adenoma.** Parotid tumor showing cords of basaloid cells arranged in a trabecular pattern.

basement membrane. Similar hyaline droplets also are often found among the epithelial cells. The microscopic appearance is similar to that of a dermal cylindroma, one of the skin tumors with which it is often associated.

Treatment and Prognosis



The treatment of basal cell adenoma is similar to that of pleomorphic adenoma and consists of complete surgical removal. Recurrence is rare for most histopathologic subtypes. However, the membranous subtype has a 25%–37% recurrence rate, possibly related to its multifocal nature.

The malignant counterpart of the basal cell adenoma is the **basal cell adenocarcinoma.** Most basal cell adenocarcinomas arise *de novo,* but some examples develop from malignant degeneration of a preexisting basal cell adenoma. Fortunately, these tumors have a relatively good prognosis; although local recurrence is common, the tumor rarely metastasizes or results in death.

◆ DUCTAL PAPILLOMAS (SIALADENOMA PAPILLIFERUM; INTRADUCTAL PAPILLOMA; INVERTED DUCTAL PAPILLOMA)

A number of salivary gland tumors can be characterized microscopically by a papillomatous pattern, the most common being Warthin tumor (papillary cystadenoma lymphomatosum). The **sialadenoma papilliferum, intraductal papilloma,** and **inverted ductal papilloma** are three rare salivary tumors that also show unique papillomatous features.

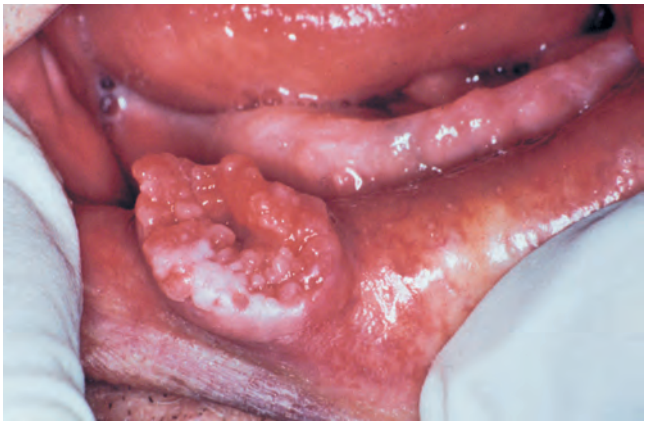
It also should be mentioned that, on occasion, the common squamous papilloma (see page 355) of the oral mucosa will arise at the site where a minor salivary gland duct merges with the surface epithelium. Because of this location, such squamous papillomas may contain scattered mucous cells within the exophytic papillary growth, and these lesions have sometimes been called *ductal papillomas.* However, it should be emphasized that these lesions are surface papillomas and not primary salivary gland tumors.

• **Fig. 11.53 Sialadenoma Papilliferum.** Exophytic papillary mass on the palate. (Courtesy of Dr. Peter Lyu.)

Clinical Features

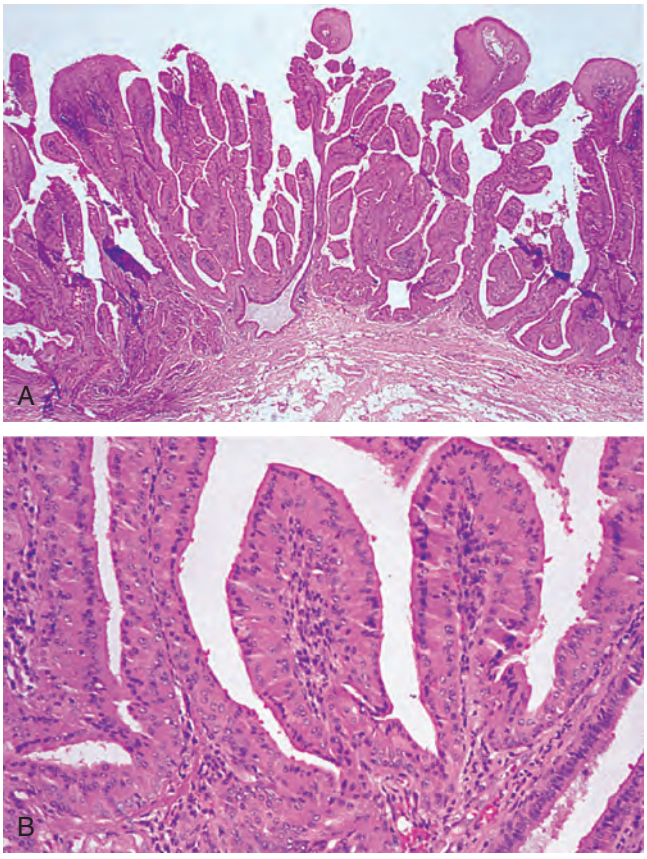
The sialadenoma papilliferum occurs almost exclusively in the minor salivary glands, especially on the palate (80% of all cases), although it also has been reported in the parotid gland. It usually is seen in middle-aged and older adults and has a 1.7:1 male-to-female ratio. The tumor appears as an exophytic, papillary surface growth that is clinically similar to the common squamous papilloma (Fig. 11.53).

The intraductal papilloma is an ill-defined lesion that often has been confused with other salivary gland lesions, such as the papillary cystadenoma. It usually occurs in adults and is most common in the minor salivary glands, where it appears as a submucosal swelling.



The inverted ductal papilloma is a rare tumor that has been described only in the minor salivary glands of adults. The lower lip and mandibular vestibule are the most common locations. The lesion usually appears as an asymptomatic nodule, which sometimes may show a pit or indentation in the overlying surface mucosa (Fig. 11.54).

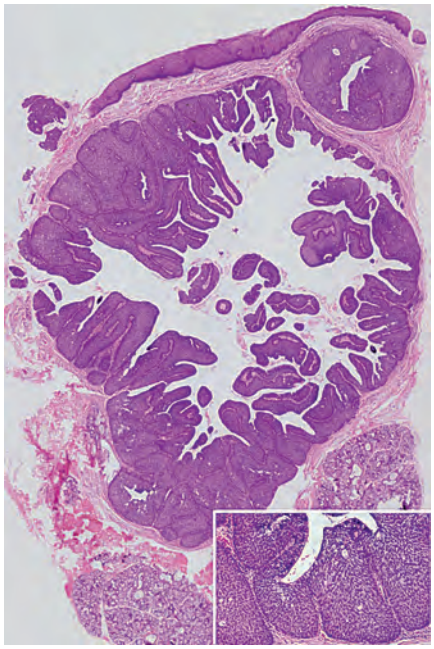
Histopathologic Features



At low-power magnification, the sialadenoma papilliferum is somewhat similar to the squamous papilloma, exhibiting multiple exophytic papillary projections that are covered by stratified squamous epithelium. This epithelium is contiguous with a proliferation of papillomatous ductal epithelium found below the surface and extending downward into the deeper connective tissues (Fig. 11.55). Multiple ductal lumina are formed, which characteristically are lined by a double-rowed layer of cells consisting of a luminal layer of tall columnar cells and a basilar layer of smaller cuboidal cells. These ductal cells sometimes have an oncocytic appearance. An inflammatory infiltrate of plasma cells, lymphocytes, and neutrophils is characteristically present.

Because of their microscopic similarity, the sialadenoma papilliferum has been considered to be an analogue of the cutaneous syringocystadenoma papilliferum. This concept is supported by the consistent finding of *BRAF* V600E mutations in classic sialadenoma papilliferum, which also have

dentlearn.ir



• **Fig. 11.54 Inverted Ductal Papilloma.** Exophytic mass with central papillary projections on the lower labial mucosa. (Courtesy of Dr. Amy Bogardus.)

• **Fig. 11.55 Sialadenoma Papilliferum. A,** Low-power view showing a papillary surface tumor with associated ductal structures in the superficial lamina propria. **B,** High-power view of cystic areas lined by papillary, oncocytic epithelium.

been identified in 52% of cases of syringocystadenoma papilliferum. However, oncocytic variants of sialadenoma papilliferum do not exhibit this mutation, suggesting that this pattern may represent a distinctly different lesion or subtype.

The intraductal papilloma exhibits a dilated, unicystic structure that is located below the mucosal surface. It is lined by a single or double row of cuboidal or columnar epithelium, which has multiple arborizing papillary projections

• **Fig. 11.56 Inverted Ductal Papilloma.** Papillary intraductal proliferation located beneath the mucosal surface. Higher-power view shows both squamous cells and mucous cells *(inset)*. (Courtesy of Dr. Dean K. White.)

into the cystic lumen. In contrast, the inverted ductal papilloma is composed primarily of a proliferation of squamoid epithelium with multiple thick, bulbous papillary projections that fill the ductal lumen (Fig. 11.56). This epithelium may be contiguous with the overlying mucosal epithelium, communicating with the surface through a small pore-like opening. Although the tumor is primarily squamous in nature, the luminal lining cells of the papillary projections are often cuboidal or columnar in shape, with scattered mucus-producing cells. *In situ* hybridization analysis has shown positivity for human papillomavirus (HPV) types 6 and 11 in both the surface and inverted epithelium of some inverted ductal papillomas.

Treatment and Prognosis

All three forms of ductal papilloma are best treated by conservative surgical excision. Recurrence is rare.

◆ MUCOEPIDERMOID CARCINOMA

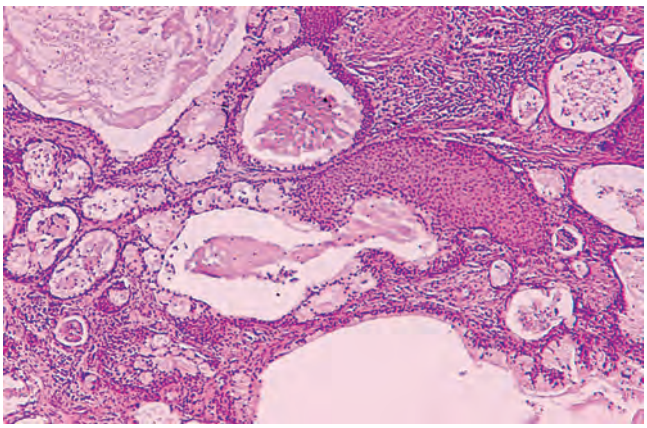
Mucoepidermoid carcinoma is the most common salivary gland malignancy. Because of its highly variable biologic potential, it was originally called **mucoepidermoid tumor.** The term recognized one subset that acted in a malignant fashion and a second group that appeared to behave in a benign fashion with favorable prognosis. However, researchers later recognized that even low-grade tumors occasionally will exhibit malignant behavior; therefore, the term *mucoepidermoid carcinoma* is the preferred designation.

dentlearn.ir

The pathogenesis of this tumor is uncertain, although radiation exposure may be one risk factor. Recent series have reported that 59%–86% of mucoepidermoid carcinomas will show *MAML2* rearrangements, resulting in the production of *CRTC1::MAML2* or *CRTC3::MAML2* gene fusions. Such gene rearrangements have been identified more frequently in low- and intermediate-grade tumors.

Clinical Features

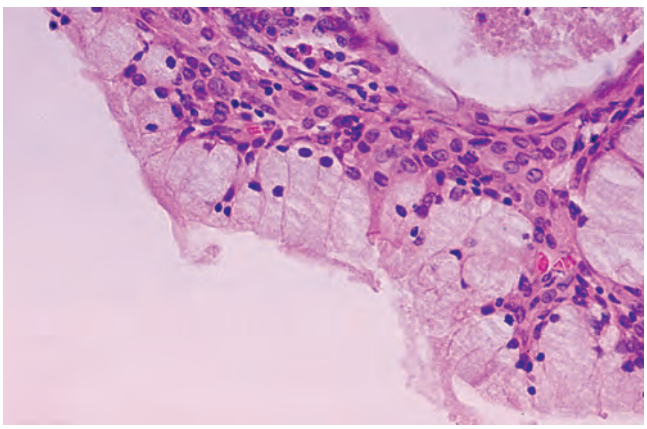
Most large series show mucoepidermoid carcinoma to be the most common malignant salivary gland neoplasm, comprising 4%–10% of all major gland tumors and 13%–23% of minor gland tumors. The tumor occurs fairly evenly over a wide age range, extending from the second to seventh decades of life. Rarely is it seen in the first decade of life. However, mucoepidermoid carcinoma is the most common malignant salivary gland tumor in children.



The mucoepidermoid carcinoma is most common in the parotid gland and usually appears as an asymptomatic swelling. Most patients are aware of the lesion for 1 year or less, although some report a mass of many years' duration. Pain or facial nerve palsy may develop, usually in association with high-grade tumors. The minor glands constitute the second most common site, especially the palate (Fig. 11.57). Minor gland tumors also typically appear as asymptomatic swellings, which are sometimes fluctuant and have a blue or red color that can be mistaken clinically for a mucocele. Although the lower lip, floor of mouth, tongue, and retromolar pad areas are uncommon locations for salivary gland neoplasia, the mucoepidermoid carcinoma is the most common salivary tumor in each of these sites (Fig. 11.58). Intraosseous tumors also may develop in the jaws (see page 496).

Histopathologic Features

As its name implies, the *mucoepidermoid carcinoma* is composed of a mixture of mucus-producing cells and squamous (epidermoid) cells (Figs. 11.59–11.61). The mucous cells vary in shape but contain abundant foamy cytoplasm that stains positively with mucin stains. The epidermoid cells are characterized by squamoid features, often demonstrating a polygonal shape, abundant eosinophilic cytoplasm, and intercellular bridges, but rarely overt keratinization. In addition, a third type of cell—the intermediate cell—is typically present and



• **Fig. 11.58 Mucoepidermoid Carcinoma.** Mass of the tongue.

• **Fig. 11.60 Mucoepidermoid Carcinoma.** This low-grade tumor shows numerous large mucous cells surrounding a cystic space.

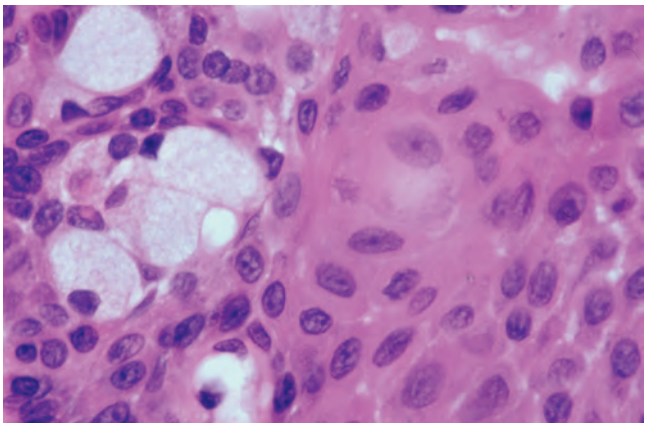
dentlearn.ir

is believed to be a progenitor of both the mucous and the epidermoid cells. Intermediate cells vary in appearance from small, basaloid ("maternal") cells to slightly larger ovoid cells with scant, pale eosinophilic cytoplasm. Some tumors also show variable numbers of clear cells, which sometimes can predominate the microscopic picture (Fig. 11.62). An associated lymphoid infiltrate is not unusual and may be so prominent in some cases that the lesion can be mistaken for a metastatic tumor within a lymph node. Other variants of mucoepidermoid carcinoma can demonstrate numerous oncocytes or prominent sclerosis of the tumor stroma.

Traditionally, mucoepidermoid carcinomas have been categorized into one of three histopathologic grades based on the following:

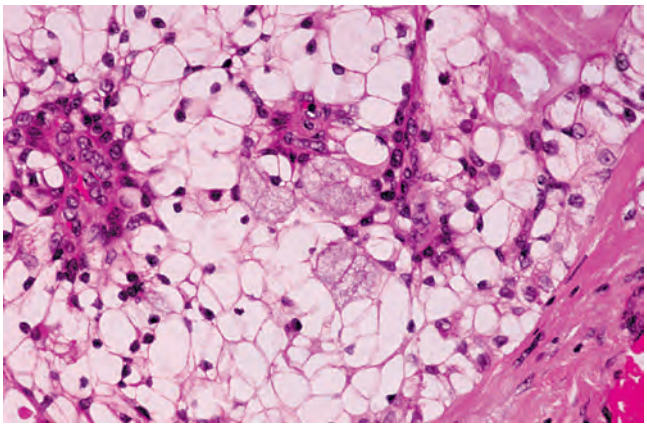
1. Amount of cyst formation
2. Degree of cytologic atypia
3. Relative numbers of mucous, epidermoid, and intermediate cells

Low-grade tumors show prominent cyst formation, minimal cellular atypia, and a relatively high proportion of mucous cells. **High-grade** tumors consist of solid islands of squamous and intermediate cells, which can demonstrate considerable pleomorphism and mitotic activity (Fig. 11.63). Mucus-producing cells may be infrequent, and the tumor sometimes can be difficult to distinguish from squamous cell carcinoma.



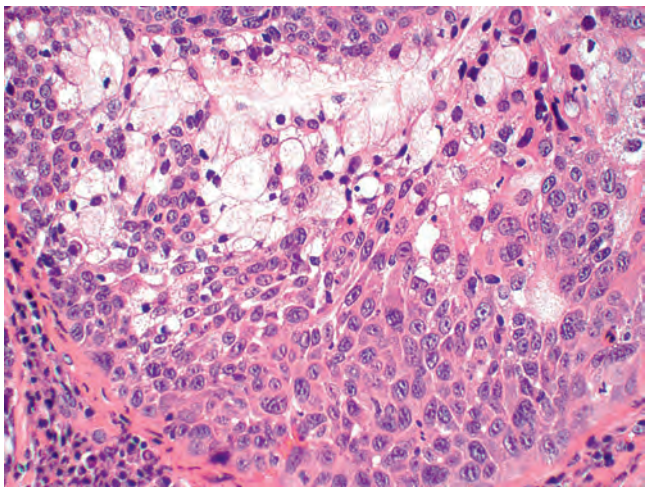
Intermediate-grade tumors show features that fall between those of the low-grade and high-grade neoplasms. Cyst formation occurs but is less prominent than that observed in low-grade tumors. All three major cell types are present, but the intermediate cells usually predominate. Cellular atypia may or may not be observed.

However, some authors have found that the relative proportion of the three different cell types does not necessarily correlate with prognosis. To overcome this, two expert groups have proposed evaluation schemes based on significant microscopic parameters, to which relative point values have been assigned to determine the grade of the tumor (Table 11.13).



Treatment and Prognosis

The treatment of mucoepidermoid carcinoma is predicated by the location, histopathologic grade, and clinical stage of the tumor. Early-stage tumors of the parotid often can be treated by subtotal parotidectomy with preservation of the facial nerve. Advanced tumors may necessitate total removal of the parotid gland, with sacrifice of the facial nerve. Submandibular gland tumors are treated by total removal of the gland. Mucoepidermoid carcinomas of the minor glands usually are treated by assured surgical excision. For low-grade neoplasms, only a modest margin of surrounding normal tissue may need to be removed, but high-grade or large tumors warrant wider resection, similar to that required for squamous cell carcinomas. If there is underlying bone destruction, then the involved bone must be excised.



Neck dissection is indicated for patients with clinical evidence of metastatic disease and also may be considered for patients with larger or high-grade tumors. Postoperative radiation therapy also may be used for more aggressive tumors.

III	4 or more

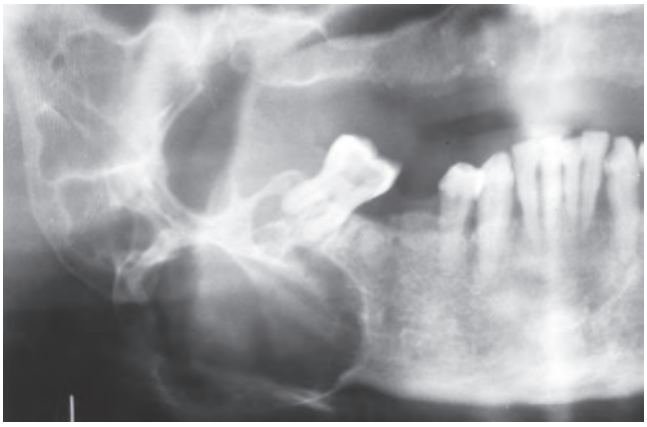
From Auclair PL, Goode RK, Ellis GL: Mucoepidermoid carcinoma of intraoral salivary glands: evaluation and application of grading criteria in 143 cases, *Cancer* 69:2021–2030, 1992; Brandwein MS, Ivanov K, Wallace DI, et al: Mucoepidermoid carcinoma: a clinicopathologic study of 80 patients with special reference to histological grading, *Am J Surg Pathol* 25:835–845, 2001.

The prognosis depends on the grade and stage of the tumor. Patients with low-grade tumors generally have a good prognosis. For most primary sites, local recurrences or regional metastases are uncommon, and around 90%–98% of patients are cured. The prognosis for those with intermediate-grade tumors is only slightly worse than that for low-grade tumors. The outlook for patients with high-grade tumors is more guarded, with only 30%64% of patients surviving. Historically, tumors that exhibit *CRTC1::MAML2* or *CRTC3::MAML2* fusion genes have shown a better prognosis than tumors without such translocations. However, some recent articles have questioned the prognostic significance of this finding.

For unknown reasons, submandibular gland tumors are associated with a poorer outlook than those in the parotid gland. Mucoepidermoid carcinomas of the oral minor salivary glands generally have a good prognosis, probably because they are mostly low- to intermediate-grade tumors. However, tumors of the tongue, floor of the mouth, and oropharynx are less predictable and may exhibit more aggressive behavior.

◆ INTRAOSSEOUS MUCOEPIDERMOID CARCINOMA (CENTRAL MUCOEPIDERMOID CARCINOMA)

On rare occasions, salivary gland tumors arise centrally within the jaws. The most common and best-recognized intrabony salivary tumor is the **intraosseous mucoepidermoid carcinoma**, which comprises about 2%–3% of all mucoepidermoid carcinomas. However, other salivary tumors have been reported to develop within the jaws, including adenoid cystic carcinoma, benign and malignant mixed tumors, adenocarcinoma, acinic cell adenocarcinoma, epithelial-myoepithelial carcinoma, and monomorphic adenoma.



Several hypotheses have been proposed to explain the pathogenesis of intraosseous salivary tumors. One theory suggests that they may arise from ectopic salivary gland tissue that was developmentally entrapped within the jaws. However, the discovery of ectopic salivary tissue is uncommon in biopsy specimens from the jaws; therefore, this seems an unlikely source for most intrabony salivary tumors. Some maxillary tumors may arise from glands of the sinus lining, but this is often difficult to prove or disprove. The most likely source for most intraosseous tumors is odontogenic epithelium. Mucus-producing cells are common in odontogenic cyst linings, especially dentigerous cysts (see page 685). In addition, many intraosseous mucoepidermoid carcinomas develop in association with impacted teeth or odontogenic cysts.

Clinical and Radiographic Features

Intraosseous mucoepidermoid carcinomas are most common in middle-aged adults and affect women twice as often as men. They are more common in the mandible than in the maxilla and are most often seen in the molar-ramus area. The most frequent presenting symptom is cortical swelling, although some lesions may be discovered as incidental findings on radiographs. Pain, trismus, and paresthesia are reported less frequently.

Radiographs usually reveal either a unilocular or multilocular radiolucency with well-defined borders (Fig. 11.64). However, some examples are characterized by a more irregular and ill-defined area of bone destruction. Some cases are associated with an unerupted tooth and, therefore, clinically may suggest an odontogenic cyst or tumor.

dentlearn.ir

• **Fig. 11.64 Intraosseous Mucoepidermoid Carcinoma.** Multilocular lesion of the posterior mandible. (Courtesy of Dr. Joseph F. Finelli.)

Histopathologic Features

The microscopic appearance of intraosseous mucoepidermoid carcinoma is similar to that of its soft tissue counterpart. Most tumors are low-grade lesions, although high-grade mucoepidermoid carcinomas also have been reported within the jaws.

Treatment and Prognosis

The primary treatment modality for patients with intraosseous mucoepidermoid carcinoma is surgery; adjunctive radiation therapy also sometimes is used. Radical surgical resection offers a better chance for cure than do more conservative procedures, such as enucleation or curettage. The local recurrence rate with conservative treatment is 40%, in contrast to 11%–13% for more radical treatment. Metastasis has been reported in about 9% of cases. The overall prognosis is fairly good; around 10% of patients die, usually as a result of local recurrence of the tumor.

◆ ACINIC CELL CARCINOMA

The **acinic cell carcinoma** is a salivary gland malignancy with cells that show serous acinar differentiation. Because many of these tumors act in a nonaggressive fashion and are associated with a good prognosis, this neoplasm formerly was called **acinic cell tumor,** a nonspecific designation that did not indicate whether the lesion was benign or malignant. However, because some of these tumors do metastasize or recur and cause death, it is generally agreed today that acinic cell carcinoma should be considered a malignancy.

Many cases previously reported as acinic cell carcinoma, but which are poor in zymogen granules, would be reclassified today as examples of a recently delineated salivary neoplasm—secretory carcinoma (see next topic). This is especially true for purported acinic cell carcinomas in nonparotid sites. Therefore, evaluation of the literature and data on acinic cell carcinoma prior to 2010 is made more difficult.

• **Fig. 11.65 Acinic Cell Carcinoma.** Large, firm mass of the right parotid gland.

Clinical Features

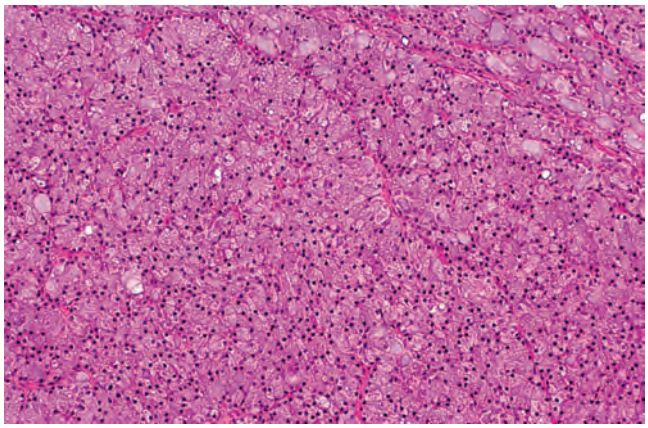
Around 85%–90% of all acinic cell carcinomas occur in the parotid gland, a logical finding because this is the largest gland and one that is composed entirely of serous elements (Fig. 11.65). Most surveys have shown that this neoplasm makes up 2%–3% of all parotid tumors, although one study showed it represented 8.6% of all parotid tumors (see Table 11.5). It is much less common in the submandibular gland, which is the site for only 2.7%–5% of these tumors. About 9% of all acinic cell carcinomas reportedly develop in the oral minor salivary glands, with the buccal mucosa, lips, and palate being the most common sites. Overall, around 1.3%–3.8% of all minor salivary gland tumors have been reported to be acinic cell carcinomas, although it is likely that many of these cases would be reclassified today as secretory carcinoma.

The tumor occurs over a broad age range, with a relatively even peak prevalence stretching from the second to the seventh decades of life; the mean age is in the middle 40s to early 50s. The tumor usually appears as a slowly growing mass, and the lesion often is present for many months or years before a diagnosis is made. The tumor may be otherwise asymptomatic, although associated pain or tenderness sometimes is reported. Facial nerve paralysis is an infrequent but ominous sign for parotid tumors.

Histopathologic Features

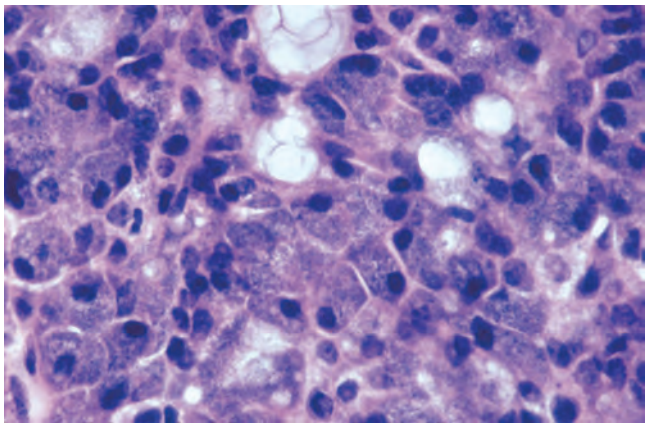
Acinic cell carcinomas are highly variable in their microscopic appearance. The tumor often is well circumscribed and sometimes may even appear encapsulated; however, some tumors exhibit an infiltrative growth pattern. The most characteristic cell is one with features of the serous acinar cell, with abundant granular basophilic cytoplasm and a round, darkly stained eccentric nucleus. These cells are fairly uniform in appearance, and mitotic activity is uncommon. Other cells may resemble intercalated duct cells, and some tumors also have cells with a clear, vacuolated cytoplasm. On rare occasions, the tumor may demonstrate features of high-grade transformation, including pleomorphism, increased mitotic activity, and necrosis.

dentlearn.ir



Several growth patterns have been described. The **solid** variety consists of numerous well-differentiated acinar cells arranged in a pattern that resembles normal parotid gland tissue (Figs. 11.66 and 11.67). In the **microcystic** variety, multiple small cystic spaces are created that may contain some mucinous or eosinophilic material. In the **papillary-cystic** variety, larger cystic areas are formed that are lined by epithelium having papillary projections into the cystic spaces. The **follicular** variety has an appearance similar to that of thyroid tissue. A lymphoid infiltrate, sometimes with germinal center formation, is not unusual.

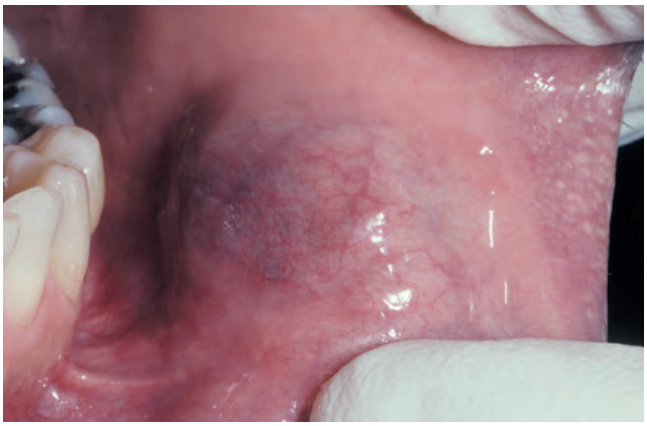
Acinic cell carcinoma shows a positive immunohistochemical reaction for DOG1, which can be helpful in distinguishing it from other salivary tumors, especially secretory carcinoma. In addition, nuclear NR4A3 immunostaining recently has been reported to be a sensitive and specific marker for acinic cell carcinoma.



Treatment and Prognosis

Acinic cell carcinomas confined to the superficial lobe of the parotid gland are best treated by lobectomy; for those in the deep lobe, total parotidectomy is usually necessary. The facial nerve may need to be sacrificed if it is involved by tumor. Submandibular tumors are managed by total removal of the gland, and minor gland tumors are treated with assured surgical excision. Lymph node dissection is not indicated unless there is clinical evidence of metastatic disease. Adjunctive radiation therapy may be considered for uncontrolled local disease.

The acinic cell carcinoma is associated with one of the better overall prognoses of any of the malignant salivary gland tumors. Approximately 10%–20% of patients have recurrences locally, and metastases develop in 8%–11% of patients. However, the tumor sometimes exhibits a protracted course, with recurrences noted years or decades after initial treatment. About 10% of patients with low- and intermediate-grade tumors will die of their disease; however, high-grade tumors show a much worse prognosis with a death rate of approximately 60%.



• **Fig. 11.66 Acinic Cell Carcinoma.** Parotid tumor demonstrating sheet of granular, basophilic serous acinar cells.

• **Fig. 11.67 Acinic Cell Carcinoma.** High-power view of serous cells with basophilic, granular cytoplasm.

◆ SECRETORY CARCINOMA (MAMMARY ANALOGUE SECRETORY CARCINOMA)

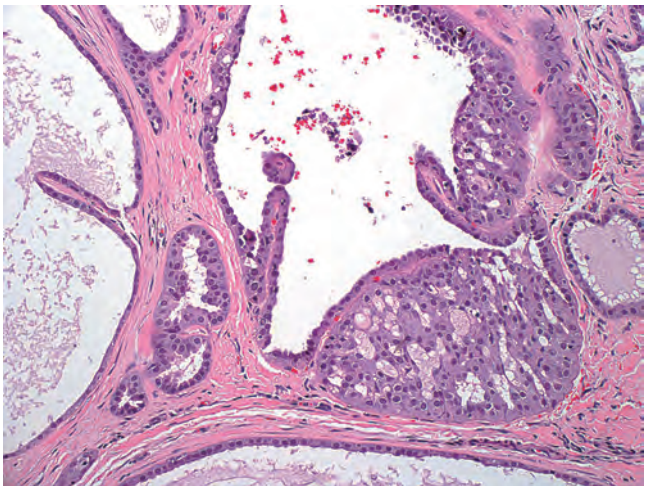
Secretory carcinoma is a recently recognized salivary gland malignancy with histopathologic and molecular features that are similar to secretory carcinoma of the breast. Both of these tumors harbor a balanced chromosomal translocation, t(12;15)(p13;q25), which results in the formation of an *ETV6::NTRK3* fusion gene. Recently, some examples have been associated with other molecular abnormalities, such as *ETV6::RET*, *ETV6::MET*, or other unknown fusion partners. Prior to its recognition in 2010, many examples of secretory carcinoma probably were diagnosed as acinic cell carcinoma, which has overlapping light microscopic features (see legend for Fig. 11.68).

• **Fig. 11.68 Secretory Carcinoma.** Bluish swelling of the anterior buccal mucosa, which could be mistaken clinically for a mucocele. (This tumor originally was diagnosed as acinic cell carcinoma before secretory carcinoma was recognized as a distinct entity. This same image was used to illustrate an acinic cell carcinoma in the third edition of this text!)

dentlearn.ir

Clinical Features

The most common site of origin for the secretory carcinoma is the parotid gland, which accounts for 68% of reported cases. The minor salivary glands (24%) and submandibular gland (8%) are less frequent sites. The lips, buccal mucosa, and palate are the most common intraoral subsites (Fig. 11.68). The mean age is 47 years, and the tumor has been reported to occur slightly more often in males than in females. The lesion usually presents as a slowly growing, painless mass, which the patient may have noticed for months or many years. Occasional examples have been associated with some degree of discomfort.



Histopathologic Features

Secretory carcinoma of salivary gland origin shows microscopic features that are similar to those of secretory carcinoma of the breast. The tumor cells typically exhibit bland, vesicular nuclei surrounded by slightly granular or vacuolated cytoplasm. These cells are variably arranged as solid, tubular, microcystic, or macrocystic structures. Larger cystic spaces may exhibit papillary infolding of tumor cells with a "hobnail" appearance (Fig. 11.69). Mitotic figures are usually rare. However, occasional examples can show high-grade transformation characterized by nuclear pleomorphism, atypical mitoses, perineural invasion, and necrosis.

The tumor cells show diffuse immunoreactivity for S-100 protein, vimentin, and mammaglobin. The *ETV6* translocation and fusion gene can be confirmed via fluorescent *in situ* hybridization (FISH), reverse transcription-polymerase chain reaction (RT-PCR), or next-generation sequencing (NGS). Recent studies have shown that pan-Trk immunohistochemistry can reliably identify tumors with the *ETV6::NTRK3* fusion.

Treatment and Prognosis

Although data on treatment and outcome are limited, secretory carcinoma usually appears to be a low-grade malignancy with a generally favorable prognosis. However, examples with high-grade transformation may demonstrate a more aggressive course, with local tumor recurrence and/or metastases resulting in patient death. Treatment most often consists of surgical resection, sometimes supplemented by adjuvant radiation therapy, especially for more aggressive tumors. It has been suggested that tumors with less common, unusual molecular features may be associated with a worse prognosis.

• **Fig. 11.69 Secretory Carcinoma.** Medium-power view showing papillary-cystic spaces and small solid islands.

◆ MALIGNANT MIXED TUMORS (CARCINOMA EX PLEOMORPHIC ADENOMA; CARCINOMA EX MIXED TUMOR; CARCINOSARCOMA; METASTASIZING MIXED TUMOR)

Malignant mixed tumors represent malignant counterparts to the benign mixed tumor or pleomorphic adenoma. These uncommon neoplasms constitute 2%–4% of all salivary tumors and can be divided into three categories:

1. Carcinoma ex pleomorphic adenoma (carcinoma ex mixed tumor)
2. Carcinosarcoma
3. Metastasizing mixed tumor

The most common of these is the **carcinoma ex pleomorphic adenoma,** which is characterized by malignant transformation of the epithelial component of a previously benign pleomorphic adenoma. The **carcinosarcoma** is a rare "mixed" tumor in which both carcinomatous and sarcomatous elements are present. The **metastasizing mixed tumor** has histopathologic features that are identical to the common pleomorphic adenoma (mixed tumor). In spite of its benign appearance, however, the lesion metastasizes. The metastatic tumor also has a benign microscopic appearance, usually similar to that of the primary lesion.

Clinical Features

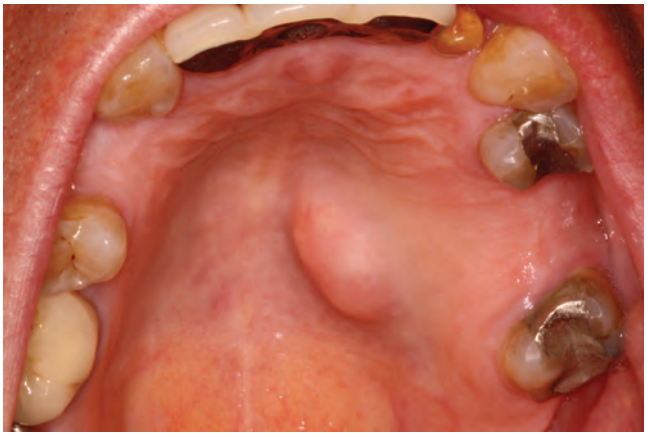
Carcinoma Ex Pleomorphic Adenoma

There is fairly convincing evidence that the carcinoma ex pleomorphic adenoma represents a malignant transformation within what was previously a benign neoplasm. First of all, the mean age of patients with this tumor is about 10–15 years older than that for the benign pleomorphic adenoma. It is most common in middle-aged and older adults, with peak prevalence in the sixth to eighth decades of life. In addition, patients may report that a mass has been present for many years, sometimes undergoing a recent rapid growth with associated pain or ulceration. However, some tumors may have a short duration. The histopathologic features, which are discussed later, also support malignant transformation of a benign pleomorphic adenoma. It has been noted that the risk for malignant change in a pleomorphic adenoma increases with the duration of the tumor.

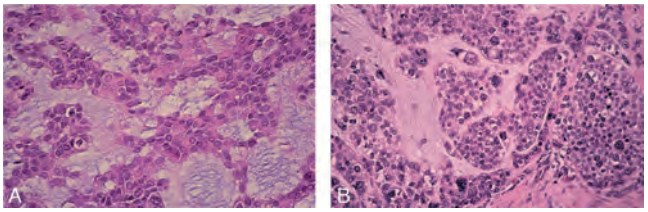
More than 80% of cases of carcinoma ex pleomorphic adenoma are seen within the major glands, primarily the parotid gland (Fig. 11.70). Nearly two-thirds of minor salivary gland

dentlearn.ir

• **Fig. 11.70 Carcinoma Ex Pleomorphic Adenoma.** Mass of the parotid gland.



• **Fig. 11.71 Carcinoma Ex Pleomorphic Adenoma.** Granular exophytic and ulcerated mass filling the vault of the palate.



cases occur on the palate (Fig. 11.71). Although pain or recent rapid growth is not unusual, many cases present as a painless mass that is indistinguishable from a benign tumor (Fig. 11.72). Parotid tumors may produce facial nerve palsy.

Carcinosarcoma

The carcinosarcoma is an extremely rare tumor. Most cases have been reported in the parotid gland, but the lesion also has been seen in the submandibular gland and minor salivary glands. The clinical signs and symptoms are similar to those of the carcinoma ex pleomorphic adenoma. Some patients

• **Fig. 11.72 Carcinoma Ex Pleomorphic Adenoma.** Smooth-surfaced nodular mass of the left posterior hard palate.

• **Fig. 11.73 Carcinoma Ex Pleomorphic Adenoma. A,** Medium-power view of the benign portion of the tumor showing sheets of plasmacytoid myoepithelial cells within a myxoid background. **B,** Malignant portion of the tumor showing epithelial cells with pleomorphic nuclei.

have a previous history of a benign pleomorphic adenoma, although other cases appear to arise *de novo*.

Metastasizing Mixed Tumor

The metastasizing mixed tumor is also quite rare. As with other malignant mixed tumors, most cases originate in the parotid gland, but the primary tumor also may occur in the submandibular gland or minor salivary glands. Metastases have been found most frequently in the bones or lung, but they also can occur in other sites, such as regional lymph nodes, skin, or the liver. Most patients have a history of a benign mixed tumor, which may have been excised many years earlier. Many times the primary tumor exhibits multiple recurrences before metastasis occurs.

Histopathologic Features

Carcinoma Ex Pleomorphic Adenoma

The carcinoma ex pleomorphic adenoma shows a variable microscopic appearance. Areas of typical benign pleomorphic adenoma usually can be found and may constitute most or only a small portion of the lesion. However, extensive sampling may be required to identify the benign component in some cases. Within the tumor are areas of malignant degeneration of the epithelial component, characterized by cellular pleomorphism and abnormal mitotic activity (Fig. 11.73). This change is most often in the form of a poorly differentiated adenocarcinoma (such as, salivary duct

dentlearn.ir

carcinoma), but other patterns also can develop, including myoepithelial carcinoma, polymorphous low-grade adenocarcinoma, mucoepidermoid carcinoma, and adenoid cystic carcinoma.

Based on the pattern of growth, carcinoma ex pleomorphic adenoma can be divided into three subcategories: *invasive, minimally invasive,* or *noninvasive.* Invasive carcinoma ex pleomorphic adenoma shows malignant cells penetrating greater than 1.5 mm from the tumor capsule into adjacent tissues. Minimally invasive tumors show extracapsular invasion that measures 1.5 mm or less. Noninvasive tumors may be discovered as a small malignant focus within the center of an encapsulated pleomorphic adenoma but without violation of the tumor capsule. Because such tumors have a markedly better prognosis than invasive tumors, they also have been designated as **carcinoma *in situ* ex mixed tumor** or **intracapsular carcinoma ex pleomorphic adenoma.**

Carcinosarcoma

The carcinosarcoma is a biphasic tumor, demonstrating both carcinomatous and sarcomatous areas. The epithelial component usually consists of a poorly differentiated adenocarcinoma or an undifferentiated carcinoma. The sarcomatous portion often predominates the tumor and is usually in the form of chondrosarcoma but also may show characteristics of osteosarcoma, fibrosarcoma, liposarcoma, rhabdomyosarcoma, or malignant fibrous histiocytoma. Some lesions have evidence of an origin from a benign mixed tumor.

Metastasizing Mixed Tumor

The metastasizing mixed tumor has microscopic features of a benign pleomorphic adenoma, within both the primary and the metastatic sites. Malignant histopathologic changes are not observed.

Treatment and Prognosis

Carcinoma Ex Pleomorphic Adenoma

Invasive carcinoma ex pleomorphic adenoma usually is best treated by wide excision, possibly in conjunction with local lymph node dissection and adjunctive radiation therapy. The prognosis is guarded; the overall 5-year survival rate ranges from 25% to 69%, but this rate drops to 10%–35% at 15 years. The prognosis is related to the histopathologic subtype of the malignant component. One study showed that well-differentiated carcinomas, such as polymorphous low-grade adenocarcinoma, have nearly a 90% 5-year survival rate. However, the outlook is much worse for patients with tumors that are poorly differentiated or that have invaded more than 6 mm beyond the residual capsule or benign residual tumor. In contrast, the prognosis for noninvasive or minimally invasive carcinoma ex pleomorphic adenoma approaches that for benign mixed tumor. However, rare examples of metastasis or tumor death have been documented in these latter groups.

Carcinosarcoma

Carcinosarcomas are treated by radical surgical excision, which may be combined with radiation therapy and chemotherapy. The prognosis is poor, with around 60% of patients dying from local recurrence or metastatic disease.

Metastasizing Mixed Tumor

The treatment for a metastasizing mixed tumor consists of surgical excision of both the primary tumor and the metastatic sites. A mortality rate of approximately 40% has been reported.

◆ ADENOID CYSTIC CARCINOMA

The **adenoid cystic carcinoma** is one of the more common and best-recognized salivary malignancies. Because of its distinctive histopathologic features, it originally was called a **cylindroma,** and this term still is heard sometimes as a synonym for this neoplasm. However, use of the term *cylindroma* should be avoided because it does not convey the malignant nature of the tumor, and also because this same term is used for a skin adnexal tumor that has a markedly different clinical presentation and prognosis. Over 80% of adenoid cystic carcinomas will exhibit overexpression of the *MYB* oncogene, frequently in association with a chromosomal translocation, t(6;9)(q22-23;p23-24), and resultant *MYB::NFIB* fusion gene.

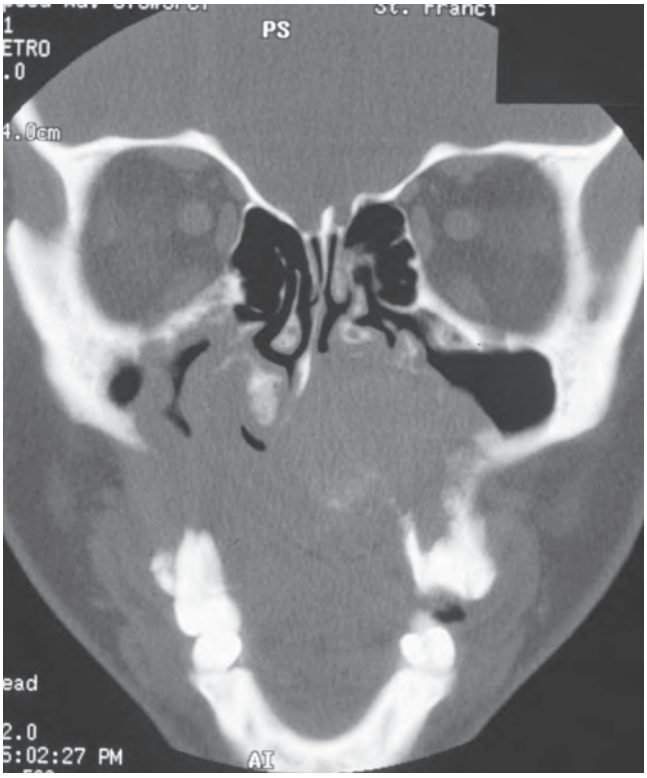
Clinical and Radiographic Features

The adenoid cystic carcinoma can occur in any salivary gland site, but approximately 60% develop within the various minor salivary glands. The parotid gland is the second most common location, followed by the submandibular gland. The palate is the most common site for minor gland tumors (Figs. 11.74 and 11.75). Rare intraosseous examples also have been reported in the jaws. On an individual basis,

• **Fig. 11.74 Adenoid Cystic Carcinoma.** Subtle nodular swelling of the left hard palate.

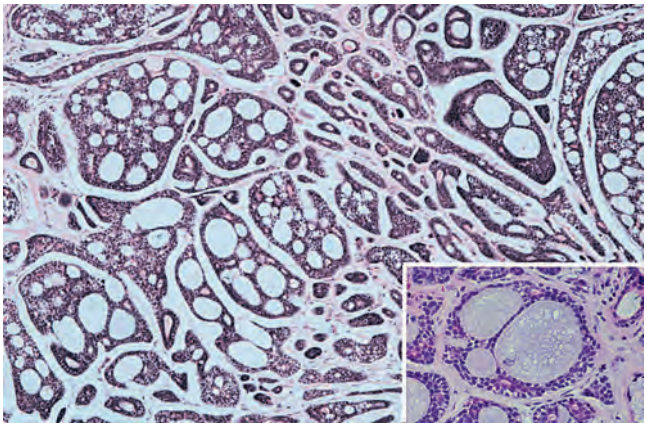
dentlearn.ir

• **Fig. 11.75 Adenoid Cystic Carcinoma.** Painful mass of the hard palate and maxillary alveolar ridge. (Courtesy of Dr. George Blozis.)



however, a striking difference can be seen among the various glands. In the parotid gland, the adenoid cystic carcinoma is relatively rare, constituting only 2% of all tumors. In the submandibular gland, this tumor accounts for 11%–17% of all tumors and is the most common malignancy. It is also relatively common among palatal salivary neoplasms; it represents 8%–17% of all such tumors. The lesion is most common in middle-aged adults and is rare in people younger than age 20. There is a slight female predilection.

The adenoid cystic carcinoma usually appears as a slowly growing mass. Pain is a common and important finding, occasionally occurring early in the course of the disease before there is a noticeable swelling. Patients often complain of a constant, low-grade, dull ache, which gradually increases in intensity. Facial nerve paralysis may develop with parotid tumors. Palatal tumors can be smooth surfaced or ulcerated. Tumors arising in the palate or maxillary sinus often show radiographic evidence of bone destruction (Fig. 11.76).

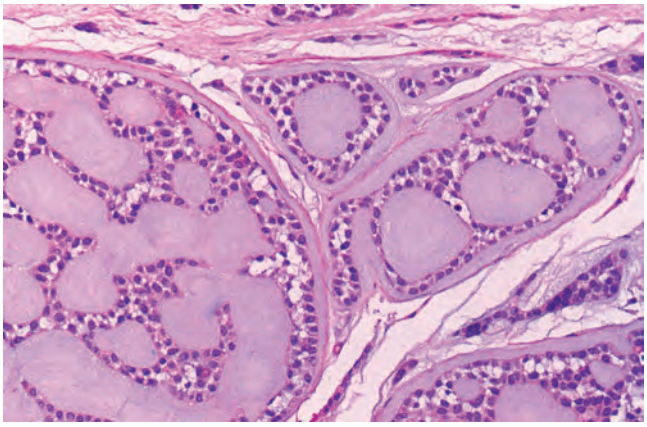


Histopathologic Features

The adenoid cystic carcinoma is composed of a mixture of abluminal myoepithelial cells and luminal ductal cells that can have a varied arrangement (Fig. 11.77). Three major patterns are recognized: (1) cribriform, (2) tubular, and (3) solid. Usually a combination of these is seen, and the tumor is classified based on the predominant pattern.

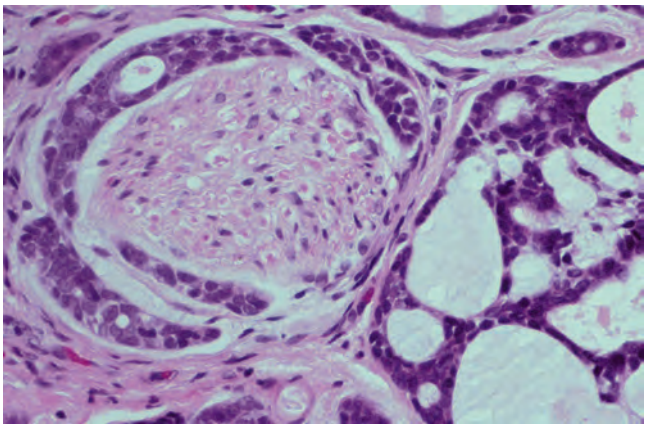
The **cribriform pattern** is the most classic and best-recognized appearance, characterized by islands of basaloid epithelial cells that contain multiple cylindrical, cystlike spaces resembling Swiss cheese. These spaces often contain a mildly basophilic mucoid material, a hyalinized eosinophilic product, or a combined mucoid-hyalinized appearance. Sometimes the hyalinized material also surrounds these cribriform islands (Fig. 11.78), or small strands of tumor are found embedded within this hyalinized "stroma." The tumor cells are small and cuboidal, exhibiting deeply basophilic nuclei and little cytoplasm. These cells are fairly uniform in appearance, and mitotic activity is rarely seen. The pathologist should be mindful that other salivary tumors, especially polymorphous

• **Fig. 11.76 Adenoid Cystic Carcinoma.** Computed tomography (CT) scan of this massive palatal tumor shows extensive destruction of the hard palate with extension of the tumor into the nasal cavity and both maxillary sinuses. (Courtesy of Dr. Kevin Riker.)



• **Fig. 11.77 Adenoid Cystic Carcinoma.** Islands of hyperchromatic cells forming cribriform and tubular structures. *Inset* shows a high-power view of a small cribriform island.

low-grade adenocarcinoma, also may exhibit areas with a cribriform pattern.



In the **tubular pattern,** the tumor cells are similar but occur as multiple small ducts or tubules within a hyalinized stroma. The tubular lumina can be lined by one to several layers of cells, and sometimes both a layer of ductal cells and myoepithelial cells can be discerned.

The **solid variant** consists of larger islands or sheets of tumor cells that demonstrate little tendency toward duct or cyst formation. Unlike the cribriform and tubular patterns,

dentlearn.ir

• **Fig. 11.78 Adenoid Cystic Carcinoma.** The tumor cells are surrounded by hyalinized material.

• **Fig. 11.79 Adenoid Cystic Carcinoma.** Perineural invasion.

cellular pleomorphism and mitotic activity, as well as focal necrosis in the center of the tumor islands, may be observed.

A highly characteristic feature of adenoid cystic carcinoma is its tendency to show perineural invasion (Fig. 11.79), which probably corresponds to the common clinical finding of pain in these patients. Sometimes the cells appear to have a swirling arrangement around nerve bundles. However, perineural invasion is not pathognomonic for adenoid cystic carcinoma; it also may be seen in other salivary malignancies, especially polymorphous low-grade adenocarcinomas.

Positive immunostaining reactions for CD43 and c-kit (CD117) in adenoid cystic carcinoma have been reported to be useful diagnostic features that can help to distinguish this tumor from polymorphous adenocarcinoma, basal cell adenoma, and canalicular adenoma. However, other authors have questioned the utility of c-kit immunostaining. The combination of p63 and p40 immunostaining has been shown to be helpful in differentiating adenoid cystic carcinoma from polymorphous adenocarcinoma (next topic). The myoepithelial cells of adenoid cystic carcinoma almost always are positive for both markers, whereas the lesional cells of polymorphous adenocarcinoma typically are positive for p63, but negative for p40. In addition, the Ki-67 cell proliferation index of adenoid cystic carcinoma is significantly greater than that observed in polymorphous adenocarcinoma (21.4% vs 2.4%). In cases where the diagnosis is uncertain, molecular testing to confirm *MYB* rearrangement can be helpful.

Treatment and Prognosis

Adenoid cystic carcinoma is a relentless tumor that is prone to local recurrence and eventual distant metastasis. Surgical resection is usually the primary treatment of choice. Adjuvant radiation therapy may slightly improve patient survival in some cases, especially for advanced stage tumors.. Because metastasis to regional lymph nodes is uncommon (6%–19% of cases), neck dissection usually is not indicated. However, elective neck dissection may be warranted for patients with a higher risk of local metastasis, such as those with larger T3 or T4 tumors, or tumors of the tongue.

Because the tumor is prone to late recurrence and metastasis, the 5-year survival rate has limited significance and does not equate to a cure. The 5-year survival rate may be as high as 68%–89%, but this rate continues to decrease over time. The 10-year survival currently ranges from 60% to 68%, and by 20 years, only 25%–40% of patients are still alive. Tumors with a solid histopathologic pattern are associated with a worse outlook than those with a cribriform or tubular arrangement. The presence of perineural invasion also is associated with a poorer prognosis. With respect to site, the prognosis is poorest for tumors arising in the maxillary sinus and submandibular gland. Better survival is observed in females, younger patients, and patients with localized disease at the time of diagnosis. Tumor DNA ploidy analysis may help to predict the prognosis of adenoid cystic carcinoma; patients with diploid tumors have been shown to have a significantly better outcome than patients with aneuploid tumors. It also has been suggested that tumors showing *MYB::NFIB* fusion may have a slightly worse prognosis.

Death usually results from local recurrence or distant metastases. Tumors of the palate or maxillary sinus may invade upward to the base of the brain. Metastases eventually occur in approximately 40%–50% of patients, most frequently involving the lungs, bone, and brain.

◆ POLYMORPHOUS ADENOCARCINOMA (POLYMORPHOUS LOW-GRADE ADENOCARCINOMA)

The **polymorphous adenocarcinoma** was first described in 1983. Before its identification as a distinct entity, examples of this tumor were categorized as pleomorphic adenoma, an unspecified form of adenocarcinoma, or sometimes as adenoid cystic carcinoma. Once recognized as a specific entity, however, it was realized that this lesion possesses distinct clinicopathologic features and is one of the more common minor salivary gland malignancies. This tumor originally was termed *polymorphous low-grade adenocarcinoma* because

dentlearn.ir

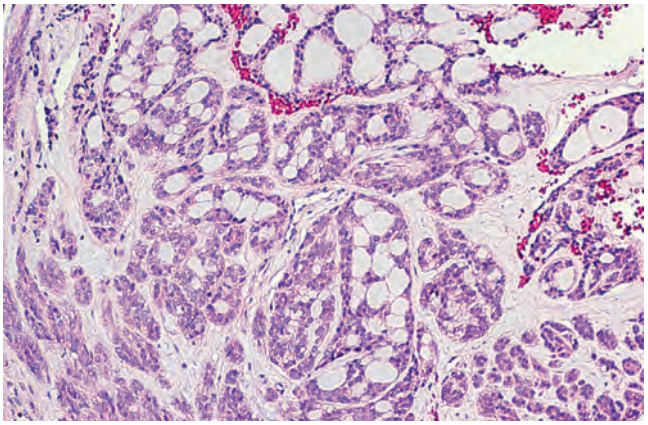
it usually behaves as a low-grade malignancy. However, occasional examples have shown high-grade transformation; therefore, the "low-grade" designation has been dropped from the name in the most recent WHO classification scheme. Recent molecular studies have shown that over 70% of polymorphous adenocarcinomas exhibit *PRKD1* hotspot mutations.

Clinical Features

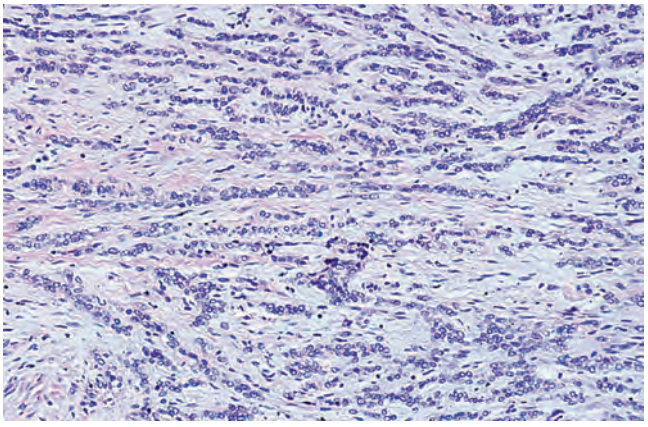
The polymorphous adenocarcinoma is almost exclusively a tumor of the minor salivary glands. However, rare examples also have been reported in the major glands, either arising *de novo* or as the malignant component of a carcinoma ex pleomorphic adenoma. Sixty-five percent occur on the hard or soft palate (Fig. 11.80), with the upper lip and buccal mucosa being the next most common locations. It is most common in older adults, having peak prevalence in the sixth to eighth decades of life. Two-thirds of all cases occur in females.

The tumor most often appears as a painless mass that may have been present for a long time with slow growth. Occasionally, it is associated with bleeding or discomfort. Palatal tumors sometimes will exhibit a rough, pebbly surface due to papillary hyperplasia of the overlying epithelium. Tumor can erode or infiltrate the underlying bone.

In 1999, a rare, distinctive group of salivary gland tumors known as **cribriform adenocarcinoma** were identified in the posterior tongue. Debate currently exists as to whether these lesions represent a unique tumor or simply a variant of polymorphous adenocarcinoma (*polymorphous adenocarcinoma, cribriform type*). Such tumors have been associated with *PRKD1, PRKD2,* or *PRKD3* gene fusions. Since its initial description, this tumor also has been identified in other minor salivary gland sites, as well as rare examples in the parotid gland.



• **Fig. 11.80 Polymorphous Adenocarcinoma.** Slow-growing, firm mass of the right posterior lateral hard palate. (Courtesy of Dr. Kevin Riker.)



Histopathologic Features

The tumor cells of polymorphous adenocarcinoma have a deceptively uniform appearance. They are round to polygonal in shape, with indistinct cell borders and pale to eosinophilic cytoplasm. The nuclei may be round, ovoid, or spindled; these nuclei usually are pale staining, although they can be more basophilic in some areas. The cells can exhibit different growth patterns, hence, the *polymorphous* term. The cells may grow in a solid pattern or form cords, ducts, or larger cystic spaces. In some tumors, a cribriform "Swiss cheese" pattern can be produced that mimics adenoid cystic carcinoma (Fig. 11.81). Mitotic figures are uncommon.

At low power, the tumor sometimes appears well circumscribed. However, the peripheral cells are usually infiltrative, invading the adjacent tissue in a single-file fashion (Fig. 11.82). Extension into underlying bone or skeletal muscle may be observed. The stroma is often mucoid in nature, or it may demonstrate hyalinization. Perineural invasion is common—another feature that may cause the tumor to be mistaken for adenoid cystic carcinoma (Fig. 11.83).

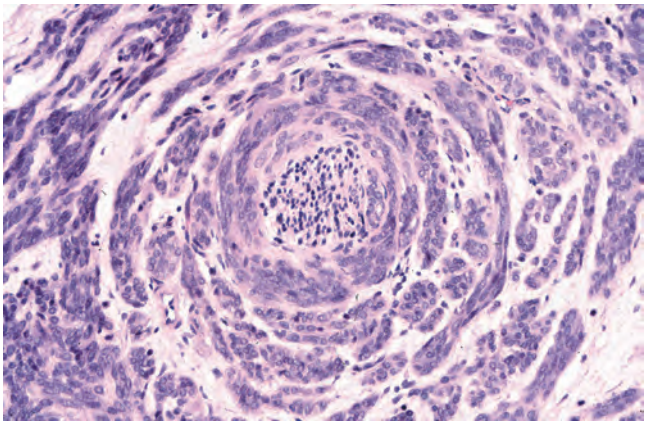
• **Fig. 11.81 Polymorphous Adenocarcinoma.** This medium-power view shows a cribriform arrangement of uniform tumor cells with pale-staining nuclei.

• **Fig. 11.82 Polymorphous Adenocarcinoma.** Pale-staining cells that infiltrate as single-file cords.

dentlearn.ir

However, a distinction between these two tumors is important because of their vastly different prognoses.

Immunohistochemical staining can be helpful in distinguishing polymorphous adenocarcinoma from other salivary gland tumors that it may mimic. Lack of staining for glial fibrillary acidic protein (GFAP) can help to differentiate this tumor from pleomorphic adenoma, which is almost always strongly positive for GFAP. Immunostains for p40 and p63 can be valuable in distinguishing polymorphous adenocarcinoma from adenoid cystic carcinoma. Polymorphous adenocarcinoma will almost always be positive for p63 but negative for p40, whereas adenoid cystic carcinoma will be positive for both markers in almost 90% of cases. When compared with adenoid cystic carcinoma, polymorphous adenocarcinoma exhibits significantly weaker expression of CD43 and c-kit (CD117). However, other authors have questioned the usefulness of c-kit immunostaining.



Cribriform adenocarcinomas are characterized by a uniform population of basaloid cells that can form solid, microcystic, cribriform, and glomeruloid structures. The cells characteristically exhibit vesicular to optically clear nuclei resembling the pattern found in papillary thyroid carcinoma.

Treatment and Prognosis

The polymorphous adenocarcinoma is best treated by wide surgical excision, sometimes including resection of the underlying bone. Metastasis to regional lymph nodes is relatively uncommon, occurring in 9%–17% of patients. Therefore, neck dissection seems unwarranted in most cases unless there is clinical evidence of cervical metastases. Distant metastases are rare, occurring in only 2%–4% of patients.

The overall prognosis is good. Recurrent disease has been reported in 9%–32.5% of all patients, but this usually can be controlled with reexcision. Death from tumor is rare but may occur secondary to direct extension into vital structures. Microscopic identification of perineural invasion does not appear to affect the prognosis.

Cribriform adenocarcinoma is associated with a high rate of regional lymph metastasis, which can occur in up to 72% of cases. Therefore, neck dissection seems appropriate in most cases, as well as possible radiation therapy. However, distant metastases are uncommon, and the overall survival rate is still relatively good.

• **Fig. 11.83 Polymorphous Adenocarcinoma.** Perineural invasion.

◆ SALIVARY ADENOCARCINOMA, NOT OTHERWISE SPECIFIED

In spite of the wide variety of salivary gland malignancies that have been specifically identified and categorized, some tumors still defy the existing classification schemes. These tumors usually are designated as **salivary adenocarcinomas, not otherwise specified (NOS).**

Clinical and Histopathologic Features

Because these adenocarcinomas represent such a diverse group of neoplasms, it is difficult to generalize about their clinical and microscopic features. Like most salivary tumors, they appear to be most common in the parotid gland, followed by the minor glands and the submandibular gland (Figs. 11.84 and 11.85). They may present as asymptomatic masses or cause pain or facial nerve paralysis. The microscopic appearance is highly variable but demonstrates features of a glandular malignancy with evidence of cellular pleomorphism, an infiltrative growth pattern, or both. These tumors exhibit a wide spectrum of differentiation, ranging from well-differentiated, low-grade neoplasms to poorly differentiated, high-grade malignancies.

As these tumors are studied more, it should be possible to classify some of them into separate, specific categories and allow more definitive analyses of their clinical and microscopic features.

Treatment and Prognosis

Because of their diversity, it is difficult to predict the prognosis for salivary adenocarcinoma (NOS), but patients with early-stage, well-differentiated tumors appear to have a better outcome. The survival rate is better for tumors of the oral

• **Fig. 11.85 Salivary Adenocarcinoma.** Mass of the posterior lateral hard palate.

cavity than for those in the major salivary glands. The reported 10-year survival rate for parotid tumors ranges from 26% to 55%; in contrast, one study reported a 10-year survival rate of 76% for intraoral tumors.

Soft Tissue Tumors

Mesenchymal soft tissue growths of the oral and maxillofacial region include both reactive tumor-like proliferations as well as true neoplasms. Virtually every different type of connective tissue has a number of both benign and malignant tumors, reflecting mutations that drive differentiation toward various tissue types, which results in a complex classification for these lesions. In addition, our knowledge of these tumors is rapidly and continuously expanding, especially as we learn more about the molecular/genetic changes that underlie many of these lesions (see Table 12.1). The discussion in this chapter will emphasize a number of the more common or more important tumors that may occur in the oral, head, and neck region.

◆ FIBROMA (IRRITATION FIBROMA; TRAUMATIC FIBROMA; FOCAL FIBROUS HYPERPLASIA; FIBROUS NODULE)

he **fibroma** is the most common "tumor" of the oral cavity. However, it is doubtful that it represents a true neoplasm in most instances; rather, it is a reactive hyperplasia of fibrous connective tissue in response to local irritation or trauma.

Clinical Features

Although the irritation fibroma can occur anywhere in the mouth, the most common location is the buccal mucosa along the bite line. Presumably, this is a consequence of trauma from biting the cheek (Figs. 12.1 and 12.2). The labial mucosa, tongue, and gingiva also are common sites (Figs. 12.3 and 12.4). It is likely that many gingival fibromas represent fibrous maturation of a preexisting pyogenic granuloma. The lesion typically appears as a smooth-surfaced pink nodule that is similar in color to the surrounding mucosa. In black patients, the mass may demonstrate gray-brown pigmentation. In some cases the surface may appear white as a result of hyperkeratosis from continued irritation. Most fibromas are sessile, although some are pedunculated. They range in size from tiny lesions that are only a couple of millimeters in diameter to large masses that are several centimeters across; however, most fibromas are 1.5 cm or less in diameter. The lesion usually produces no symptoms, unless secondary traumatic ulceration of the surface has occurred. Irritation fibromas are most common in the fourth to sixth decades of life, and the male-to-female ratio is almost 1:2 for cases submitted for biopsy.

The **frenal tag** is a commonly observed type of fibrous hyperplasia, which most frequently occurs on the maxillary labial frenum. Such lesions present as small, asymptomatic, exophytic growths attached to the thin frenum surface (Fig. 12.5). One study of 5- to 13-year-old children found the prevalence of frenal tags to be 17.1%.

Histopathologic Features

Microscopic examination of the irritation fibroma shows a nodular mass of fibrous connective tissue covered by stratified squamous epithelium (Figs. 12.6 and 12.7). This connective tissue is usually dense and collagenized, although in some cases it is looser in nature. The lesion is not encapsulated; the fibrous tissue instead blends gradually into the surrounding connective tissues. The collagen bundles may be arranged in a radiating, circular, or haphazard fashion. The covering epithelium often demonstrates atrophy of the rete ridges because of the underlying fibrous mass. However, the surface may exhibit hyperkeratosis from secondary trauma. Scattered inflammation may be seen, most often beneath the epithelial surface. Usually this inflammation is chronic and consists mostly of lymphocytes and plasma cells.

Treatment and Prognosis

The irritation fibroma is treated by conservative surgical excision; recurrence is extremely rare. However, it is important to submit the excised tissue for microscopic examination because other benign or malignant tumors may mimic the clinical appearance of a fibroma.

Because frenal tags are small, innocuous growths that are easily diagnosed clinically, no treatment is usually necessary.

◆ GIANT CELL FIBROMA

The **giant cell fibroma** is a fibrous tumor with distinctive clinicopathologic features. Unlike the traumatic fibroma, it does not appear to be associated with chronic irritation. The giant cell fibroma represents approximately 2%–5% of all oral fibrous proliferations submitted for biopsy.

dentlearn.ir

TABLE 12.1 Genetic Abnormalities of Various Soft Tissue Tumors

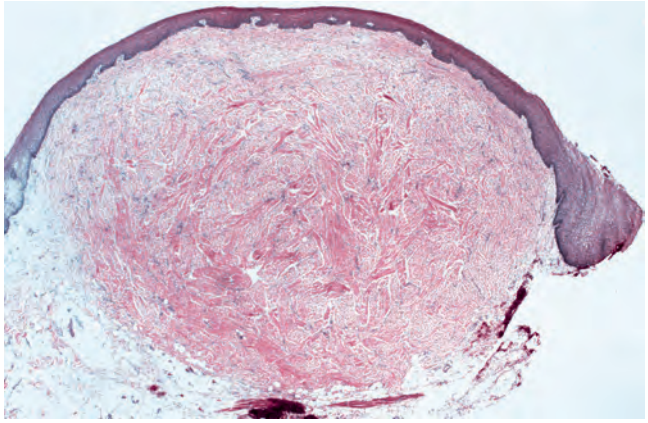
Tumor	Associated Gene Mutation/Translocation/ Rearrangement
Solitary fibrous tumor	*NAB2::STAT6* gene fusion
Sinonasal-type hemangiopericytoma	*CTNNB1* mutation
Desmoid-type fibromatosis	*CTNNB1* mutation
Congenital hemangioma	*GNAQ* or *GNA11* mutation
Capillary vascular malformation	*GNAQ* or *PI3KCA* mutation
Venous malformation	*TIE2 (TEK), PIK3CA,* or *MAP3K3* mutation
Arteriovenous malformation	*MAP2K1* mutation
Lymphatic malformation	*PIK3CA* mutation
Ectomesenchymal chondromyxoid tumor	*RREB1::MKL2* gene fusion
Embryonal rhabdomyosarcoma	Loss of heterozygosity of chromosome 11p15.5
Alveolar rhabdomyosarcoma	*PAX3::FOXO1* or *PAX7::FOXO1* gene fusion
Spindle cell/sclerosing rhabdomyosarcoma (congenital/infantile)	Gene fusions involving *VGLL2, SRF,* and *TEAD1*
Spindle cell/sclerosing rhabdomyosarcoma (adults)	*MYOD1* mutation
Monophasic synovial sarcoma	*SS18::SSX2* gene fusion
Biphasic synovial sarcoma	*SS18::SSX1* gene fusion
Alveolar soft part sarcoma	*ASPSCR1::TFE3* gene fusion

• **Fig. 12.1 Fibroma.** Pink nodule of the posterior buccal mucosa near the level of the occlusal plane.

• **Fig. 12.2 Fibroma.** Black patient with a smooth-surfaced pigmented nodule on the buccal mucosa near the commissure.

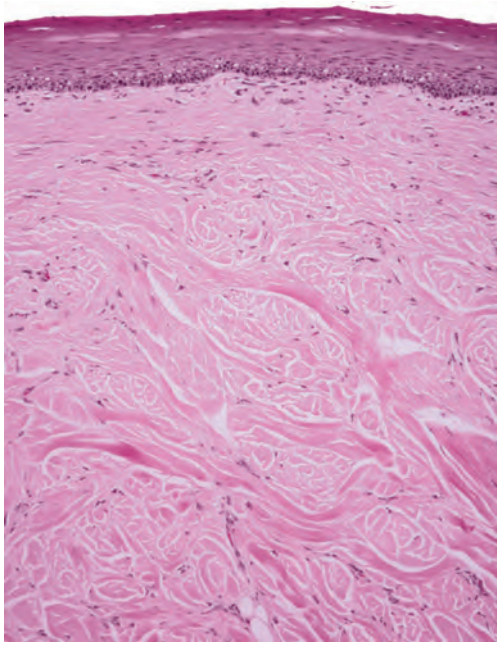
• **Fig. 12.3 Fibroma.** Lesion on the lateral border of the tongue.

• **Fig. 12.4 Fibroma.** Smooth-surfaced, pink nodular mass of the palatal gingiva between the cuspid and first bicuspid.



Clinical Features

The giant cell fibroma is typically an asymptomatic sessile or pedunculated nodule, usually less than 1 cm in size (Fig. 12.8). The surface of the mass often appears papillary; therefore, the lesion may be clinically mistaken for a papilloma (Fig. 12.9). Compared with the common irritation



dentlearn.ir

• **Fig. 12.5 Frenal Tag.** A small fingerlike projection of tissue attached to the maxillary labial frenum.

• **Fig. 12.6 Fibroma.** Low-power view showing an exophytic nodular mass of dense fibrous connective tissue.

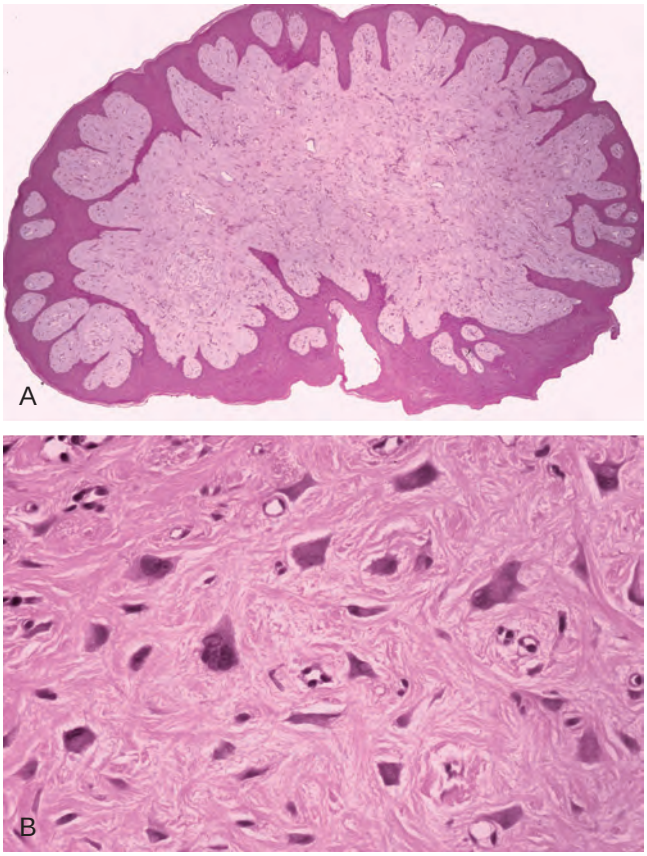
• **Fig. 12.7 Fibroma.** Higher-power view demonstrating dense collagen beneath the epithelial surface.

• **Fig. 12.8 Giant Cell Fibroma.** Exophytic nodule on the dorsum of the tongue.

• **Fig. 12.9 Giant Cell Fibroma.** Papillary growth on the lingual mandibular gingiva. Because of the rough surface, this lesion would be easily mistaken for a papilloma.

fibroma, the lesion usually occurs at a younger age. In about 60% of cases, the lesion is diagnosed during the first three decades of life. Some studies have suggested a slight female predilection. Approximately 50% of all cases occur on the gingiva. The mandibular gingiva is affected twice as often as the maxillary gingiva. The tongue and palate also are common sites.

The **retrocuspid papilla** is a microscopically similar developmental lesion that occurs on the gingiva lingual to the mandibular cuspid. It is frequently bilateral and typically appears as a small, pink papule that measures less than 5 mm in diameter (Fig. 12.10). Retrocuspid papillae are quite common, having been reported in 25%–99% of children and young adults. The prevalence in older adults drops to 6%–19%, suggesting that the retrocuspid papilla represents a normal anatomic variation that disappears with age.



Histopathologic Features

Microscopic examination of the giant cell fibroma reveals a mass of vascular fibrous connective tissue, which is usually loosely arranged (Fig. 12.11). The hallmark is the presence

dentlearn.ir

• **Fig. 12.10 Retrocuspid Papilla.** Bilateral papular lesions on the gingiva lingual to the mandibular canines (*arrows*).

• **Fig. 12.11 Giant Cell Fibroma. A,** Low-power view showing a nodular mass of fibrous connective tissue covered by stratified squamous epithelium. Note the elongation of the rete ridges. **B,** High-power view showing multiple large stellate-shaped and multinucleated fibroblasts.

of numerous large, stellate fibroblasts within the superficial connective tissue. These cells may contain several nuclei. Frequently, the surface of the lesion is pebbly. The covering epithelium often is thin and atrophic, although the rete ridges may appear narrow and elongated.

Treatment and Prognosis

The giant cell fibroma is treated by conservative surgical excision. Recurrence is rare. Because of their characteristic appearance, retrocuspid papillae should be recognized clinically and do not need to be excised.

◆ EPULIS FISSURATUM (INFLAMMATORY FIBROUS HYPERPLASIA; DENTURE INJURY TUMOR; DENTURE EPULIS)

The **epulis fissuratum** is a tumor-like hyperplasia of fibrous connective tissue that develops in association with the flange of an ill-fitting complete or partial denture. Although the simple term *epulis* sometimes is used synonymously for epulis fissuratum, *epulis* is actually a generic term that can be applied to any tumor of the gingiva or alveolar mucosa. Therefore, some authors have advocated not using this term, preferring to call these lesions *inflammatory fibrous hyperplasia* or other descriptive names. However, the term *epulis fissuratum* is still widely used today and is well understood by virtually all clinicians. Other examples of epulides include the **giant cell epulis (peripheral giant cell granuloma)** (see page 527), **ossifying fibroid epulis (peripheral ossifying fibroma)** (see page 529), and **congenital epulis** (see page 546).

Clinical Features

The epulis fissuratum typically appears as a single or multiple fold or folds of hyperplastic tissue in the alveolar vestibule (Figs. 12.12 and 12.13). Most often, there are two folds of tissue, and the flange of the associated denture fits conveniently into the fissure between the folds. The redundant tissue is usually firm and fibrous, although some lesions appear erythematous and ulcerated, similar to the appearance of a pyogenic granuloma. Occasional examples of epulis fissuratum demonstrate surface areas of inflammatory papillary hyperplasia (see page 519). The size of the lesion can vary from localized hyperplasias less than 1 cm in size to massive lesions that involve most of the length of the vestibule. The epulis fissuratum usually develops on the facial aspect of the alveolar ridge, although occasional lesions are seen lingual to the mandibular alveolar ridge (Fig. 12.14).

The epulis fissuratum most often occurs in middle-aged and older adults, as would be expected with a denture-related lesion. It may occur on either the maxilla or mandible. The anterior portion of the jaws is affected much more often than the posterior areas. There is a pronounced female predilection; most studies show that two-thirds to three-fourths of all cases submitted for biopsy occur in women.

Another similar but less common fibrous hyperplasia, often called a **fibroepithelial polyp** or **leaflike denture fibroma,** occurs on the hard palate beneath a maxillary denture. This characteristic lesion is a flattened pink mass that is attached to the palate by a narrow stalk (Fig. 12.15). Usually, the flattened mass is closely applied to the palate and sits in a

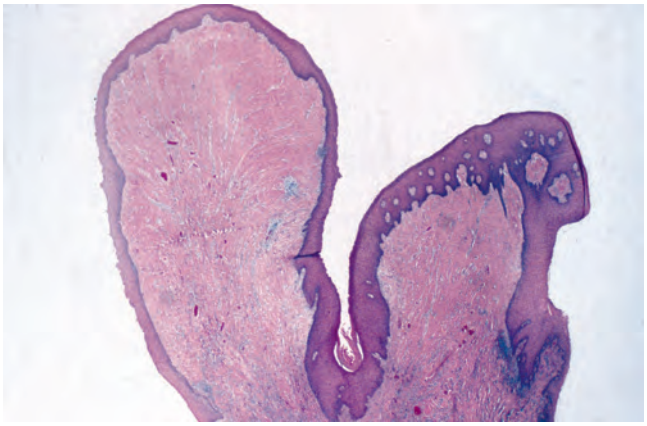
• **Fig. 12.13 Epulis Fissuratum. A,** Several folds of hyperplastic tissue in the maxillary vestibule. **B,** An ill-fitting denture fits into the fissure between two of the folds. (Courtesy of Dr. William Bruce.)

• **Fig. 12.14 Epulis Fissuratum.** Redundant folds of tissue arising in the floor of the mouth in association with a mandibular denture.



• **Fig. 12.15 Fibroepithelial Polyp.** Flattened mass of tissue arising on the hard palate beneath a maxillary denture; note its pedunculated nature. Because of its serrated edge, this lesion also is known as a *leaf-like denture fibroma.* Associated inflammatory papillary hyperplasia is visible in the palatal midline.

slightly cupped-out depression. However, it is easily lifted up with a probe, which demonstrates its pedunculated nature. The edge of the lesion often is serrated and resembles a leaf.

Histopathologic Features

Microscopic examination of the epulis fissuratum reveals hyperplasia of the fibrous connective tissue. Often multiple folds and grooves occur where the denture impinges on the tissue (Fig. 12.16). The overlying epithelium is frequently hyperparakeratotic and demonstrates irregular hyperplasia of the rete ridges. In some instances, the epithelium shows inflammatory papillary hyperplasia (see page 519) or pseudoepitheliomatous (pseudocarcinomatous) hyperplasia. Focal areas of ulceration are not unusual, especially at the base of the grooves between the folds. A variable chronic inflammatory infiltrate is present; sometimes, it may include

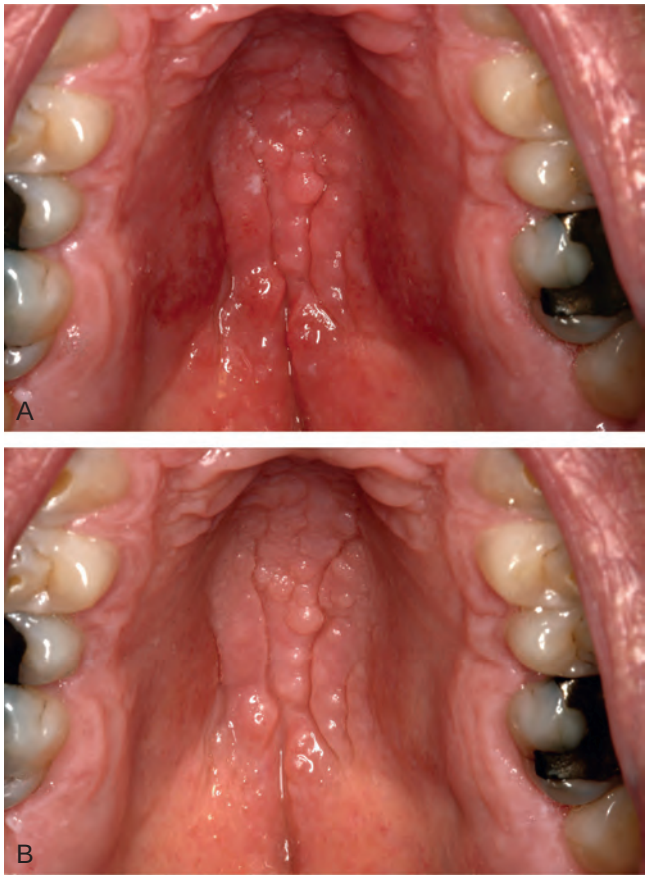
dentlearn.ir

• **Fig. 12.16 Epulis Fissuratum.** Low-power photomicrograph demonstrating folds of hyperplastic fibrovascular connective tissue covered by stratified squamous epithelium.

eosinophils or show lymphoid follicles. If minor salivary glands are included in the specimen, then they usually show chronic sialadenitis.

In rare instances, the formation of osteoid or chondroid is observed. This unusual-appearing product, known as **osseous and chondromatous metaplasia,** is a reactive phenomenon caused by chronic irritation by the ill-fitting denture (see page 309). The irregular nature of this bone or cartilage can be microscopically disturbing, and the pathologist should not mistake it for a sarcoma.

The denture-related fibroepithelial polyp has a narrow core of dense fibrous connective tissue covered by stratified squamous epithelium. Like the epulis fissuratum, the overlying epithelium may be hyperplastic.



Treatment and Prognosis

The treatment of the epulis fissuratum or fibroepithelial polyp consists of surgical removal, with microscopic examination of the excised tissue. The ill-fitting denture should be remade or relined to prevent a recurrence of the lesion.

◆ INFLAMMATORY PAPILLARY HYPERPLASIA (DENTURE PAPILLOMATOSIS)

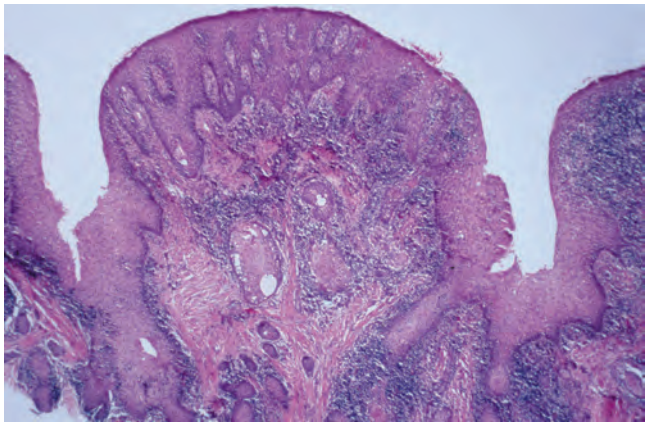
Inflammatory papillary hyperplasia is a reactive tissue growth that usually, although not always, develops beneath a denture. Some investigators classify this lesion as part of the spectrum of denture stomatitis (see page 205). Although the exact pathogenesis is unknown, the condition most often appears to be related to the following:

- An ill-fitting denture
- Poor denture hygiene
- Wearing the denture 24 hours a day

• **Fig. 12.17 Inflammatory Papillary Hyperplasia With Secondary Candidiasis. A,** Erythematous, pebbly appearance of the palatal vault. **B,** Resolution of the erythema following antifungal therapy.

Approximately 20% of patients who wear their dentures 24 hours a day have inflammatory papillary hyperplasia. *Candida* organisms also have been suggested as a cause, but any possible role appears uncertain.

Clinical Features

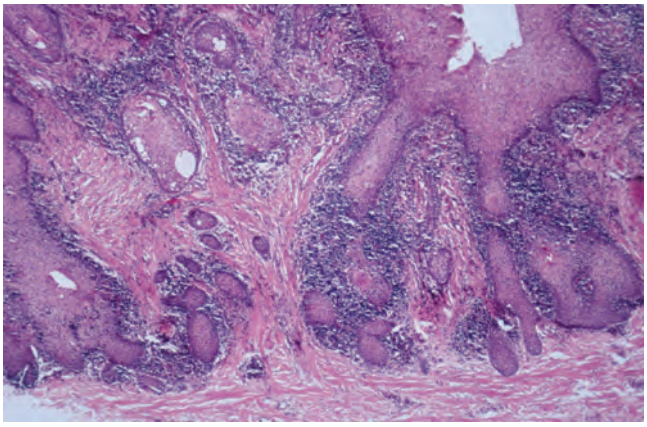


Inflammatory papillary hyperplasia usually occurs on the hard palate beneath a denture base (Figs. 12.17 and 12.18). Early lesions may involve only the palatal vault, although advanced cases cover most of the palate. Less frequently, this hyperplasia develops on the edentulous mandibular alveolar ridge or on the surface of an epulis fissuratum. On rare occasions, the condition occurs on the palate of a patient without a denture, especially in people who habitually breathe through their mouth or have a high palatal vault. *Candida*-associated palatal papillary hyperplasia also has been reported in dentate patients with human immunodeficiency virus (HIV) infection.

Inflammatory papillary hyperplasia is usually asymptomatic. The mucosa is erythematous and has a pebbly or papillary surface. Many cases are associated with denture stomatitis.

dentlearn.ir

• **Fig. 12.18 Inflammatory Papillary Hyperplasia.** An advanced case exhibiting more pronounced papular lesions of the hard palate.



• **Fig. 12.19 Inflammatory Papillary Hyperplasia.** Medium-power view showing fibrous and epithelial hyperplasia resulting in papillary surface projections. Heavy chronic inflammation is present.

Histopathologic Features

The mucosa in inflammatory papillary hyperplasia exhibits numerous papillary growths on the surface that are covered by hyperplastic, stratified squamous epithelium (Fig. 12.19). In advanced cases, this hyperplasia is pseudoepitheliomatous in appearance, and the pathologist should not mistake it for carcinoma (Fig. 12.20). The connective tissue can vary from loose and edematous to densely collagenized. A chronic inflammatory cell infiltrate is usually seen, which consists of lymphocytes and plasma cells. Less frequently, polymorphonuclear leukocytes are also present. If underlying salivary glands are present, then they often show sclerosing sialadenitis.

Treatment and Prognosis

For very early lesions of inflammatory papillary hyperplasia, removal of the denture may allow the erythema and edema to subside, and the tissues may resume a more normal appearance. The condition also may show improvement after topical or systemic antifungal therapy. For more advanced and collagenized lesions, many clinicians prefer to excise the hyperplastic tissue before fabricating a new denture. Various surgical methods have been used, including the following:

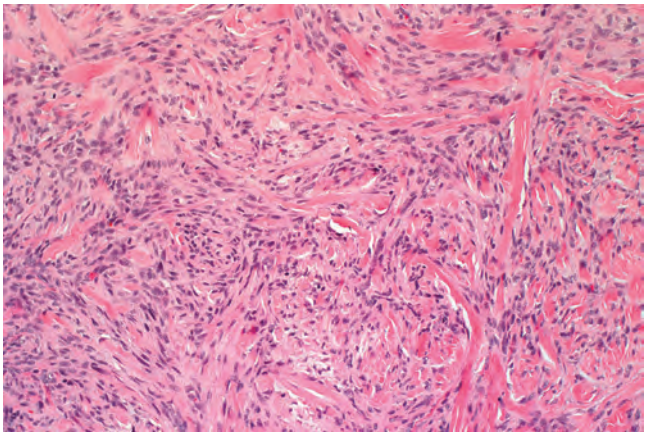
• **Fig. 12.20 Inflammatory Papillary Hyperplasia.** Higher-power view showing pseudoepitheliomatous hyperplasia of the epithelium. This epithelium has a bland appearance that should not be mistaken for carcinoma.

- Partial-thickness or full-thickness surgical blade excision
- Curettage
- Electrosurgery
- Cryosurgery
- Laser surgery

After surgery, the existing denture can be lined with a temporary tissue conditioner that acts as a palatal dressing and promotes greater comfort. After healing, the patient should be encouraged to leave the new denture out at night and to keep it clean.

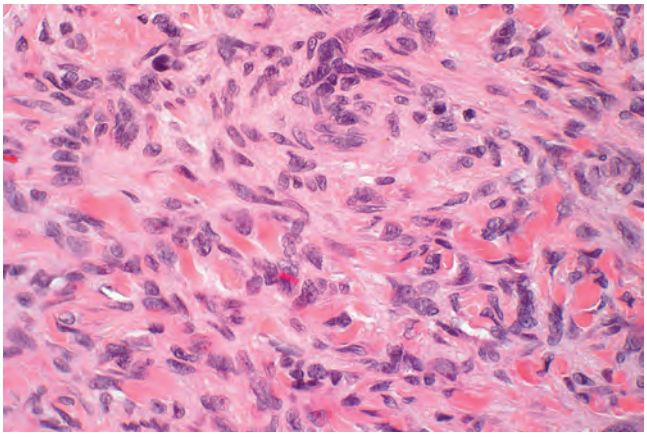
◆ FIBROUS HISTIOCYTOMA

Fibrous histiocytomas are a diverse group of tumors that exhibit fibroblastic and histiocytic differentiation, although the cell of origin is uncertain. Because of the variable nature of these lesions, an array of terms has been used for them, including **dermatofibroma, sclerosing hemangioma, fibroxanthoma,** and **nodular subepidermal fibrosis.** Unlike other fibrous growths discussed previously in this chapter, the fibrous histiocytoma is generally considered to represent a true neoplasm.



Clinical Features

The fibrous histiocytoma can develop almost anywhere in the body. The most common site is the skin of the extremities, where the lesion is called a *dermatofibroma.* Tumors of the oral and perioral region are rare, and it is likely that many previously reported examples would be reclassified today as *solitary fibrous tumors* (see next topic). Rare intrabony lesions of the jaws also have been reported. Oral fibrous histiocytomas tend to occur in middle-aged and older adults; cutaneous examples are most frequent in young adults. The tumor is usually a painless nodular mass and can vary in size from a few millimeters to several centimeters in diameter (Fig. 12.21). Deeper tumors tend to be larger.



dentlearn.ir

• **Fig. 12.21 Fibrous Histiocytoma.** Nodular mass on the dorsum of the tongue.

• **Fig. 12.22 Fibrous Histiocytoma.** Medium-power view of a skin tumor (*dermatofibroma*) showing spindle-shaped cells arranged in a storiform pattern.

• **Fig. 12.23 Fibrous Histiocytoma.** High-power view demonstrating spindle-shaped cells with vesicular nuclei.

Histopathologic Features

Microscopically, the fibrous histiocytoma is characterized by a cellular proliferation of spindle-shaped fibroblastic cells with vesicular nuclei (Figs. 12.22 and 12.23). The margins of the tumor often are not sharply defined. The tumor cells are arranged in short, intersecting fascicles, known as a *storiform* pattern because of its resemblance to the irregular, whorled appearance of a straw mat. Rounded histiocyte-like cells, lipid-containing xanthoma cells, or multinucleated giant cells can be seen occasionally, as may scattered lymphocytes. The stroma may demonstrate areas of myxoid change or focal hyalinization.

Treatment and Prognosis

Local surgical excision is the treatment of choice. Recurrence is uncommon, especially for superficial tumors. Larger lesions of the deeper soft tissues have a greater potential to recur.

◆ SOLITARY FIBROUS TUMOR

The **solitary fibrous tumor** was initially described as a pleural neoplasm that was believed to arise from either mesothelial cells or submesothelial fibroblasts. However, examples of this tumor were later identified in a number of other anatomic sites, including the head and neck region. The term **hemangiopericytoma** originally was used for a rare soft tissue neoplasm that presumably was derived from pericytes (i.e., cells with processes that encircled endothelial cells of capillaries). However, a pericytic origin appears doubtful, and there is now general agreement that most so-called hemangiopericytomas represent cellular variants within the spectrum of solitary fibrous tumor. On the molecular level, solitary fibrous tumors have been shown to harbor a recurrent chromosomal translocation resulting in the fusion of the *NAB2* and *STAT6* genes.

In addition, a neoplasm microscopically similar to the hemangiopericytoma-like pattern of solitary fibrous tumor has been recognized in the sinonasal tract. This tumor does show myoid, pericyte-like differentiation and is thought to represent a separate entity known as a **sinonasal-type hemangiopericytoma (glomangiopericytoma; myopericytoma).** Recent studies have shown that this tumor harbors mutations of the *CTNNB1* gene that encodes for β-catenin.

Clinical Features

Solitary fibrous tumors have been reported primarily in adults and are rare in children. The tumor often is described as a slow-growing, painless, submucosal, or deep soft tissue mass that is easily removed from the surrounding tissues (Fig. 12.24). Solitary fibrous tumors of the oral cavity are most common in the buccal mucosa, which accounts for approximately 45% of such cases. Other common sites in the head and neck region include the sinonasal tract and the orbit.

Sinonasal-type hemangiopericytoma occurs primarily in middle-aged and older adults. Common presenting symptoms include nasal obstruction and epistaxis.

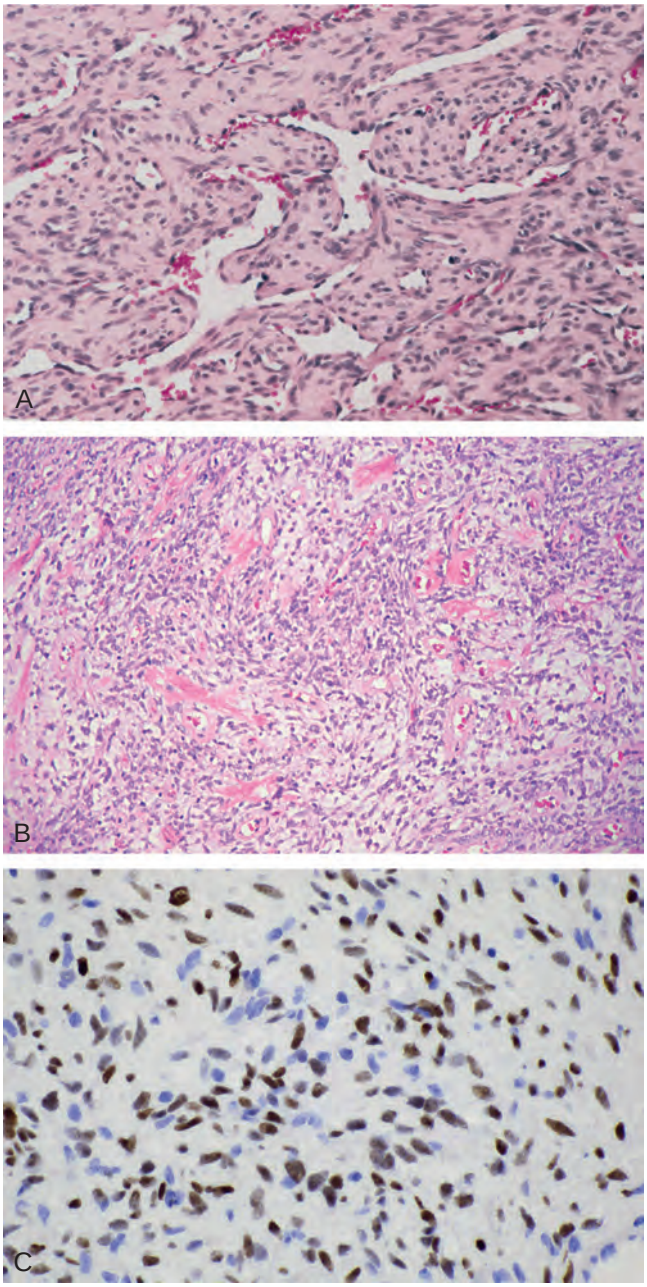
dentlearn.ir

• **Fig. 12.24 Solitary Fibrous Tumor.** Nodular mass of the left retromolar pad. (Courtesy of Dr. Caroline Bissonnette.)

Histopathologic Features

Solitary fibrous tumors are usually well-circumscribed lesions that exhibit a variable microscopic appearance. At one end of the spectrum, the lesional cells appear as tightly packed cells and surround endothelium-lined vascular channels—hence the concept of hemangiopericytoma. The cells are haphazardly arranged and demonstrate round to ovoid nuclei and indistinct cytoplasmic borders. The blood vessels often show irregular branching, which results in a characteristic "staghorn" and "antlerlike" appearance (Fig. 12.25, *A*).

At the other end of the spectrum, the cells are more spindled and arranged in either short fascicles or in a disorganized fashion ("patternless pattern") (see Fig. 12.25, *B*). The tumor often demonstrates alternating hypercellular and hypocellular zones with a variable degree of myxoid background change. Prominent hyalinized collagen bundles are characteristically observed in the hypocellular areas. Immunohistochemical studies show the lesional cells to be positive for CD34, bcl-2, and STAT6 in nearly all cases (see Fig. 12.25, *C*).



The identification of 4 or more mitoses per 10 high-power fields suggests a rapidly growing tumor that is capable of metastasis. The presence of necrosis also suggests malignancy. However, it is difficult to predict microscopically whether a particular tumor will act in a benign or malignant fashion.

Sinonasal-type hemangiopericytomas have a more prominent spindle cell pattern, with the cells arranged in a more orderly fashion. Mitotic figures are rare or absent. The vascular component is less intricate, and less interstitial collagen is found among the tumor cells. Most examples will express smooth muscle actin and nuclear β-catenin, but, in contrast to solitary fibrous tumor, the cells are usually negative for STAT6, CD34, and bcl-2.

Treatment and Prognosis

For solitary fibrous tumors with a benign histopathologic appearance, local excision is the treatment of choice. More extensive surgery is required for tumors with malignant characteristics. Oral examples usually behave in a benign fashion, although as many as 10% of extrapleural solitary fibrous tumors have been reported to show malignant behavior. Therefore, long-term follow-up of patients with this tumor is recommended.

The sinonasal-type hemangiopericytoma usually has a favorable prognosis with a recurrence rate of approximately 17%. Rare examples of locally aggressive or metastatic tumors have been reported.

• **Fig. 12.25 Solitary Fibrous Tumor. A,** "Staghorn" blood vessels surrounded by haphazardly arranged cells. **B,** Moderately cellular fibrous proliferation ("patternless pattern") with prominent vascularity, slightly myxoid areas, and scattered dense collagen bundles. **C,** Immunohistochemistry showing strong nuclear positivity for STAT6.

dentlearn.ir

◆ FIBROMATOSIS (DESMOID-TYPE FIBROMATOSIS)

The **fibromatoses** are a broad group of fibrous proliferations that have a biologic behavior and histopathologic pattern that is intermediate between those of benign fibrous lesions and fibrosarcoma. A number of different forms of fibromatosis are recognized throughout the body, and they often are named based on their particular clinicopathologic features. In the soft tissues of the head and neck, these lesions are frequently called **juvenile aggressive fibromatoses**, **desmoid-type fibromatoses**, or **extraabdominal desmoids.** Similar lesions within the bone have been called **desmoplastic fibromas** (see page 663). Individuals with familial adenomatous polyposis and Gardner syndrome (see page 656) have a greatly increased risk for developing desmoid-type fibromatosis. Activating *CTNNB1* gene mutations (located at chromosome 3p21) are detected in approximately 85% of cases.

Clinical and Radiographic Features

Soft tissue fibromatosis of the head and neck is a firm, painless mass, which may exhibit rapid or insidious growth (Fig. 12.26). The lesion most frequently occurs in children or young adults; hence, the term **juvenile fibromatosis.** However, cases also have been seen in middle-aged adults. The most common head and neck sites are the maxillary sinus and paramandibular soft tissue region, although the lesion can occur almost anywhere. The tumor can grow to considerable size, resulting in significant facial disfigurement. Destruction of adjacent bone may be observed on radiographs and other imaging studies.

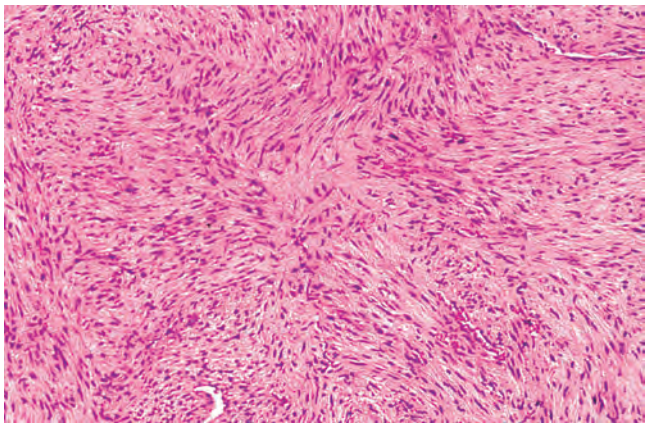
Histopathologic Features

Soft tissue fibromatosis is characterized by a cellular proliferation of spindle-shaped cells that are arranged in streaming fascicles and are associated with a variable amount of collagen (Fig. 12.27). The lesion is usually poorly circumscribed and infiltrates the adjacent tissues. Hyperchromatism and pleomorphism of the cells should not be observed. Immunohistochemistry for smooth muscle actin (SMA) may be positive, which could be confused with other lesions showing myofibroblastic differentiation. However, desmoid-type fibromatoses typically show strong positivity for β-catenin in the cell nuclei.

Treatment and Prognosis

Because of its locally aggressive nature, the preferred treatment for soft tissue fibromatosis is wide excision that includes a generous margin of adjacent normal tissues. Adjuvant chemotherapy or radiation therapy sometimes has been used for incompletely resected or recurrent tumors. A 30% recurrence rate has been reported for aggressive fibromatosis of the head and neck. Metastasis does not occur.

◆ MYOFIBROMA (MYOFIBROMATOSIS)



Myofibroma is a rare spindle cell neoplasm that consists of myofibroblasts (i.e., cells with both smooth muscle and fibroblastic features). Such cells are not specific for this lesion, however, because they also can be identified in other fibrous proliferations. Most myofibromas occur as solitary lesions, but some patients develop a multicentric tumor process known as **myofibromatosis.**

Clinical and Radiographic Features

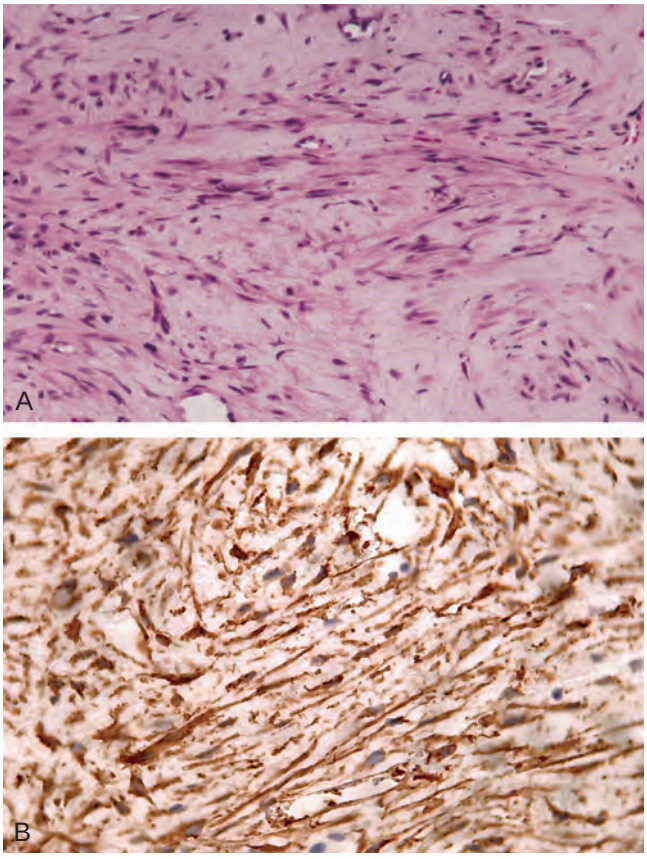
Although myofibromas are rare neoplasms, they demonstrate a predilection for the head and neck region. Solitary tumors develop most frequently in the first four decades of life, with a mean age of 23 years. The most common oral location is the mandible, followed by the alveolar mucosa/gingiva, buccal mucosa, and tongue. The tumor is typically a painless mass that sometimes exhibits rapid enlargement (Fig. 12.28). Intrabony tumors create radiolucent defects that usually tend to be poorly defined, although some may be well defined or multilocular (Fig. 12.29). Multicentric

• **Fig. 12.26 Fibromatosis.** Locally aggressive proliferation of fibrous connective tissue of the lingual mandibular gingival mucosa.

• **Fig. 12.27 Fibromatosis.** Streaming fascicles of fibroblastic cells that demonstrate little pleomorphism.

dentlearn.ir

• **Fig. 12.28 Myofibroma.** Smooth-surfaced, nodular mass of the maxillary facial gingiva. (Courtesy of Dr. John Duckworth.)



• **Fig. 12.29 Myofibroma.** Computed tomography (CT) scan showing an expansile lytic mass of the posterior mandible on the left side of the illustration. (Courtesy of Dr. Timothy Armanini.)

myofibromatosis primarily affects neonates and infants who may have tumors of the skin, subcutaneous tissue, muscle, bone, and viscera. The number of tumors can vary from several to more than 100.

Histopathologic Features

Myofibromas are composed of interlacing bundles of spindle cells with tapered or blunt-ended nuclei and eosinophilic cytoplasm (Fig. 12.30, *A*). Nodular fascicles may alternate with more cellular zones, imparting a biphasic appearance to the tumor. Scattered mitoses are not uncommon. Centrally, the lesion is often more vascular with a hemangiopericytoma-like appearance. The tumor cells are positive for smooth muscle actin and muscle-specific actin with immunohistochemistry (see Fig. 12.30, *B*), but they are negative for desmin and β-catenin.

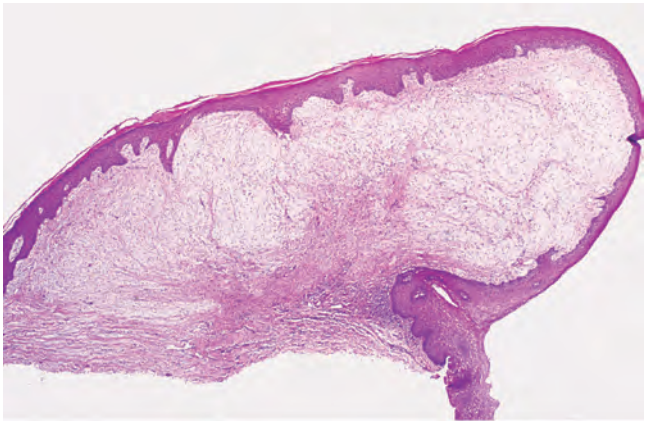
• **Fig. 12.30 Myofibroma. A,** Proliferation of spindle-shaped cells with both fibroblastic and smooth muscle features. **B,** Immunohistochemistry showing strong positivity for smooth muscle actin.

Treatment and Prognosis

Solitary myofibromas are usually treated by surgical excision. A small percentage of tumors will recur after treatment, but typically these can be controlled with reexcision. Multifocal tumors arising in soft tissues and bone rarely recur after surgical removal. Spontaneous regression may occur in some cases. However, myofibromatosis involving the viscera or vital organs in infants can act more aggressively and sometimes proves to be fatal within a few days after birth.

◆ ORAL FOCAL MUCINOSIS

Oral focal mucinosis is an uncommon tumor-like mass that is believed to represent the oral counterpart of cutaneous focal mucinosis or a cutaneous myxoid cyst. The cause is unknown, although the lesion may result from overproduction of hyaluronic acid by fibroblasts.

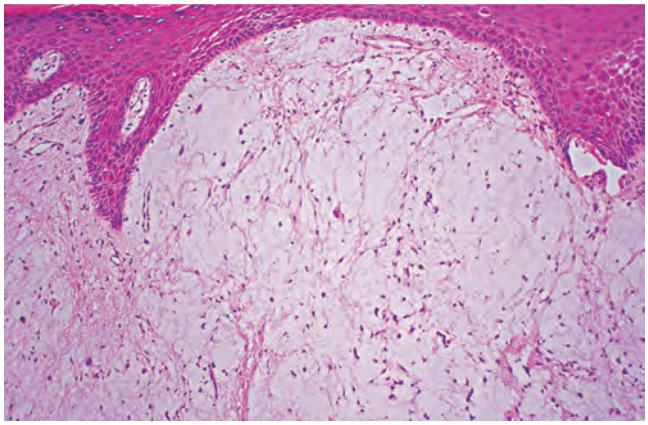


Clinical Features

Oral focal mucinosis is most common in young adults and shows a 2:1 female-to-male predilection. The gingiva is the most common site, accounting for over half of all cases. The hard palate is the second most common location. The

dentlearn.ir

• **Fig. 12.31 Oral Focal Mucinosis.** Nodular mass arising from the gingiva between the mandibular first and second molars.



• **Fig. 12.32 Oral Focal Mucinosis.** Low-power view showing a nodular mass of loose, myxomatous connective tissue.

lesion usually presents as a sessile or pedunculated, painless nodular mass that is the same color as the surrounding mucosa (Fig. 12.31). The surface is typically smooth and nonulcerated, although occasional cases exhibit a lobulated appearance. The size varies from a few millimeters up to 2 cm in diameter. The patient often has been aware of the mass for many months or years before the diagnosis is made.

Histopathologic Features

Microscopic examination of oral focal mucinosis shows a well-localized but nonencapsulated area of loose, myxomatous connective tissue surrounded by denser, normal collagenous connective tissue (Figs. 12.32 and 12.33). The lesion is usually found just beneath the surface epithelium and often causes flattening of the rete ridges. The fibroblasts within the mucinous area can be ovoid, fusiform, or stellate, and they may demonstrate delicate, fibrillar processes. Few capillaries are seen within the lesion, especially compared with the surrounding denser collagen. Similarly, no significant inflammation is observed, although a perivascular lymphocytic infiltrate often is noted within the surrounding collagenous connective tissue. No appreciable reticulin is evident within the lesion, and special stains suggest that the mucinous product is hyaluronic acid.

• **Fig. 12.33 Oral Focal Mucinosis.** High-power view demonstrating the myxomatous change.

Treatment and Prognosis

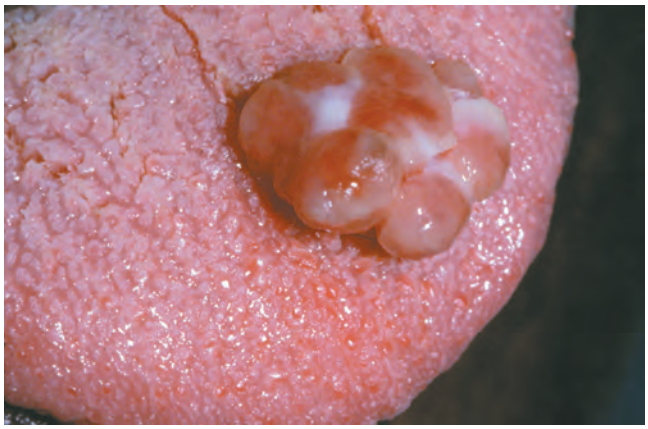
Oral focal mucinosis is treated by surgical excision and does not tend to recur.

◆ PYOGENIC GRANULOMA (LOBULAR CAPILLARY HEMANGIOMA)

The **pyogenic granuloma** is a common tumor-like growth of the oral cavity that traditionally has been considered to be nonneoplastic in nature.* However, some pyogenic granulomas with a lobular endothelial growth pattern (known as *lobular capillary hemangiomas*) currently are categorized as *vascular tumors* under the classification scheme of the International Society for the Study of Vascular Anomalies (see Box 12.2, page 547).

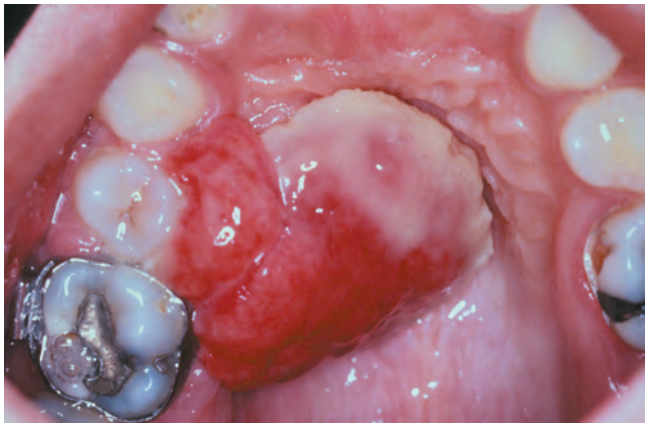
Although originally theorized to be caused by pyogenic organisms, the pyogenic granuloma is now believed to be unrelated to infection. Instead, this lesion is thought to represent an exuberant tissue response related to local irritation, poor hygiene, or hormonal factors. In spite of its name, it is not a true granuloma.

Clinical Features



The pyogenic granuloma is a smooth or lobulated mass that is usually pedunculated, although some lesions are sessile (Figs. 12.34–12.36). The surface is characteristically ulcerated and ranges from pink to red to purple, depending on the age of the lesion. Young pyogenic granulomas are highly vascular in appearance; older lesions tend to become more

*However, some pyogenic granulomas (also known as *lobular capillary hemangiomas*) currently are categorized as *vascular tumors* under the classification scheme of the International Society for the Study of Vascular Anomalies (see Box 12.2, page 547).



dentlearn.ir

• **Fig. 12.34 Pyogenic Granuloma.** Erythematous, hemorrhagic mass arising from the maxillary anterior gingiva.

• **Fig. 12.35 Pyogenic Granuloma.** Ulcerated and lobulated mass on the dorsum of the tongue.

• **Fig. 12.36 Pyogenic Granuloma.** Unusually large lesion arising from the palatal gingiva in association with an orthodontic band. The patient was pregnant.

collagenized and pink. They vary from small growths only a few millimeters in size to larger lesions that may measure several centimeters in diameter. Typically, the mass is painless, although it often bleeds easily because of its extreme vascularity. Pyogenic granulomas may exhibit rapid growth, which may create alarm for both the patient and the clinician, who may fear that the lesion might be malignant.

Oral pyogenic granulomas show a striking predilection for the gingiva, which accounts for approximately 75%–85% of all cases. Gingival irritation and inflammation that result from poor oral hygiene may be a precipitating factor in many patients. However, the lobular microscopic variant (lobular capillary hemangioma) tends to occur more frequently on the lips, tongue, and buccal mucosa. A history of trauma before the development of the lesion is not unusual, especially for extragingival pyogenic granulomas. Lesions are slightly more common on the maxillary gingiva than the mandibular gingiva; anterior areas are more frequently affected than posterior areas. These lesions are much more common on the facial aspect of the gingiva than the lingual aspect; some extend between the teeth and involve both the facial and the lingual gingiva.

Although the pyogenic granuloma can develop at any age, it is most common in children and young adults. Most studies also demonstrate a female predilection, possibly because of the vascular effects of female hormones. Pyogenic granulomas of the gingiva frequently develop in pregnant women, so much so that the terms *pregnancy tumor* or *granuloma gravidarum* often are used. Such lesions may begin to develop during the first trimester, and their prevalence increases up through the seventh month of pregnancy. The gradual rise in development of these lesions throughout pregnancy may be related to the increasing levels of estrogen and progesterone as the pregnancy progresses. After pregnancy and the return of normal hormone levels, some of these pyogenic granulomas resolve without treatment or undergo fibrous maturation and resemble a fibroma (Fig. 12.37).

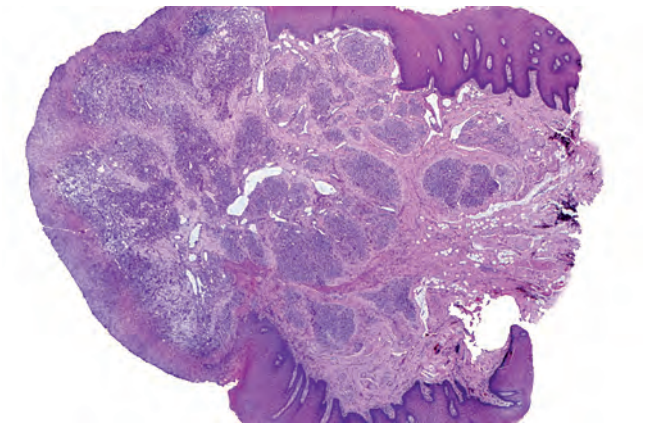
Epulis granulomatosa is a term used to describe hyperplastic growths of granulation tissue that sometimes arise in healing extraction sockets (Fig. 12.38). These lesions resemble pyogenic granulomas and usually represent a granulation tissue reaction to bony sequestra in the socket.

Histopathologic Features

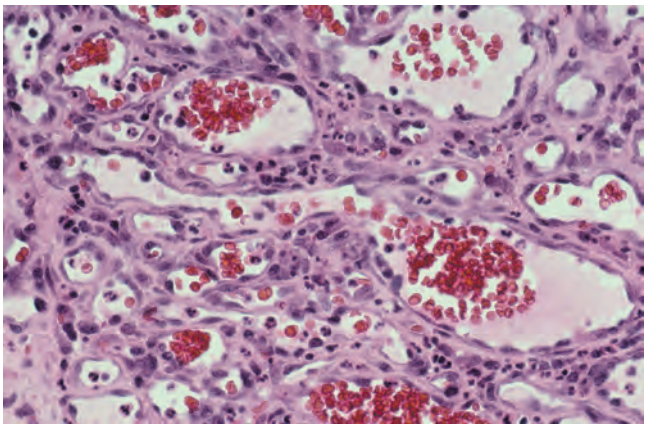
Microscopic examination of pyogenic granulomas shows a highly vascular proliferation that resembles granulation tissue (Figs. 12.39 and 12.40). Numerous small and larger endothelium-lined channels are formed that are engorged with red blood cells. In some examples, the vessels are organized in lobular aggregates—hence, the term *lobular capillary hemangioma.* The surface is usually ulcerated and replaced by a thick fibrinopurulent membrane. A mixed inflammatory cell infiltrate of neutrophils, plasma cells, and lymphocytes is evident. Neutrophils are most prevalent near the ulcerated surface; chronic inflammatory cells are found deeper in the specimen. Older lesions may have areas with a more fibrous appearance. In fact, many gingival fibromas probably represent pyogenic granulomas that have undergone fibrous maturation.

dentlearn.ir

• **Fig. 12.37 Pyogenic Granuloma. A,** Large gingival mass in a pregnant woman just before childbirth. **B,** The mass has decreased in size and undergone fibrous maturation 3 months after childbirth. (Courtesy of Dr. George Blozis.)



• **Fig. 12.38 Epulis Granulomatosa.** Nodular mass of granulation tissue that developed in a recent extraction site.



Treatment and Prognosis

The treatment of patients with pyogenic granuloma consists of conservative surgical excision, which is usually curative. The specimen should be submitted for microscopic examination to rule out other more serious diagnoses. For gingival lesions, the excision should extend down to periosteum and the adjacent teeth should be thoroughly scaled to remove any source of continuing irritation. A recurrence rate of 3%–15% has been reported in most studies. In rare instances, multiple recurrences have been noted.

For lesions that develop during pregnancy, usually treatment should be deferred unless significant functional or aesthetic problems develop. The recurrence rate is higher for pyogenic granulomas removed during pregnancy, and some lesions will resolve spontaneously after parturition.

• **Fig. 12.39 Pyogenic Granuloma.** Low-power view showing an exophytic mass of granulation-like tissue with an ulcerated surface. Note the lobular endothelial proliferation in the deeper connective tissue.

• **Fig. 12.40 Pyogenic Granuloma.** Higher-power view showing capillary blood vessels and scattered inflammation.

◆ PERIPHERAL GIANT CELL GRANULOMA

The **peripheral giant cell granuloma** is a relatively common tumor-like growth of the oral cavity. It probably does not represent a true neoplasm but rather is a reactive lesion caused by local irritation or trauma. In the past, it often was called a *peripheral giant cell reparative granuloma,* but any reparative nature appears doubtful. Some investigators believe that the giant cells show immunohistochemical features of osteoclasts, whereas other authors have suggested that the lesion is formed by cells from the mononuclear phagocyte system. The peripheral giant cell granuloma bears

dentlearn.ir

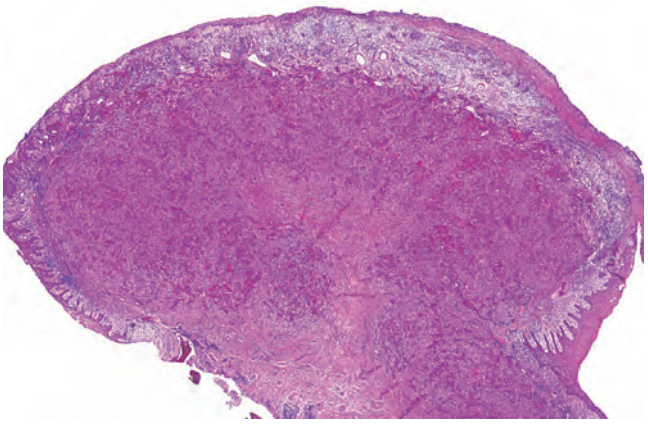
a close microscopic resemblance to the **central giant cell granuloma** (see page 631), and some pathologists believe that it may represent a soft tissue counterpart of this intraosseous lesion.

Clinical and Radiographic Features

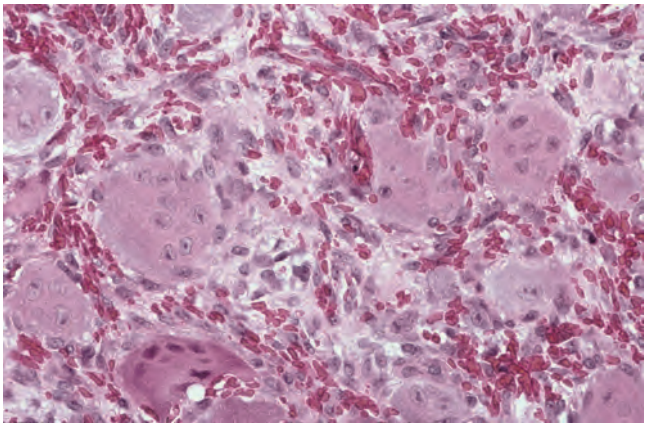
The peripheral giant cell granuloma occurs exclusively on the gingiva or edentulous alveolar ridge, presenting as a red or red-blue nodular mass (Figs. 12.41 and 12.42). Examples also have been reported to arise adjacent to dental implants. Most lesions are smaller than 2 cm in diameter, although larger ones are seen occasionally. The lesion can be sessile or pedunculated and may or may not be ulcerated. The clinical appearance is similar to the more common pyogenic granuloma of the gingiva (see page 525), although the peripheral giant cell granuloma often is more blue-purple compared with the bright red of a typical pyogenic granuloma.

Peripheral giant cell granulomas can develop at almost any age, especially during the first through sixth decades of life. The mean age in several large series ranges from 31 to 46 years. Approximately 55% of cases occur in females. It may develop in either the anterior or posterior regions of the gingiva or alveolar mucosa, and the mandible is affected more often than the maxilla (ratio = 3:2). Although the peripheral giant cell granuloma develops within soft tissue, "cupping" resorption of the underlying alveolar bone sometimes is seen. On occasion, it may be difficult to determine whether the mass arose as a peripheral lesion or as a central giant cell granuloma that eroded through the cortical plate into the gingival soft tissues.

Histopathologic Features



Microscopic examination of a peripheral giant cell granuloma shows a proliferation of multinucleated giant cells within a background of plump ovoid and spindle-shaped mesenchymal cells (Figs. 12.43 and 12.44). The giant cells may contain only a few nuclei or up to several dozen. Some of these cells may have large, vesicular nuclei; others demonstrate small, pyknotic nuclei. Mitotic figures are fairly common in the background mesenchymal cells. Abundant hemorrhage is characteristically found throughout the mass, which often results in deposits of hemosiderin pigment, especially at the periphery of the lesion.



• **Fig. 12.41 Peripheral Giant Cell Granuloma.** Nodular blue-purple mass of the mandibular gingiva.

• **Fig. 12.42 Peripheral Giant Cell Granuloma.** Ulcerated mass of the mandibular gingiva.

• **Fig. 12.43 Peripheral Giant Cell Granuloma.** Low-power view showing a nodular proliferation of multinucleated giant cells within the gingiva.

• **Fig. 12.44 Peripheral Giant Cell Granuloma.** High-power view showing scattered multinucleated giant cells within a hemorrhagic background of ovoid and spindle-shaped mesenchymal cells.

dentlearn.ir

The overlying mucosal surface is ulcerated in about 50% of cases. A zone of dense fibrous connective tissue usually separates the giant cell proliferation from the mucosal surface. Adjacent acute and chronic inflammatory cells are frequently present. Areas of reactive bone formation or dystrophic calcifications are not unusual.

Treatment and Prognosis

The treatment of the peripheral giant cell granuloma consists of local surgical excision down to the underlying bone. The adjacent teeth should be carefully scaled to remove any source of irritation and to minimize the risk of recurrence. Approximately 10%–18% of lesions are reported to recur, and reexcision must be performed.

On rare occasions, lesions indistinguishable from peripheral giant cell granulomas have been seen in patients with hyperparathyroidism (see page 840). They apparently represent the so-called osteoclastic brown tumors associated with this endocrine disorder. Although brown tumors of hyperparathyroidism are more likely to be intraosseous in location and mimic a central giant cell granuloma, this endocrine disease also needs to be considered in patients with peripheral giant cell lesions.

◆ PERIPHERAL OSSIFYING FIBROMA (OSSIFYING FIBROID EPULIS; PERIPHERAL FIBROMA WITH CALCIFICATION)

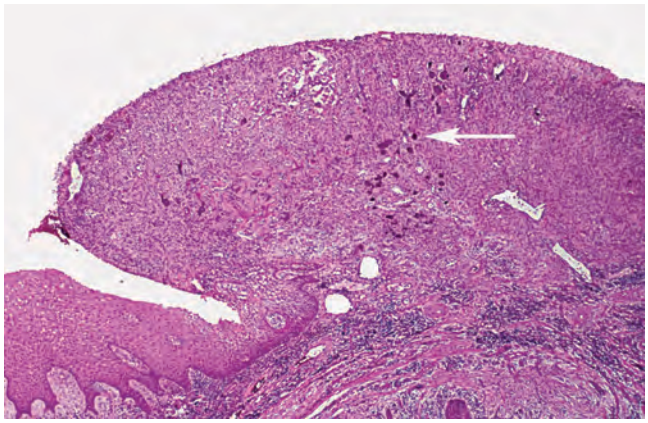
The **peripheral ossifying fibroma** is a relatively common gingival growth that is considered to be reactive rather than neoplastic in nature. The pathogenesis of this lesion is uncertain. Because of their clinical and histopathologic similarities, researchers believe that some peripheral ossifying fibromas develop initially as pyogenic granulomas that undergo fibrous maturation and subsequent calcification. However, not all peripheral ossifying fibromas may develop in this manner. The mineralized product probably has its origin from cells of the periosteum or periodontal ligament.

Considerable confusion has existed over the nomenclature of this lesion, and several terms have been used to describe its variable histopathologic features. In the past, the terms *peripheral odontogenic fibroma* (see page 733) and *peripheral ossifying fibroma* often were used synonymously, but the peripheral odontogenic fibroma is now considered to be a distinct and separate entity. In addition, in spite of the similarity in names, the peripheral ossifying fibroma does not represent the soft tissue counterpart of the central ossifying fibroma (see page 652).

Clinical Features

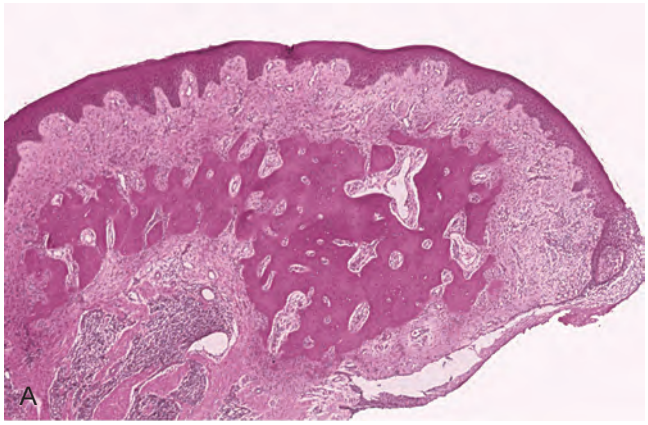
The peripheral ossifying fibroma occurs exclusively on the gingiva. It appears as a nodular mass, either pedunculated or sessile, that usually emanates from the interdental papilla (Figs. 12.45 and 12.46). The color ranges from red to pink, and the surface is frequently, but not always, ulcerated. The growth probably begins as an ulcerated lesion; older ones are more likely to demonstrate healing of the ulcer and an intact surface. Red, ulcerated lesions often are mistaken for pyogenic granulomas; the pink, nonulcerated ones are clinically similar to irritation fibromas. Most lesions are less than 2 cm in size, although larger ones occasionally occur. The lesion often has been present for many weeks or months before the diagnosis is made.

• **Fig. 12.45 Peripheral Ossifying Fibroma.** This red, ulcerated mass of the maxillary gingiva has recurred twice. Such ulcerated lesions are easily mistaken for a pyogenic granuloma.

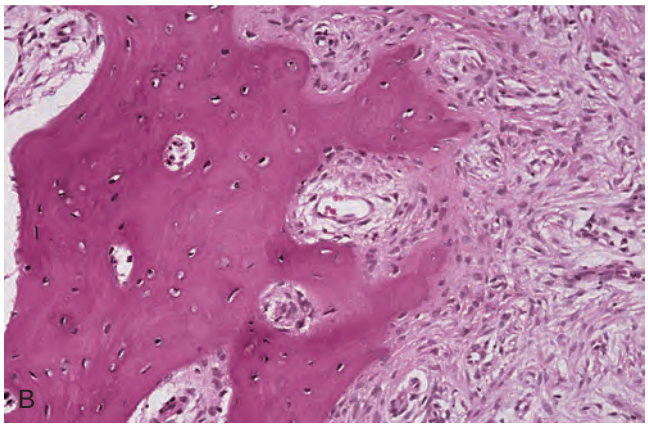


• **Fig. 12.46 Peripheral Ossifying Fibroma.** Pink, nonulcerated mass arising from the maxillary gingiva. The remaining roots of the first molar are present.

The peripheral ossifying fibroma is predominantly a lesion of teenagers and young adults, with peak prevalence between the ages of 10 and 19. Almost two-thirds of all cases occur in females. There is a slight predilection for the maxillary arch, and more than 50% of all cases occur in the incisor-cuspid region. Usually, the teeth are unaffected; rarely, there can be migration and loosening of adjacent teeth.



Histopathologic Features



The basic microscopic pattern of the peripheral ossifying fibroma is one of a fibrous proliferation associated with the formation of a mineralized product (Figs. 12.47 and 12.48). If the epithelium is ulcerated, then the surface is

dentlearn.ir

• **Fig. 12.47 Peripheral Ossifying Fibroma.** Ulcerated gingival mass demonstrating focal early mineralization (*arrow*).

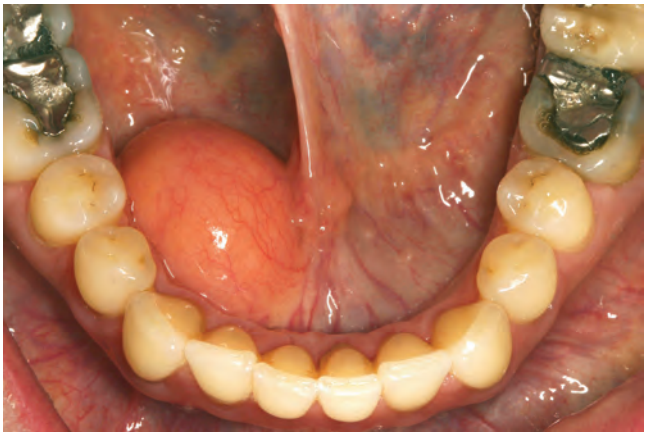
• **Fig. 12.48 Peripheral Ossifying Fibroma. A,** Nonulcerated fibrous mass of the gingiva showing central bone formation. **B,** Higher-power view showing trabeculae of bone with adjacent fibrous connective tissue.

covered by a fibrinopurulent membrane with a subjacent zone of granulation tissue. The deeper fibroblastic component often is cellular, especially in areas of mineralization. In some cases, the fibroblastic proliferation and associated mineralization is only a small component of a larger mass that resembles a fibroma or pyogenic granuloma.

The type of mineralized component is variable and may consist of bone, cementum-like material, or dystrophic calcifications. Frequently, a combination of products is formed. Usually, the bone is woven and trabecular in type, although older lesions may demonstrate mature lamellar bone. Trabeculae of unmineralized osteoid are not unusual. Less frequently, ovoid droplets of basophilic cementum-like material are formed. Dystrophic calcifications are characterized by multiple granules, tiny globules, or large, irregular masses of basophilic mineralized material. Such dystrophic calcifications are more common in early, ulcerated lesions; older, nonulcerated examples are more likely to demonstrate well-formed bone or cementum. In some cases, multinucleated giant cells may be found, usually in association with the mineralized product.

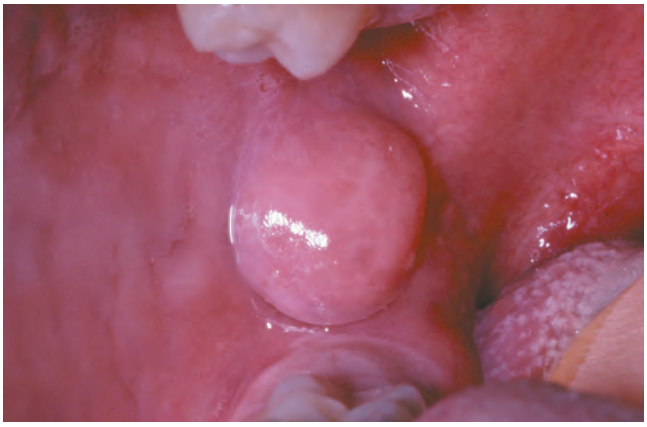
Treatment and Prognosis

The treatment of choice for the peripheral ossifying fibroma is local surgical excision with submission of the specimen for histopathologic examination. The mass should be excised down to periosteum because recurrence is more likely if the base of the lesion is allowed to remain. In addition, the adjacent teeth should be thoroughly scaled to eliminate any possible irritants. Periodontal surgical techniques, such as repositioned flaps or connective tissue grafts, may be necessary to repair the gingival defect in an aesthetic manner, particularly in the anterior maxillary region. Although excision is usually curative, a recurrence rate of 8%–16% has been reported.



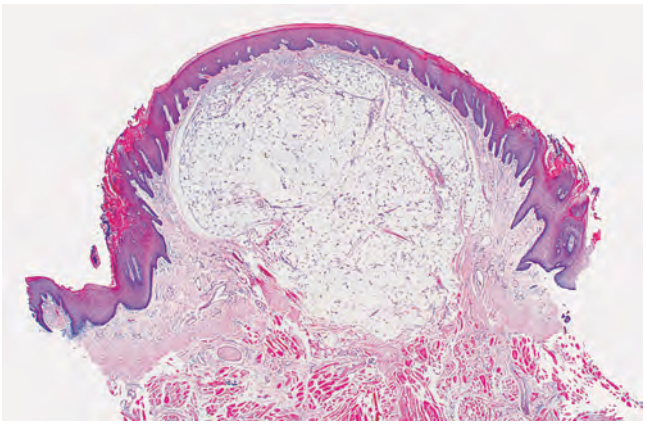
◆ LIPOMA

The **lipoma** is a benign tumor of fat. Although it represents by far the most common mesenchymal neoplasm, most examples occur on the trunk and proximal portions of the extremities. Lipomas of the oral and maxillofacial region are much less frequent, accounting for only 1%–4% of all such tumors. The pathogenesis of lipomas is uncertain, but they appear to be more common in obese people. However, the metabolism of lipomas is completely independent of the normal body fat. If the caloric intake is reduced, then lipomas do not decrease in size, although normal body fat may be lost.

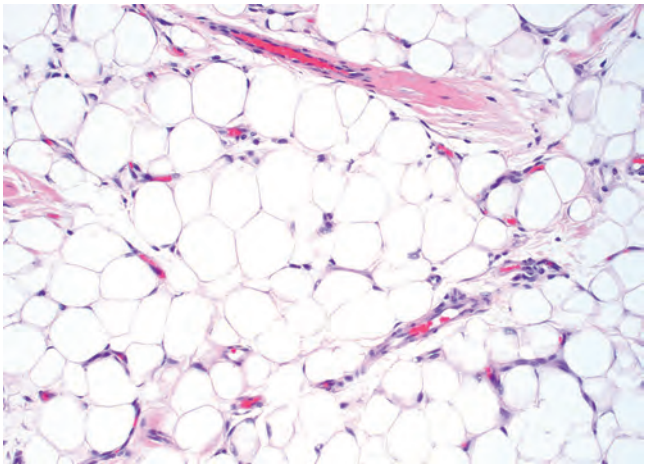


Clinical Features

Oral lipomas are usually soft, smooth-surfaced nodular masses that can be sessile or pedunculated (Figs. 12.49 and 12.50). Typically, the tumor is asymptomatic and often has been noted for many months or years before diagnosis. Most are less than 3 cm in size, but occasional lesions can become much larger. Although a subtle or more obvious yellow hue often is detected clinically, deeper examples may appear pink. The buccal mucosa and buccal vestibule are the most common intraoral sites and account for nearly 50% of all cases. Some buccal cases may not represent true tumors, but rather herniation of the buccal fat pad through the buccinator muscle, which may occur after local trauma in young children or subsequent to surgical removal of third molars in older patients. Less common sites include the tongue, lips, and floor of the mouth. Most patients are 40 years



dentlearn.ir



• **Fig. 12.49 Lipoma.** Soft, yellow nodular mass in the floor of the mouth. (Courtesy of Dr. Michael Tabor.)

• **Fig. 12.50 Lipoma.** Nodular mass of the posterior buccal mucosa.

• **Fig. 12.51 Lipoma.** Low-power view of a tumor of the tongue demonstrating a mass of mature adipose tissue.

• **Fig. 12.52 Lipoma.** High-power view showing the similarity of the tumor cells to normal fat.

of age or older; lipomas are uncommon in children. Lipomas of the oral and maxillofacial region have shown a fairly balanced sex distribution in most studies.

Histopathologic Features

Most oral lipomas are composed of mature fat cells that differ little in microscopic appearance from the surrounding normal fat (Figs. 12.51 and 12.52). The tumor is usually well circumscribed and may demonstrate a thin fibrous capsule. A distinct lobular arrangement of the cells often is seen. On rare occasions, central cartilaginous or osseous metaplasia may occur within an otherwise typical lipoma.

A number of microscopic variants have been described. The most common of these is the **fibrolipoma,** which is characterized by a significant fibrous component intermixed with the lobules of fat cells. The remaining variants are rare.

The **angiolipoma** consists of an admixture of mature fat and numerous small blood vessels. The **spindle cell lipoma** demonstrates variable amounts of uniform-appearing spindle cells in conjunction with a more typical lipomatous component. These spindle cells are positive for CD34 with immunohistochemistry. Some spindle cell lipomas exhibit a mucoid background *(myxoid lipoma)* and may be confused with myxoid liposarcomas. **Pleomorphic lipomas** are characterized by the presence of spindle cells plus bizarre, hyperchromatic giant cells; they can be difficult to distinguish from a pleomorphic liposarcoma. **Intramuscular (infiltrating) lipomas** often are more deeply situated and have an infiltrative growth pattern that extends between skeletal muscle bundles. The term **sialolipoma** was coined to describe tumors that secondarily entrap salivary gland tissue.

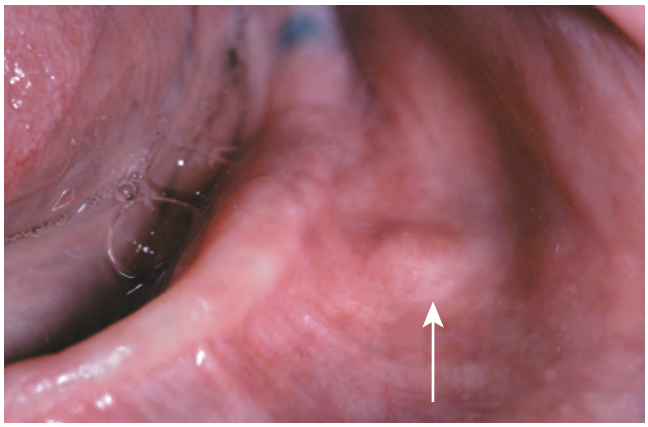
Traumatized oral lipomas can show degenerative cellular changes that can be mistaken for a form of well-differentiated liposarcoma known as *atypical lipomatous tumor*. Negative immunohistochemical expression for MDM2 and CDK4 can help to avoid overdiagnosis of such tumors as low-grade malignancies.

Treatment and Prognosis

Lipomas are treated by conservative local excision, and recurrence is rare. Most microscopic variants do not affect the prognosis. Intramuscular lipomas have a higher recurrence

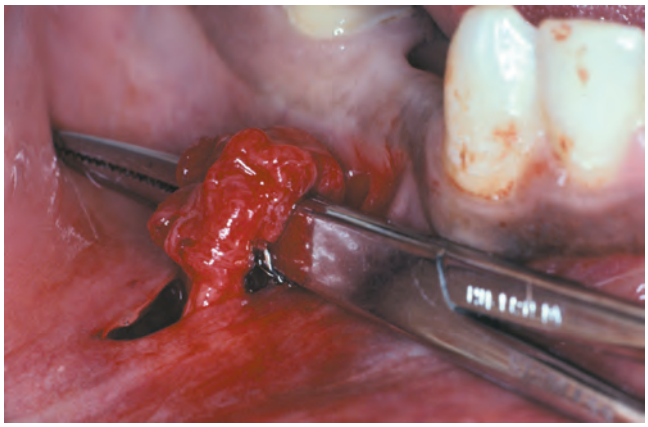
dentlearn.ir

rate because of their infiltrative growth pattern, but this variant is rare in the oral and maxillofacial region.



◆ TRAUMATIC NEUROMA (AMPUTATION NEUROMA)

The **traumatic neuroma** is not a true neoplasm but a reactive proliferation of neural tissue after transection or other damage of a nerve bundle. After a nerve has been damaged or severed, the proximal portion attempts to regenerate and reestablish innervation of the distal segment by the growth of axons through tubes of proliferating Schwann cells. If these regenerating elements encounter scar tissue or otherwise cannot reestablish innervation, then a tumor-like mass may develop at the site of injury.

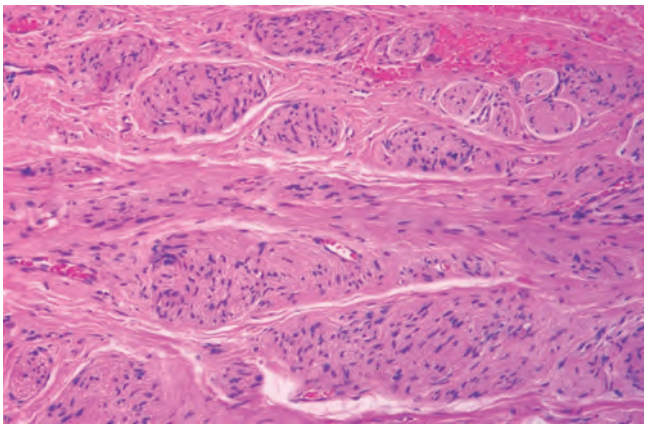


Clinical and Radiographic Features

Traumatic neuromas of the oral mucosa are typically smooth-surfaced, nonulcerated nodules. They can develop at any location but are most common in the mental foramen area, tongue, and lower lip (Figs. 12.53 and 12.54). A history of trauma often can be elicited; some lesions arise subsequent to tooth extraction or other surgical procedures. Intraosseous traumatic neuromas may demonstrate a radiolucent defect on oral radiographs. Examples also may occur at other head and neck sites; it has been estimated that traumatic neuromas of the greater auricular nerve develop in 5%–10% of patients undergoing surgery for pleomorphic adenomas of the parotid gland.

Traumatic neuromas can occur at any age, but they are diagnosed most often in middle-aged adults. They appear to be slightly more common in women. Many traumatic neuromas are associated with altered nerve sensations that can range from anesthesia to dysesthesia to overt pain. Although pain has been traditionally considered a hallmark of this lesion, studies indicate that only one-fourth to one-third of oral traumatic neuromas are painful. This pain can be intermittent or constant and ranges from mild tenderness or burning to severe radiating pain. Neuromas of the mental nerve are frequently painful, especially when impinged on by a denture or palpated.

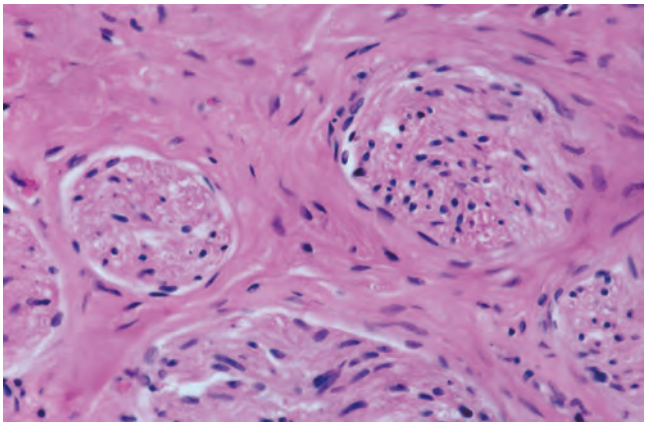
• **Fig. 12.53 Traumatic Neuroma.** Painful nodule of the mental nerve as it exits the mental foramen *(arrow)*.



• **Fig. 12.54 Traumatic Neuroma.** Note the irregular nodular proliferation along the mental nerve that is being exposed at the time of surgery.

Histopathologic Features

Microscopic examination of traumatic neuromas shows a haphazard proliferation of mature, myelinated and unmyelinated nerve bundles within a fibrous connective tissue stroma that ranges from densely collagenized to myxomatous in nature (Figs. 12.55 and 12.56). An associated mild chronic inflammatory cell infiltrate may be present. Traumatic neuromas with inflammation are more likely to be painful than those without significant inflammation.



Treatment and Prognosis

The treatment of choice for the patient with a traumatic neuroma is surgical excision, including a small portion of the involved proximal nerve bundle. Most lesions do not recur; in some cases, however, the pain persists or returns at a later date.

• **Fig. 12.55 Traumatic Neuroma.** Low-power view showing the haphazard arrangement of nerve bundles within the background fibrous connective tissue.

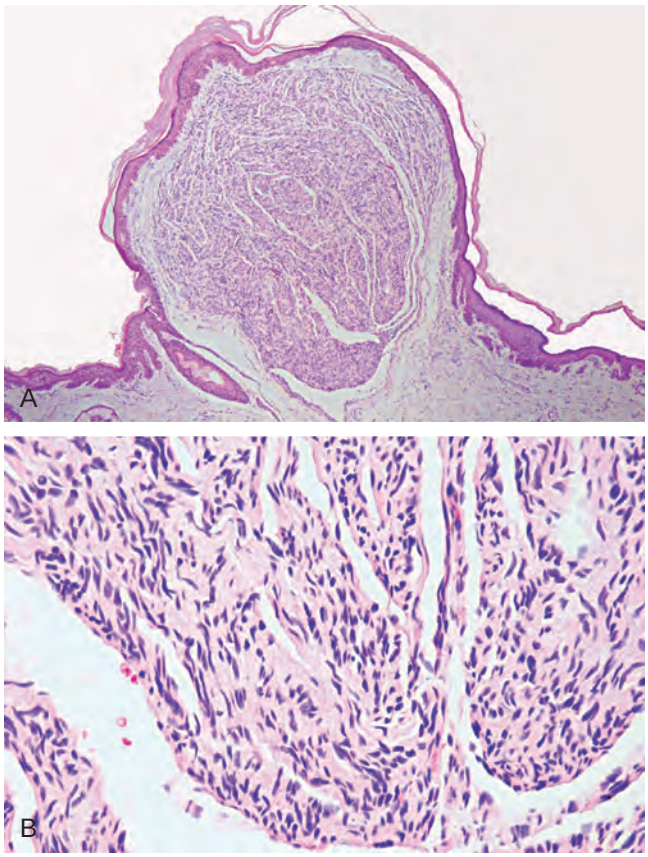
dentlearn.ir

• **Fig. 12.56 Traumatic Neuroma.** High-power view showing cross-sectioned nerve bundles within dense fibrous connective tissue.

• **Fig. 12.57 Palisaded Encapsulated Neuroma.** Small, painless nodule of the lateral hard palate.

◆ PALISADED ENCAPSULATED NEUROMA (SOLITARY CIRCUMSCRIBED NEUROMA)

The **palisaded encapsulated neuroma** is a benign neural tumor with distinctive clinical and histopathologic features. It represents one of the more common superficial nerve tumors, especially in the head and neck region. The cause is uncertain, but some authors have speculated that trauma may play an etiologic role; the tumor is generally considered to represent a reactive lesion rather than a true neoplasm.

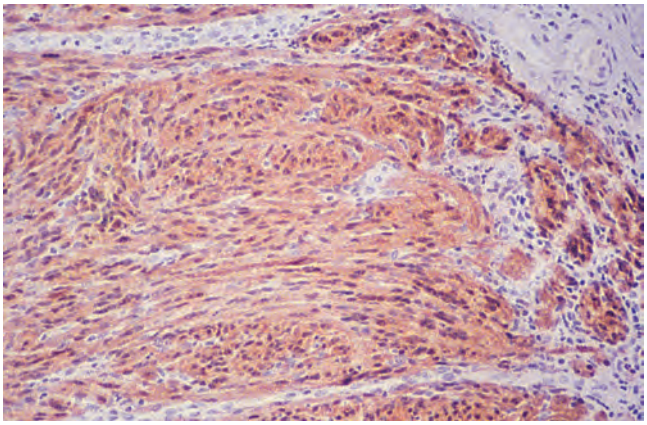


Clinical Features

The palisaded encapsulated neuroma shows a striking predilection for the face, which accounts for approximately 90% of reported cases. The nose and cheek are the most common specific sites. The lesion is most frequently diagnosed between the fifth and seventh decades of life, although the tumor often has been present for many months or years. It is a smooth-surfaced, painless, dome-shaped papule or nodule that is usually less than 1 cm in diameter.

Oral palisaded encapsulated neuromas are not uncommon, although many are probably diagnosed microscopically as neurofibromas or schwannomas. The lesion appears most frequently on the hard palate (Fig. 12.57), gingiva, and labial mucosa, although it also may occur in other oral locations.

Histopathologic Features



Palisaded encapsulated neuromas appear well circumscribed and often encapsulated (Fig. 12.58), although this capsule may be incomplete, especially along the superficial aspect of the tumor. Some lesions have a lobulated appearance. The tumor consists of moderately cellular interlacing fascicles of spindle cells that are consistent with Schwann cells. The nuclei are characteristically wavy and pointed, with no significant pleomorphism or mitotic activity. Although the nuclei show a similar parallel orientation within the fascicles, the more definite palisading and Verocay bodies

• **Fig. 12.58 Palisaded Encapsulated Neuroma. A,** Low-power view showing a well-circumscribed, nodular proliferation of neural tissue. **B,** Higher-power view demonstrating spindle cells with wavy nuclei.

typical of the Antoni A tissue of a schwannoma are usually not seen. Special stains reveal the presence of numerous axons within the tumor (a feature not seen in schwannoma) and the cells show a positive immunohistochemical reaction for S-100 protein (Fig. 12.59). Negative immunoreactivity for glial fibrillary acidic protein (GFAP) may be helpful in distinguishing the palisaded encapsulated neuroma from other neural tumors. Because the tumor is not always encapsulated and the cells are usually not truly palisaded, some

dentlearn.ir

• **Fig. 12.59 Palisaded Encapsulated Neuroma.** Immunohistochemical reaction demonstrating spindle-shaped cells that are strongly positive for S-100 protein.

pathologists prefer **solitary circumscribed neuroma** as a better descriptive term for this lesion.

Treatment and Prognosis

The treatment for the palisaded encapsulated neuroma consists of conservative local surgical excision. Recurrence is rare. However, specific recognition of this lesion is important because it is not associated with neurofibromatosis or multiple endocrine neoplasia (MEN) type 2B.

◆ SCHWANNOMA (NEURILEMOMA)

The **schwannoma** is a benign neural neoplasm of Schwann cell origin. It is relatively uncommon, although 25%–48% of all cases occur in the head and neck region. Bilateral schwannomas of the auditory-vestibular nerve are a characteristic feature of the hereditary condition, **neurofibromatosis type II (NF2).** Multiple schwannomas also occur in another genetic disorder known as **schwannomatosis** (Table 12.2).

Clinical and Radiographic Features

The solitary schwannoma is a slow-growing, encapsulated tumor that typically arises in association with a nerve trunk. As it grows, it pushes the nerve aside. Usually, the mass is asymptomatic, although tenderness or pain may occur in some instances. The lesion is most common in young and middle-aged adults and can range from a few millimeters to several centimeters in size.

The tongue and lips are the most common locations for oral schwannomas, although the tumor can occur almost anywhere in the mouth (Fig. 12.60). On occasion, the tumor arises centrally within bone and may produce bony expansion. Intraosseous examples are most common in the posterior mandible and usually appear as either unilocular or multilocular radiolucencies on radiographs. Pain and paresthesia are not unusual for intrabony tumors.

NF2 is an autosomal dominant condition caused by a mutation of a tumor suppressor gene (*NF2*) on chromosome 22, which codes for a protein known as *merlin.* In addition to bilateral schwannomas ("acoustic neuromas") of the vestibular nerve, patients also develop schwannomas of peripheral nerves, plus meningiomas and gliomas of the central nervous system (CNS). On occasion, neurofibromas and *café au lait* skin pigmentation may be observed. Characteristic symptoms include progressive sensorineural deafness, dizziness, and tinnitus.

Schwannomatosis is related to mutations of the *SMARCB1* and *LZTR1* genes on chromosome 22. Patients develop multiple painful schwannomas at various sites but without involvement of the auditory-vestibular nerve.

Histopathologic Features

The schwannoma is usually an encapsulated tumor that demonstrates two microscopic patterns in varying amounts: (1) **Antoni A** and (2) **Antoni B.** Streaming fascicles of spindle-shaped Schwann cells characterize Antoni A tissue. These cells often form a palisaded arrangement around central acellular, eosinophilic areas known as **Verocay bodies** (Fig. 12.61). These Verocay bodies consist of reduplicated basement membrane and cytoplasmic processes. Antoni B tissue is less cellular and less organized; the spindle cells are randomly arranged within a loose, myxomatous stroma. Typically, neurites cannot be demonstrated within the tumor mass. The tumor cells will show a diffuse, positive immunohistochemical reaction for S-100 protein.

Degenerative changes can be seen in some older tumors **(ancient schwannomas).** These changes consist of hemorrhage, hemosiderin deposits, inflammation, fibrosis, and nuclear atypia. However, these tumors are still benign, and the pathologist must be careful not to mistake these alterations for evidence of a sarcoma. Another rare variant is the **plexiform schwannoma,** which is characterized grossly and microscopically by a multinodular, plexiform growth pattern. Such tumors occasionally are associated with NF2 or schwannomatosis.

Treatment and Prognosis

The solitary schwannoma is treated by surgical excision, and the lesion should not recur. Malignant transformation does not occur or is extremely rare.

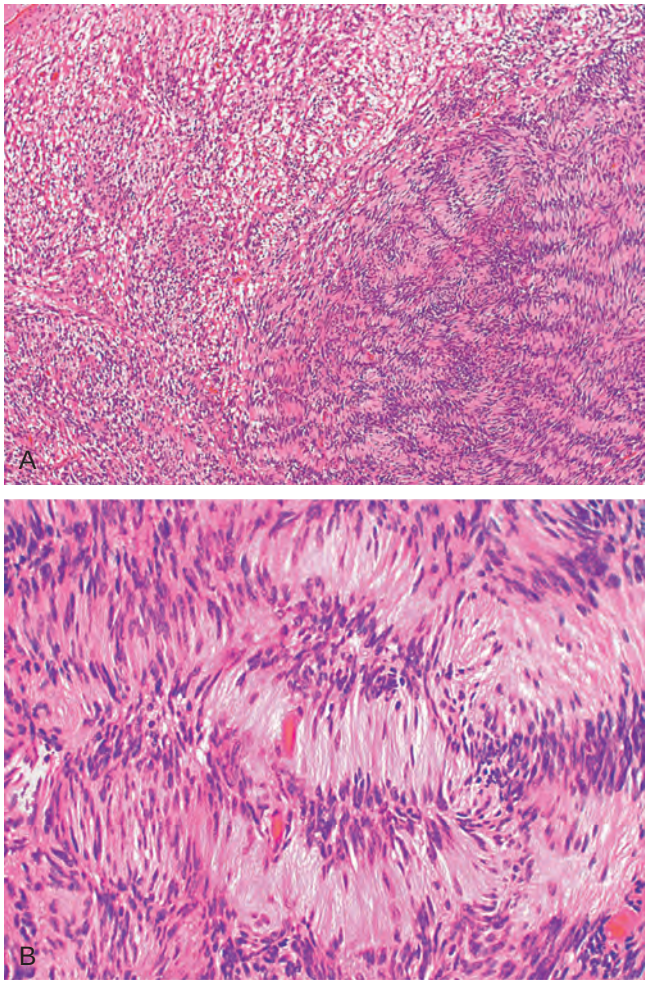
Vestibular schwannomas in patients with NF2 are difficult to manage. Surgical removal is indicated for large symptomatic tumors, but this often results in deafness and risks facial nerve damage. Stereotactic radiosurgery may be considered for older adult or frail patients, as well as for individuals who decline traditional surgery. Bevacizumab, a monoclonal antibody directed against vascular endothelial growth factor (VEGF)-A, may help to induce tumor shrinkage and improve hearing in up to half of affected patients.

◆ NEUROFIBROMA

The **neurofibroma** is the most common type of peripheral nerve neoplasm. It arises from a mixture of cell types, including Schwann cells and perineural fibroblasts.

dentlearn.ir

TABLE 12.2 Hereditary Neural and Neuroendocrine Syndromes



Syndrome	Inheritance Pattern	Gene Mutation	Frequency	Common or Significant Clinical Features
Neurofibromatosis type I (NF1)	Autosomal dominant	*NF1* gene (chromosome 17q11.2)	1 in 2,500–3,000 births	Neurofibromas (especially plexiform type) *Café au lait* pigmentation Axillary and groin freckling Lisch nodules of the iris Optic glioma Epilepsy Hypertension Malignant peripheral nerve sheath tumor (8%–13% of patients)
Neurofibromatosis type II (NF2)	Autosomal dominant	*NF2* gene (chromosome 22q12.2)	1 in 25,000–87,000 births	Bilateral schwannomas ("acoustic neuromas") of the vestibular nerve (cranial nerve VIII) Cranial and spinal meningiomas Other cranial nerve and spinal schwannomas Cutaneous schwannomas Subcapsular cataracts *Café au lait* pigmentation (less common than in NF1) Cutaneous neurofibromas (uncommon)
Schwannomatosis	Autosomal dominant (although most cases have been sporadic)	*SMARCB1* gene or *LZTR1* gene (chromosome 22q11)	1 in 40,000 births	Multiple noncutaneous schwannomas (without involvement of cranial nerve VIII) Chronic pain associated with schwannomas
Multiple endocrine neoplasia type 1 (MEN 1)	Autosomal dominant	*MEN1* gene (chromosome 11q13)	1 in 20,000–40,000 births	Parathyroid tumors Pancreatic islet tumors Anterior pituitary tumors Adrenocortical tumors
Multiple endocrine neoplasia type 2A (MEN 2A)	Autosomal dominant	*RET* proto-oncogene (chromosome 10q11.2)	1 in 36,000–125,000 births	
Classical MEN 2A		95% of examples caused by mutations in codons 609, 611, 618, 620, and 634		MTC (90%) Pheochromocytoma (30%) Primary hyperparathyroidism (10%)
MEN 2A with cutaneous lichen amyloidosis		Most frequently caused by mutation in codon 634; occasionally associated with variants of codons 611 and 804		MTC (95%) Pheochromocytoma (50%) Primary hyperparathyroidism (15%)
MEN 2A with Hirschsprung disease		Caused by mutations in codons 609, 611, 618, and 620		MTC (80%) Pheochromocytoma (20%) Primary hyperparathyroidism (5%)
Familial medullary thyroid carcinoma		Associated with mutations in various codons (e.g., 533, 768, 804)		Patients develop only MTC Rarely develop other neuroendocrine tumors
Multiple endocrine neoplasia type 2B (MEN 2B)	Autosomal dominant	*RET* proto-oncogene (chromosome 10q.11.2; most frequently codon M918T [95%]; 5% at codon A883F)	1 in 400,000–4,000,000 births	MTC (100%) Pheochromocytoma (50%) Oral mucosal neuromas (88%) Intestinal ganglioneuromatosis (67%) Marfanoid habitus (73%) Corneal nerve hypertrophy (45%) Alacrima ("tearless crying") (40%)

MTC, medullary thyroid carcinoma.

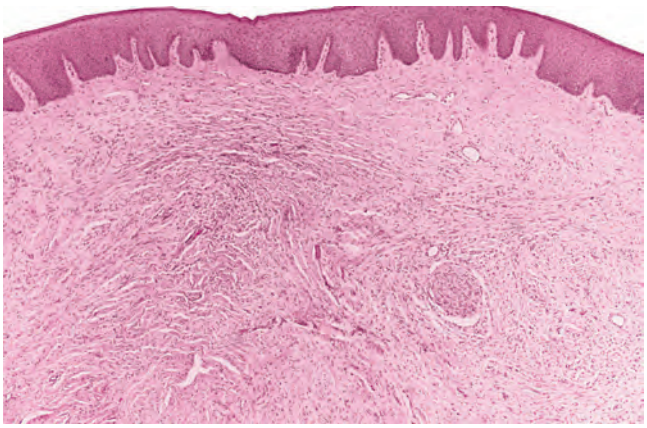
Clinical and Radiographic Features

Neurofibromas can arise as solitary tumors or be a component of neurofibromatosis (see page 537). Solitary tumors are most common in young adults and present as

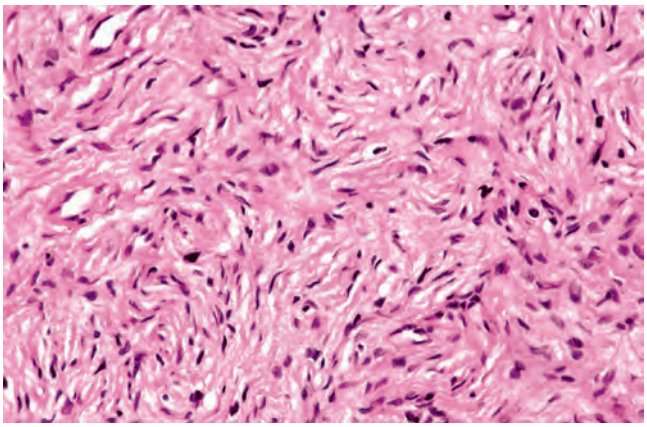
• **Fig. 12.62 Neurofibroma.** Smooth-surfaced, nodular mass of the maxillary gingiva and alveolar mucosa. (Courtesy of Dr. Neal Lemmerman.)

• **Fig. 12.63 Neurofibroma.** Intraosseous tumor filling the right mandibular ramus. (Courtesy of Dr. Paul Allen.)



slow-growing, soft, painless lesions that vary in size from small nodules to larger masses. The skin is the most frequent location for neurofibromas, but lesions of the oral cavity are not uncommon (Fig. 12.62). The tongue, palate, and gingiva are the most common intraoral sites. On rare occasions, the tumor can arise centrally within bone, where it may produce a well-demarcated or poorly defined unilocular or multilocular radiolucency (Fig. 12.63).

Histopathologic Features



The solitary neurofibroma often is well circumscribed, especially when the proliferation occurs within the perineurium of the involved nerve. Tumors that proliferate outside the perineurium may not appear well demarcated and tend to blend with the adjacent connective tissues.

The tumor is composed of interlacing bundles of spindle-shaped cells that often exhibit wavy nuclei (Figs. 12.64 and 12.65). These cells are associated with delicate collagen bundles and variable amounts of myxoid matrix. Mast cells tend to be numerous and can be a helpful diagnostic feature. Sparsely distributed small axons usually can be demonstrated within the tumor tissue by using silver stains. Immunohistochemically,

dentlearn.ir

• **Fig. 12.64 Neurofibroma.** Low-power view showing a cellular tumor mass below the epithelial surface.

• **Fig. 12.65 Neurofibroma.** High-power view showing spindle-shaped cells with wavy nuclei.

the tumor cells show a scattered, positive reaction for S-100 protein.

Treatment and Prognosis

The treatment for solitary neurofibromas is local surgical excision, and recurrence is rare. Any patient with a lesion that is diagnosed as a neurofibroma should be evaluated clinically for the possibility of **neurofibromatosis** (see next topic). Malignant transformation of solitary neurofibromas can occur, although the risk appears to be remote, especially compared with that in patients with neurofibromatosis.

◆ NEUROFIBROMATOSIS TYPE I (VON RECKLINGHAUSEN DISEASE OF THE SKIN)

Neurofibromatosis type I is a relatively common hereditary condition that is estimated to occur in one of every 2,500–3,000 births (see Table 12.2, page 535). Several forms of neurofibromatosis have been recognized, but the most common type is **neurofibromatosis type I (NF1),** which is discussed here. This form of the disease, also known as **von Recklinghausen disease of the skin,** accounts for 85%–97% of neurofibromatosis cases and is inherited as an autosomal dominant trait (although 50% of all patients have no family history and apparently represent new mutations). It is caused by a wide variety of germline mutations of the *NF1* gene, which is located on chromosome region 17q11.2 and is responsible for a tumor suppressor protein product known as *neurofibromin.* The type and severity of the clinical manifestations are highly dependent on the specific mutational site in the *NF1* gene. *NF1* gene microdeletions and mutations of certain *NF1* codons are associated with more severe clinical features, whereas other *NF1* mutations confer a much milder clinical phenotype. Therefore, genetic testing is important to determine the specific mutation that is present.

Clinical and Radiographic Features

The current diagnostic criteria for NF1 are summarized in Box 12.1. Patients have multiple neurofibromas that can occur anywhere in the body but are most common on the skin. Cutaneous neurofibromas can vary from small papules to larger soft nodules, which often demonstrate the "buttonhole" sign (the ability to be invaginated into the subcutis by the tip of the index finger and then reappear when

• BOX 12.1 Diagnostic Criteria for Neurofibromatosis Type I (NF1)*

A. The diagnostic criteria for NF1 are met in an individual who does not have a parent diagnosed with NF1 if two or more of the following are present:
   1. Six or more *café au lait* macules more than 5 mm in greatest diameter in prepubertal individuals and more than 15 mm in greatest diameter in postpubertal individuals†
   2. Freckling in the axillary or inguinal region†
   3. Two or more neurofibromas of any type *or* one plexiform neurofibroma
   4. Optic pathway glioma
   5. Two or more iris Lisch nodules identified by slit lamp examination or two or more choroidal abnormalities—defined as bright, patchy nodules imaged by optical coherence tomography/near-infrared reflectance imaging
   6. A distinctive osseous lesion such as sphenoid dysplasia,‡ anterolateral bowing of the tibia, or pseudoarthrosis of a long bone
   7. A heterozygous pathogenic *NF1* variant with a variant allele fraction of 50% in apparently normal tissue such as white blood cells

B. A child of a parent who meets the diagnostic criteria specified in A merits diagnosis of NF1 if one or more of the criteria in A are present

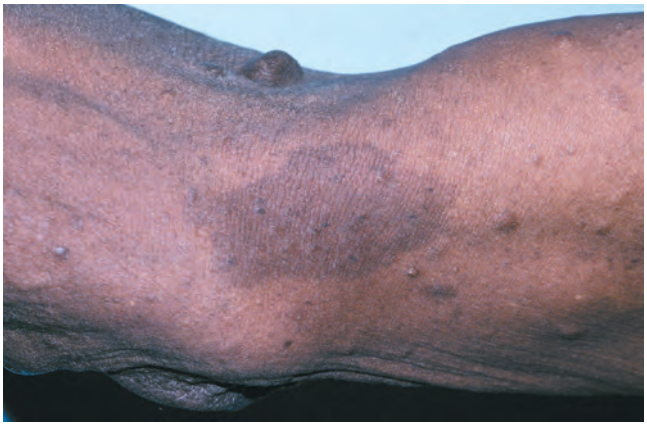
*From Legius E, Messiaen L, Wolkenstein P, et al: Revised diagnostic criteria for neurofibromatosis type 1 and Legius syndrome: an international consensus recommendation, Genet Med 23:1506–1513, 2021.

†If only *café au lait* macules and freckling are present, the diagnosis is most likely NF1 but exceptionally the person might have another diagnosis such as Legius syndrome. At least one of the two pigmentary findings (*café au lait* macules or freckling) should be bilateral.

‡Sphenoid wing dysplasia is not a separate criterion in case of an ipsilateral orbital plexiform neurofibroma.

dentlearn.ir

• **Fig. 12.66 Neurofibromatosis Type I.** Multiple tumors of the trunk and arms.



• **Fig. 12.67 Neurofibromatosis Type I.** Baggy, pendulous neurofibroma of the lower neck.

pressure is released) (Fig. 12.66). The plexiform variant of neurofibroma, which feels like a "bag of worms," is considered pathognomonic for NF1. Some plexiform neurofibromas may evolve into massive baggy, pendulous masses (**elephantiasis neuromatosa**), which can exhibit increased pigmentation and hypertrichosis (Fig. 12.67).

The tumors may be present at birth, but they often begin to appear during puberty and may continue to develop slowly throughout adulthood. Accelerated growth may be seen during pregnancy. There is a wide variability in the expression of the disease. Some patients have only a few neurofibromas; others have literally hundreds or thousands of tumors. However, two-thirds of patients have relatively mild disease.

Another highly characteristic feature is the presence of ***café au lait*** (coffee with milk) pigmentation on the skin (Fig. 12.68). These spots occur as yellow-tan to dark-brown macules that vary in diameter from 1 to 2 mm to several centimeters. In NF1, this pigmentation typically has a smooth edge ("coast of California"), in contrast to the irregular border ("coast of Maine") of the *café au lait* spots that may occur with polyostotic fibrous dysplasia (see page 643). The pigmentation usually is present at birth or it may

• **Fig. 12.68 Neurofibromatosis Type I.** Same patient as depicted in Fig. 12.66. Note the *café au lait* pigmentation on the arm.

• **Fig. 12.69 Neurofibromatosis Type I.** Diffuse neurofibroma resulting in unilateral enlargement of the tongue.

develop during the first year of life. Freckling of the axilla **(Crowe sign)** or of other intertriginous zones is also a highly suggestive sign.

Lisch nodules, translucent brown-pigmented spots on the iris, are found in nearly all affected individuals. The most common general medical problem is hypertension, which may develop secondary to coarctation of the aorta, pheochromocytoma, or renal artery stenosis. Other possible abnormalities include CNS tumors, macrocephaly, mental deficiency, seizures, short stature, and scoliosis.

Studies indicate that oral manifestations may occur in as many as 72%–92% of cases, especially if a detailed clinical and radiographic examination is performed. The most commonly described finding is enlargement of the fungiform papillae, which has been reported in up to 50% of patients; however, the specificity of this finding for neurofibromatosis is unknown. Only about 25%–37% of patients will develop actual intraoral neurofibromas (Fig. 12.69). Radiographic

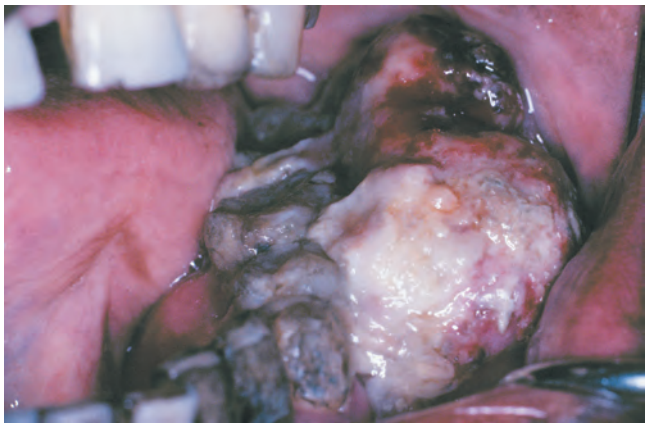
dentlearn.ir

findings may include enlargement of the mandibular foramen, enlargement or branching of the mandibular canal, increased bone density, concavity of the medial surface of the ramus, and increase in dimension of the coronoid notch. Cephalometric analysis often shows a short length of the mandible, maxilla, and cranial base.

Several unusual clinical variants of NF1 have been described. On occasion, the condition can present with unilateral involvement that, in the head and neck, may mimic hemifacial hyperplasia (see page 37). Such examples could represent *mosaic NF1*, being caused by a postzygotic somatic mutation later in embryonic development (rather than a germline mutation), which results in more limited areas of involvement. In patients with mosaic NF1, the risk for transmission to offspring can vary from 0% to 50%, depending on the degree to which the gonads may be affected by the mutation.

Several patients with NF1 have been described with central giant cell granulomas of the jaw. In addition, Legius syndrome and Noonan syndrome can show overlapping clinical features with NF1.

Treatment and Prognosis



There is no specific therapy for NF1, and treatment often is directed toward prevention or management of complications. Facial neurofibromas can be removed for cosmetic purposes. Carbon dioxide (CO_2) laser and dermabrasion have been used successfully for extensive lesions. NF1 patients with prominent hemifacial enlargement may require more significant cosmetic remodeling surgery.

One of the most feared complications is the development of cancer, most often a **malignant peripheral nerve sheath tumor (neurofibrosarcoma; malignant schwannoma),** which has been reported to occur in 8%–13% of cases. These tumors are most common on the trunk and extremities, although head and neck involvement is occasionally seen (Figs. 12.70–12.72). The 5-year survival rate for malignant peripheral nerve sheath tumors associated with NF1 is 15%–50%. Other malignancies also have been associated with NF1, including CNS tumors, pheochromocytoma, leukemia, rhabdomyosarcoma, and Wilms tumor. The average lifespan of individuals with NF1 is 8–15 years less than the general population, mostly related to vascular disease and malignant neoplasms.

In recent years, there has been considerable interest in Joseph (not John) Merrick, the so-called Elephant Man. Although Merrick once was mistakenly considered to have NF1, it is now generally accepted that his horribly disfigured appearance was not because of neurofibromatosis, but that he most likely had a rare condition known as **Proteus syndrome.** Because patients with NF1 may fear acquiring a similar clinical appearance, they should be reassured that they have a different condition. The phrase "Elephant Man disease" is incorrect and misleading, and it should be avoided. Genetic counseling is extremely important for all patients with neurofibromatosis.

◆ MULTIPLE ENDOCRINE NEOPLASIA TYPE 2B

The **multiple endocrine neoplasia (MEN) syndromes** are a group of rare autosomal dominant conditions characterized by tumors or hyperplasias of the neuroendocrine tissues (see Table 12.2, page 535). MEN type 1 is caused by mutations of the *MEN1* gene located on chromosome 11. Affected individuals can develop a variety of tumors of the parathyroid glands, pancreatic islets, anterior pituitary gland, and adrenal cortex. MEN2 is caused by mutations at various sites of the RET (*RE*arranged during *T*ransfection) proto-oncogene on chromosome 10, which predispose patients to the development of medullary thyroid carcinoma (MTC). Two distinct subtypes are recognized: MEN2A and MEN2B.

MEN type 2A encompasses a family of disorders with four phenotypes (classical MEN2A; MEN2A with cutaneous lichen amyloidosis; MEN2A with Hirschsprung disease; and familial MTC syndrome). Patients with classical MEN2A are at increased risk for MTC (over 90% of patients), adrenal pheochromocytomas, and primary hyperparathyroidism. MEN2A with cutaneous lichen amyloidosis is characterized by the same triad of neuroendocrine tumors, plus the presence of pruritic lesions in the scapular region that show amyloid deposition. Patients with MEN2A with Hirschsprung disease also have congenital absence of neural ganglion cells in the wall of the colon, which results in severe constipation and the risk of developing abnormal dilatation of the colon (megacolon). Individuals with familial MTC syndrome should develop only MTC with little to no risk for other neuroendocrine tumors. However, because long-term follow-up of these patients sometimes reveals eventual development of pheochromocytomas and primary hyperparathyroidism, the relevance of this fourth category of MEN2A recently has been questioned.

Over 95% of cases of MEN type 2B are caused by a germline mutation at codon 918 (M918T) of the RET proto-oncogene, although a few examples have been described with a mutation at codon 883 (A883F). In addition to MTC and pheochromocytomas, patients develop mucosal neuromas that especially involve the oral mucous membranes. Because oral manifestations are prominent only in MEN type 2B, the remainder of the discussion is limited to this condition.

• **Fig. 12.73 Multiple Endocrine Neoplasia (MEN) Type 2B.** Note the narrow face and thick, protuberant lips.

Clinical Features

Patients with MEN type 2B usually have a marfanoid body build characterized by thin, elongated limbs with muscle wasting. The face is narrow, but the lips are characteristically thick and protuberant because of the diffuse proliferation of nerve bundles (Fig. 12.73). The upper eyelid sometimes is everted because of thickening of the tarsal plate. Small, pedunculated neuromas may be observable on the conjunctiva, eyelid margin, or cornea.

Oral mucosal neuromas are usually the first sign of the condition and may be detectable during infancy. These neuromas appear as soft, painless papules or nodules that principally affect the lips and anterior tongue but also may be seen on the buccal mucosa, gingiva, and palate (Fig. 12.74). Bilateral neuromas of the commissural mucosa are highly characteristic.

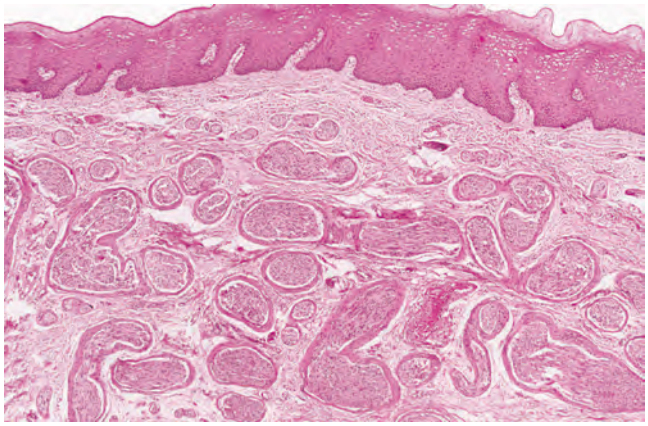
dentlearn.ir

• **Fig. 12.74 Multiple Endocrine Neoplasia (MEN) Type 2B.** Multiple neuromas along the anterior margin of the tongue.

Pheochromocytomas of the adrenal glands develop in at least 50% of all patients and become more prevalent with increasing age. These neuroendocrine tumors are frequently bilateral or multifocal. The tumor cells secrete catecholamines, which result in symptoms such as profuse sweating, intractable diarrhea, headaches, flushing, heart palpitations, and hypertension. Also, approximately 67% of patients with MEN type 2B will develop ganglioneuromatosis of the gastrointestinal tract, which can result in abdominal distention, megacolon, constipation, and diarrhea. Corneal nerve hypertrophy and alacrima ("tearless crying") also may be observed.

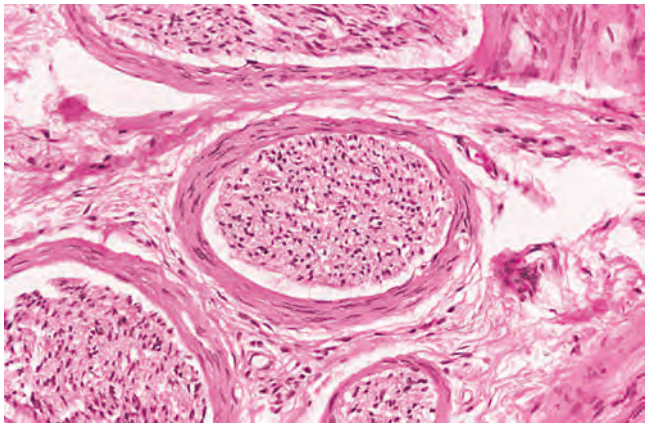
The most significant aspect of this condition is the development of MTC, which occurs in virtually all cases. This aggressive tumor arises from the parafollicular cells (C cells) of the thyroid gland, which are responsible for calcitonin production. MTC silently develops early in life and, without prophylactic thyroidectomy before 1 year of age, most patients will develop metastatic tumor during childhood or adolescence.

Laboratory Values



If MTC is present, then serum or urinary levels of calcitonin are elevated. An increase in calcitonin levels may herald the onset of the tumor, and calcitonin also can be monitored to detect local recurrences or metastases after treatment. Pheochromocytomas may result in increased levels of urinary vanillylmandelic acid (VMA) and increased epinephrine-to-norepinephrine ratios.

Histopathologic Features



The mucosal neuromas are characterized by marked hyperplasia of nerve bundles in an otherwise normal or loose connective tissue background (Figs. 12.75 and 12.76). Prominent thickening of the perineurium is typically seen.

Treatment and Prognosis

The prognosis for patients with MEN type 2B centers on early recognition of the oral features. Because of the poor prognosis for MTC, the thyroid gland should be removed as soon as possible—preferably within the first year of life. The

• **Fig. 12.75 Multiple Endocrine Neoplasia (MEN) Type 2B.** Low-power view of an oral mucosal neuroma showing marked hyperplasia of nerve bundles.

• **Fig. 12.76 Multiple Endocrine Neoplasia (MEN) Type 2B.** High-power view of the same neuroma as depicted in Fig. 12.75. Note the prominent thickening of the perineurium.

10-year survival rate after diagnosis for patients with MEN type 2B is 75% (compared to 97% for patients with MEN type 2A). It has been suggested that patients with the A883F mutation of the RET proto-oncogene may develop a less aggressive form of MTC than patients with the M918T mutation. Multikinase inhibitors with anti-*RET* activity (e.g., vandetanib, cabozantinib) recently have shown some promise in the management of MTC patients who are ineligible for surgery, but have symptomatic or progressive disease. Patients also should be observed for the development of pheochromocytomas because they may result in a life-threatening hypertensive crisis, especially if surgery with general anesthesia is performed.

◆ MELANOTIC NEUROECTODERMAL TUMOR OF INFANCY

The **melanotic neuroectodermal tumor of infancy** is a rare pigmented neoplasm that usually occurs during the first year of life. It is generally accepted that this lesion is of neural crest origin. In the past, however, a number of tissues were suggested

dentlearn.ir

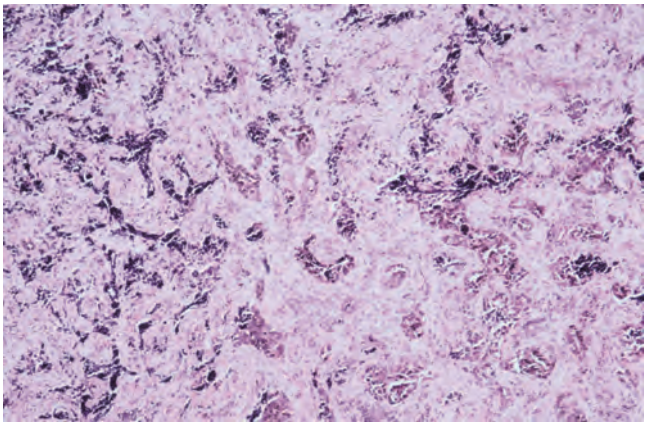
as possible sources of this tumor. These included odontogenic epithelium and retina, which resulted in various older terms for this entity, such as **pigmented ameloblastoma, retinal anlage tumor,** and **melanotic progonoma.** Because these names are inaccurate, however, they should no longer be used.

Clinical and Radiographic Features

Melanotic neuroectodermal tumor of infancy almost always develops in young children during the first year of life; only 9% of cases are diagnosed after the age of 12 months. There is a striking predilection for the maxilla, which accounts for 62% of reported cases. Less frequently reported sites include the skull (16%), mandible (8%) epididymis and testis (5%), and brain (4%). (However, the percentages for sites other than the maxilla may be artificially high, because tumors occurring at less common locations probably are more likely to be submitted and accepted for publication.) A slight male predilection has been noted.

The lesion is most common in the anterior region of the maxilla, where it classically appears as a rapidly expanding mass that is frequently blue or black (Fig. 12.77). The tumor often destroys the underlying bone and may be associated with displacement of the developing teeth (Fig. 12.78). In some instances, there may be an associated osteogenic reaction, which exhibits a "sun ray" radiographic pattern that can be mistaken for osteosarcoma.

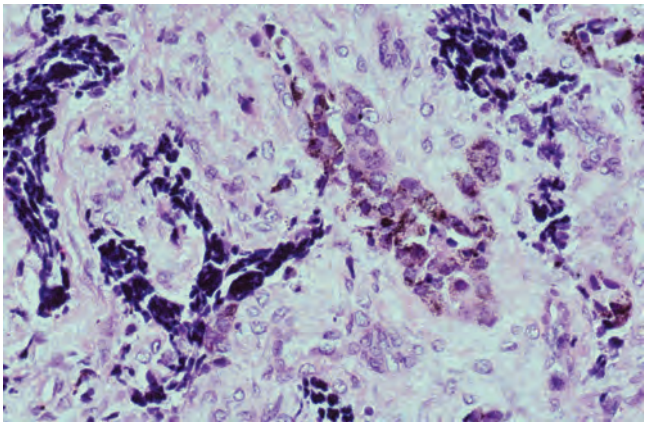
Laboratory Values



High urinary levels of vanillylmandelic acid (VMA) often are found in patients with melanotic neuroectodermal tumor of infancy. These levels may return to normal once the tumor has been resected. This finding supports the hypothesis of neural crest origin because other tumors from this tissue (e.g., pheochromocytoma and neuroblastoma) often secrete norepinephrine-like hormones that are metabolized to VMA and excreted in the urine.

Histopathologic Features

The tumor consists of a biphasic population of cells that form nests, tubules, or alveolar structures within a dense, collagenous stroma (Figs. 12.79 and 12.80). The alveolar and



• **Fig. 12.78 Melanotic Neuroectodermal Tumor of Infancy.** Radiolucent destruction of the anterior maxilla associated with displacement of the developing teeth. (Courtesy of Dr. Len Morrow.)

• **Fig. 12.77 Melanotic Neuroectodermal Tumor of Infancy.** Infant with an expansile mass of the anterior maxilla. (From Steinberg B, Shuler C, Wilson S: Melanotic neuroectodermal tumor of infancy: evidence for multicentricity, *Oral Surg Oral Med Oral Pathol* 66:666–669, 1988.)

• **Fig. 12.80 Melanotic Neuroectodermal Tumor of Infancy.** High-power view of a tumor nest demonstrating two cell types: (1) small, hyperchromatic round cells and (2) larger epithelioid cells with vesicular nuclei. Some stippled melanin pigment is also present.

dentlearn.ir

tubular structures are lined by cuboidal epithelioid cells that demonstrate vesicular nuclei and granules of dark-brown melanin pigment. The second cell type is neuroblastic in appearance and consists of small, round cells with hyperchromatic nuclei and little cytoplasm. These cells grow in loose nests and are frequently surrounded by the larger pigment-producing cells. Mitotic figures are rare.

Because of the tumor's characteristic microscopic features, immunohistochemistry usually is not essential to establish the diagnosis. However, the larger epithelioid cells typically are positive for cytokeratin, HMB-45, and neuron-specific enolase. In addition, the smaller cells usually are positive for neuron-specific enolase and synaptophysin.

Treatment and Prognosis

Despite their rapid growth and potential to destroy bone, most melanotic neuroectodermal tumors of infancy are benign. The lesion is best treated by surgical removal. Some clinicians prefer simple curettage, although others advocate that a 5-mm margin of normal tissue be included with the specimen. Recurrence of the tumor has been reported in about 20% of cases. Age at diagnosis is an important factor in predicting the risk of recurrence; infants diagnosed during the first 2 months of life have a significantly higher recurrence rate than children diagnosed after 4.5 months of age. In addition, about 7% of reported cases, mostly from the brain or skull, have acted in a malignant fashion, resulting in metastasis and death. Although this estimation of 7% is probably high (because unusual malignant cases are more likely to be reported), it underscores the potentially serious nature of this tumor and the need for careful clinical evaluation and follow-up of affected patients.

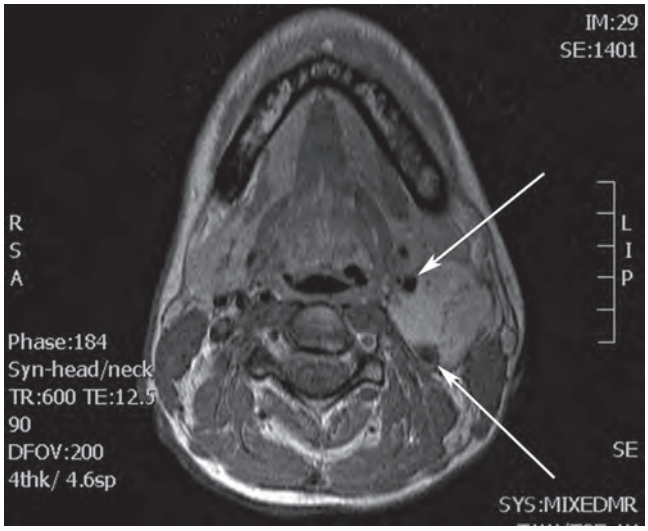
◆ PARAGANGLIOMA (CAROTID BODY TUMOR; CHEMODECTOMA; GLOMUS JUGULARE TUMOR; GLOMUS TYMPANICUM TUMOR)

The paraganglia are specialized tissues of neural crest origin that are associated with the autonomic nerves and ganglia throughout the body. Some of these cells act as chemoreceptors, such as the carotid body (located at the carotid bifurcation), which can detect changes in blood pH or oxygen tension and subsequently cause changes in respiration and heart rate. Tumors that arise from these structures are collectively known as **paragangliomas,** with the term preferably preceded by the anatomic site at which they are located. Therefore, tumors of the carotid body are appropriately known as **carotid body paragangliomas (carotid body tumors).** Other examples in the head and neck include **middle ear paragangliomas (glomus jugulare tumors; glomus tympanicum tumors), vagal paragangliomas,** and **laryngeal paragangliomas.**

Most head and neck paragangliomas occur as sporadic tumors, although 30%–40% of cases are associated with heritable germline mutations of genes that encode for subunits or cofactors of the succinate dehydrogenase enzyme. Five hereditary paraganglioma syndromes (PGL1-5) have been recognized, all of which show an autosomal dominant inheritance pattern. However, PGL1 and PGL2 exhibit an unusual "parent-of-origin—dependent effect" consistent with maternal imprinting of the disease gene. Although the gene can be inherited from either the father or mother, only paternal transmission will result in development of tumors in the offspring. Therefore, the trait may appear to skip generations within a family. Development of head and neck paragangliomas also has been described rarely in several other genetic conditions, such as neurofibromatosis type 1, multiple endocrine neoplasia type 2, and von Hippel-Lindau syndrome.

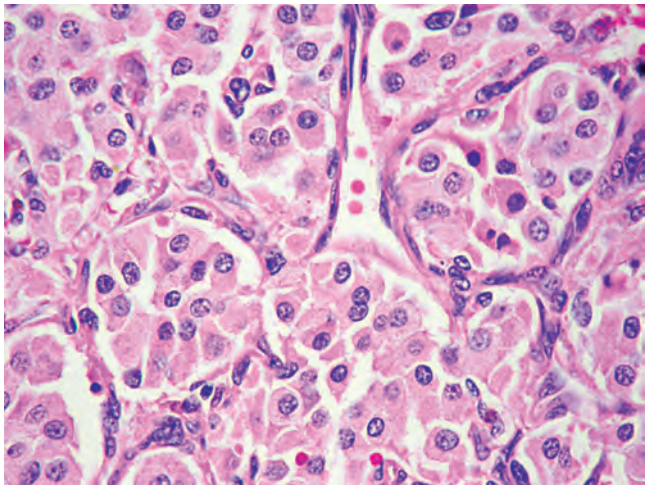
Clinical and Radiographic Features

Although paragangliomas are rare, the head and neck area is the most common site for these lesions. Isolated, mutation-negative tumors show a 4:1 female:male ratio, whereas mutation-positive examples have an equal sex distribution. The tumor usually occurs in middle-aged adults (mean age of 41–47 years), although inherited cases tend to develop in patients over a decade younger. Hereditary cases have a greater chance of being multicentric; about 37% of such patients will develop more than one tumor.



The most common type is the carotid body paraganglioma, which develops at the bifurcation of the internal and external carotid arteries (Figs. 12.81 and 12.82). Most often it is a slowly enlarging, painless mass of the upper lateral neck below the angle of the jaw. It is seen more frequently in patients who live at high altitudes, indicating that some cases may arise from chronic hyperplasia of the carotid body in response to lower oxygen levels. Angiography can help to localize the tumor and demonstrate its characteristic vascular nature.

Middle ear paragangliomas are the next most common types of these tumors. The most common symptoms include



• **Fig. 12.81 Carotid Body Paraganglioma.** Large tumor in the left neck producing a visible external swelling. (Courtesy of Dr. Terry Day.)

dentlearn.ir

• **Fig. 12.82 Carotid Body Paraganglioma.** Same patient as depicted in Fig. 12.81. The magnetic resonance image (MRI) shows a tumor mass at the carotid bifurcation. *Arrows* indicate the external and internal branches of the carotid artery. (Courtesy of Dr. Terry Day.)

• **Fig. 12.83 Carotid Body Paraganglioma.** Nested arrangement of tumor cells.

dizziness, tinnitus (a ringing or other noise in the ear), hearing loss, and cranial nerve palsies.

Histopathologic Features

The paraganglioma is characterized by round or polygonal epithelioid cells that are organized into nests or ***zellballen*** (Fig. 12.83). The overall architecture is similar to that of the normal paraganglia, except the *zellballen* are usually larger and more irregular in shape. These nests consist primarily of chief cells, which demonstrate centrally located, vesicular nuclei and somewhat granular, eosinophilic cytoplasm. These cells are positive for neuroendocrine markers, such as chromogranin and synaptophysin. Loss of SDHB expression is indicative of an hereditary type of paraganglioma. The chief cells are surrounded by a flattened layer of sustentacular cells that are immunoreactive for S-100 protein. The tumor is typically vascular and may be surrounded by a thin fibrous capsule.

Treatment and Prognosis

The treatment of paragangliomas may include surgery, radiation therapy, or both, depending on the extent and location of the tumor. Localized carotid body paragangliomas often can be treated by surgical excision with maintenance of the vascular tree. If the carotid artery is encased by tumor, it also may need to be resected, followed by vascular grafting. Although most carotid body paragangliomas can be controlled with surgery, vascular complications can lead to considerable surgical morbidity, such as intraoperative hemorrhage, stroke, and blood pressure instability. Radiation therapy may be used for unresectable tumors or as adjunctive treatment.

Because of their location near the base of the brain, middle ear paragangliomas are more difficult to manage. Hearing loss and other cranial nerve deficits are common postsurgical complications of jugular paragangliomas. Therefore, radiation therapy should be considered for primary management of such lesions. Stereotactic radiosurgery (gamma knife treatment) has shown promise in the management of primary or recurrent middle ear paragangliomas in patients who are poor surgical candidates. Stable tumors may require only active surveillance.

Approximately 6% of paragangliomas will metastasize, either to regional lymph nodes or distant sites. The risk varies from 2% for both middle ear and laryngeal tumors, to 4%–6% for carotid body tumors, and up to 16% for vagal tumors. Unfortunately, it is difficult to predict which tumors will act in a malignant fashion based on their microscopic features. However, the risk is much greater for patients with SDHB mutations (paraganglioma syndrome 4), where the rate of malignancy ranges from 30% to 50%.

◆ GRANULAR CELL TUMOR

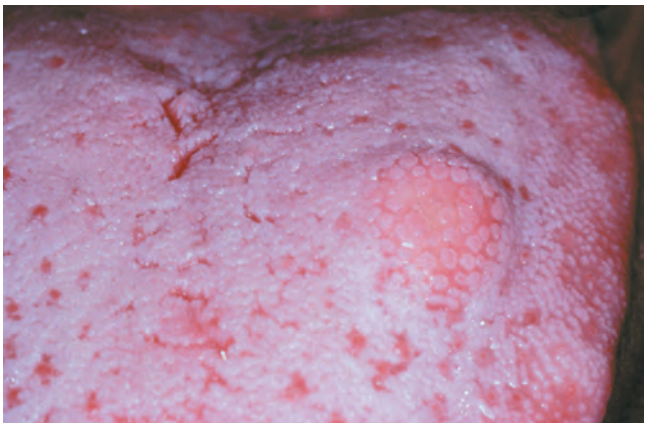
The **granular cell tumor** is an uncommon benign soft tissue neoplasm that shows a predilection for the oral cavity. Originally, this lesion was believed to be of skeletal muscle origin and was called the *granular cell myoblastoma.* However, today most investigators believe that this tumor is derived from Schwann cells, sometimes calling it a **granular cell schwannoma/neurofibroma.** However, this tumor has characteristic clinicopathologic features, and **granular cell tumor** is the preferred designation.

Clinical Features

Granular cell tumors are most common in the oral cavity and on the skin. The single most common site is the tongue, which accounts for one-third to half of all reported cases. Tongue lesions most often occur on the dorsal surface. The lips and buccal mucosa are the next most common

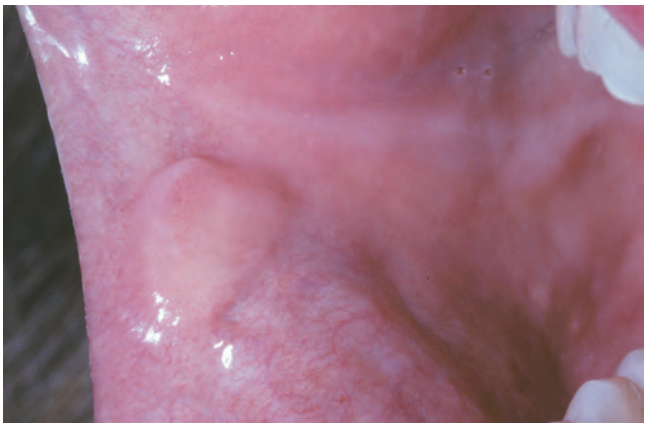
dentlearn.ir

intraoral locations. The tumor most frequently occurs in the fourth to sixth decades of life and is rare in children. There is a 3:1 female predilection.



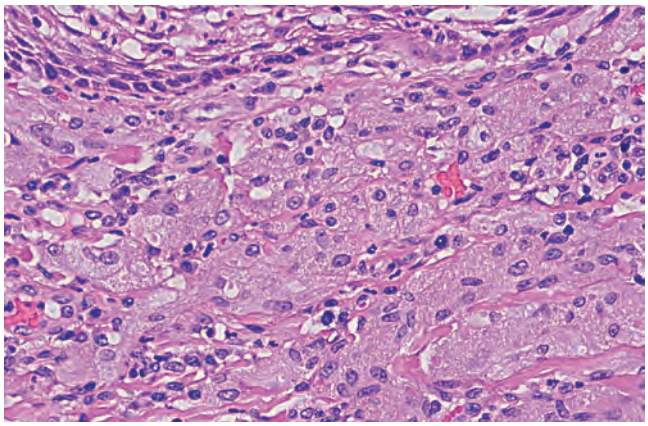
The granular cell tumor is typically an asymptomatic sessile nodule that is usually 2 cm or less in size (Figs. 12.84 and 12.85). The lesion often has been noted for many months or years, although sometimes the patient is unaware of its presence. The mass is typically pink, but some granular cell tumors appear yellow. The granular cell tumor is usually solitary, although multiple, separate tumors sometimes occur, especially in black patients.

Histopathologic Features

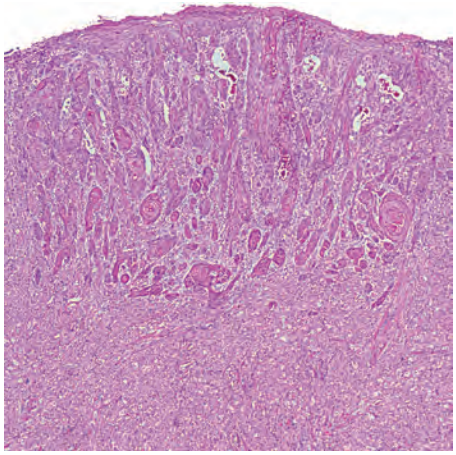


The granular cell tumor is composed of large, polygonal cells with abundant pale eosinophilic, granular cytoplasm and either dark or vesicular nuclei (Fig. 12.86). The cells are usually arranged in sheets, but they also may be found in cords and nests. The cell borders often are indistinct, which results in a syncytial appearance. The lesion is not encapsulated and often intermingles with the adjacent connective tissues. Often, there appears to be a transition from normal adjacent skeletal muscle fibers to granular tumor cells; this finding led earlier investigators to suggest a muscle origin for this tumor. Less frequently, one may see groups of granular cells that envelop small nerve bundles. Immunohistochemical analysis reveals positivity for S-100 protein within the cells—a finding that is supportive, but not diagnostic, of neural origin. The lesional cells also are positive for CD-68, calretinin, and neuron-specific enolase.

An unusual and significant microscopic finding is the presence of acanthosis or pseudoepitheliomatous (pseudocarcinomatous) hyperplasia of the overlying epithelium, which has been reported in up to 50% of all cases (Fig. 12.87). Although this hyperplasia is usually minor in degree, in some cases it may be so striking that it results in a mistaken diagnosis of squamous cell carcinoma and subsequent unnecessary cancer surgery. The pathologist must be aware of this possibility, especially when dealing with a superficial biopsy sample or a specimen from the dorsum of the tongue—an unusual location for oral cancer.



Rare examples of S-100 negative granular cell tumors have been described. However, such lesions may represent a distinctly separate non-neural neoplasm.



• **Fig. 12.84 Granular Cell Tumor.** Submucosal nodule on the dorsum of the tongue.

• **Fig. 12.85 Granular Cell Tumor.** Nodular mass of the buccal mucosa near the commissure.

• **Fig. 12.86 Granular Cell Tumor.** Medium-high–power view showing polygonal cells with abundant granular cytoplasm.

• **Fig. 12.87 Granular Cell Tumor.** Marked pseudoepitheliomatous hyperplasia overlying a granular cell tumor. Such cases may easily be mistaken for squamous cell carcinoma.

dentlearn.ir

Treatment and Prognosis

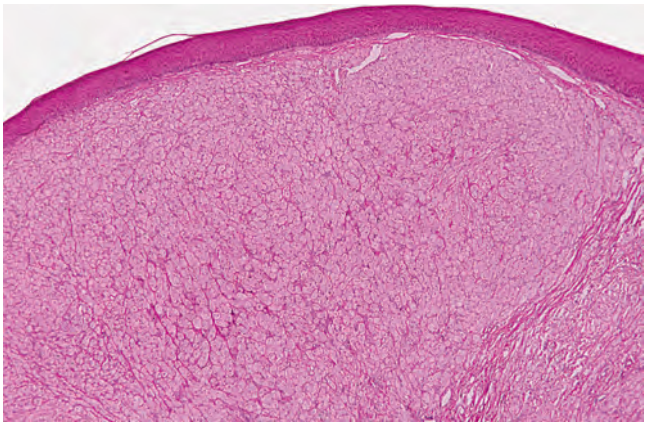
The granular cell tumor is best treated by conservative local excision, and recurrence is uncommon, even when the lesion is not entirely removed. Extremely rare examples of malignant granular cell tumor have been reported.

◆ CONGENITAL EPULIS (CONGENITAL EPULIS OF THE NEWBORN; CONGENITAL GRANULAR CELL LESION)

The **congenital epulis** is an uncommon soft tissue tumor that occurs almost exclusively on the alveolar ridges of newborns. It is often known by the redundant term, **congenital epulis of the newborn.** Rare examples also have been described on the tongue; therefore, some authors prefer using the term **congenital granular cell lesion,** because not all cases present as an *epulis* on the alveolar ridge. It also has been called **gingival granular cell tumor of the newborn,** but this term should be avoided. Although it bears a slight microscopic resemblance to the granular cell tumor (discussed previously), it exhibits ultrastructural and immunohistochemical differences that warrant its classification as a distinct and separate entity. However, the histogenesis of this tumor is still uncertain.

Clinical Features

The congenital epulis typically appears as a pink-to-red, smooth-surfaced, polypoid mass on the alveolar ridge of a newborn (Fig. 12.88). Most examples are 2 cm or less in size, although lesions as large as 7.5 cm have been reported. On occasion, the tumor has been detected *in utero* via ultrasound examination or magnetic resonance imaging (MRI). Multiple tumors develop in 10% of cases. A few rare examples on the tongue have been described in infants who also had alveolar tumors.

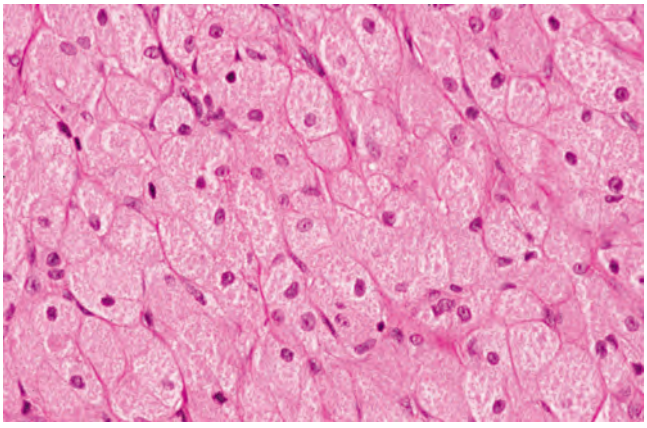


The tumor is two to three times more common on the maxillary ridge than on the mandibular ridge. It most frequently occurs lateral to the midline in the area of the developing lateral incisor and canine teeth. The congenital epulis shows a striking predilection for females, which suggests a hormonal influence in its development, although estrogen and progesterone receptors have not been detected. Nearly 90% of cases occur in females.

Histopathologic Features

The congenital epulis is characterized by large, rounded cells with abundant granular, eosinophilic cytoplasm and round to oval, lightly basophilic nuclei (Figs. 12.89 and 12.90). In older tumors, these cells may become elongated and separated by fibrous connective tissue. In contrast to the granular cell tumor, the overlying epithelium never shows pseudoepitheliomatous hyperplasia but typically demonstrates atrophy of the rete ridges. In addition, in contradistinction to the granular cell tumor, immunohistochemical analysis shows the tumor cells to be negative for S-100 protein.

Treatment and Prognosis



The congenital epulis is usually treated by surgical excision. The lesion never has been reported to recur, even with incomplete removal.

• **Fig. 12.89 Congenital Epulis.** Low-power photomicrograph showing a nodular tumor mass. Note the atrophy of the rete ridges.

• **Fig. 12.88 Congenital Epulis.** Polypoid mass of the anterior maxillary alveolar ridge in a newborn.

• **Fig. 12.90 Congenital Epulis.** High-power view of rounded cells with abundant granular cytoplasm.

dentlearn.ir

After birth, the tumor appears to stop growing and may even diminish in size. Eventual complete regression has been reported in a few patients, even without treatment (Fig. 12.91).

◆ HEMANGIOMA AND VASCULAR MALFORMATIONS

In recent years, great progress has been made in the classification and understanding of tumors and tumor-like proliferations of vascular origin. A modified classification scheme for these vascular anomalies is presented in Box 12.2.

The term **hemangioma** historically was used to describe a variety of developmental vascular anomalies. Currently, however, this term is reserved for benign vascular tumors characterized by proliferating endothelium, whereas the term **vascular malformation** is used for structural anomalies of blood vessels with normal endothelial cell turnover. Two major types of hemangioma are recognized: **infantile hemangiomas** and **congenital hemangiomas**. Infantile hemangiomas are the most common benign tumors of infancy, occurring in 4%–5% of children. They display a rapid growth phase with endothelial cell proliferation, followed by gradual involution. Most infantile hemangiomas cannot be recognized at birth but arise subsequently during the first several weeks of life. On the other hand, congenital hemangiomas are much rarer tumors that are present from birth; they may or may not undergo involution and are subclassified as *rapidly involuting congenital hemangioma [RICH], noninvoluting congenital hemangioma [NICH]*, and *partially involuting congenital hemangioma [PICH])*. Molecular studies have shown that all three subtypes of congenital hemangioma may harbor point mutations in *GNAQ* or *GNA11*.

In comparison, vascular malformations usually are present at birth but persist throughout life. They can be categorized according to the type of vessel involved (capillary, venous, or arteriovenous) and according to hemodynamic features (low flow or high flow). Vascular malformations have been associated with a wide variety of gene mutations, including *GNAQ, PI3KCA, TIE2 (TEK), MAP3K3,* and *MAP2K1* (see Table 12.1).

• BOX 12.2 Classification of Vascular Anomalies

Vascular Tumors

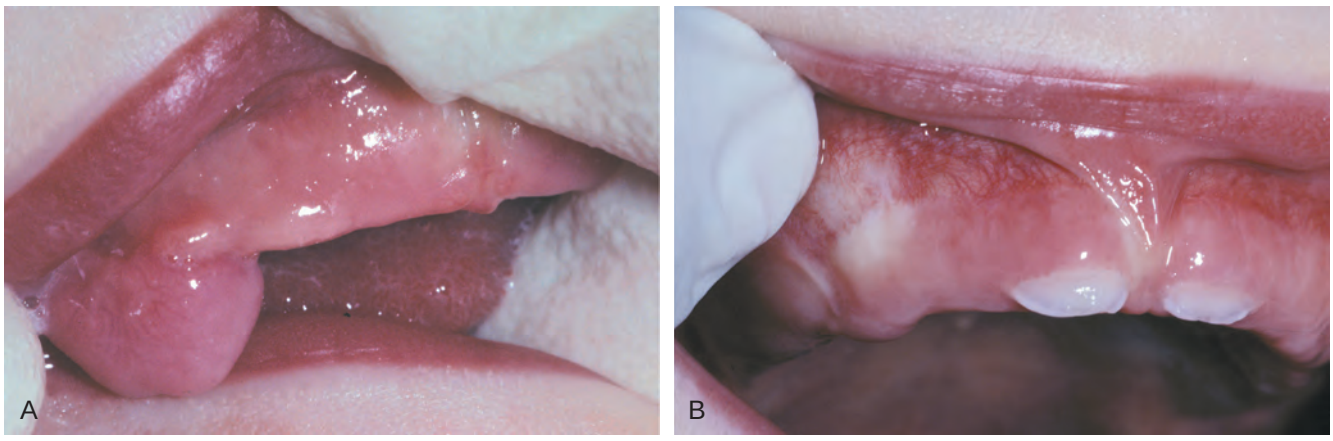
Infantile Hemangioma
Congenital hemangioma
- Noninvoluting congenital hemangioma (NICH)
- Rapidly involuting congenital hemangioma (RICH)

Partially involuting congenital hemangiom (PICH)
- Pyogenic granuloma (lobular capillary hemangioma)
- Kaposiform hemangioendothelioma
- Tufted angioma
- Epithelioid hemangioendothelioma

Angiosarcoma

Vascular Malformations

Simple
- Capillary malformation
- Venous malformation
- Lymphatic malformation
- Arteriovenous malformation



Combined malformations

Clinical and Radiographic Features

Hemangiomas

Infantile hemangiomas are much more common in females than in males (ratio of 3:1 to 5:1), and they occur more frequently in whites than in other racial groups. The most common location is the head and neck, which accounts for 60% of all cases. Eighty percent of hemangiomas occur as single lesions, but 20% of affected patients will have multiple tumors.

Infantile hemangiomas are rarely present at birth, although a pale macule with threadlike telangiectasias may be noted on the skin. During the first few weeks of life, the tumor will demonstrate rapid development that occurs at a faster pace than the infant's overall growth. Superficial tumors of the skin appear raised and bosselated with a bright-red color ("strawberry" hemangioma) (Figs. 12.92

• Fig. 12.91 Congenital Epulis. A, Nodular mass on the maxillary alveolar ridge. Instead of being excised, the lesion was monitored clinically. **B,** Clinical appearance of the child at 1 year of age. The mass has disappeared without treatment. (Courtesy of Dr. Erwin Turner.)

dentlearn.ir

and 12.93). They are firm and rubbery to palpation, and the blood cannot be evacuated by applying pressure. Deeper tumors may appear only slightly raised with a bluish hue.

The initial proliferative phase usually lasts for 6–12 months, after which the tumor grows proportionately with the child, followed by slow involution. The color gradually changes to a dull-purple hue, and the lesion feels less firm to palpation. By age 5, most of the red color is usually gone. About half of all hemangiomas will show complete resolution by 5 years of age, with 90% resolving by age 9. After tumor regression is complete, normal skin will be restored in about 50% of patients; however, up to 40% of affected individuals will show permanent changes such as atrophy, scarring, wrinkling, or telangiectasias.

Congenital hemangiomas, which are fully developed at birth, are equally divided between both sexes. Rapidly involuting congenital hemangiomas show early regression, with full involution by 9–14 months of age. Noninvoluting congenital hemangiomas grow proportionately with the child and do not undergo involution.

Complications occur in about 20% of hemangiomas. The most common problem is ulceration, which may occur with or without secondary infection. Although hemorrhage may be noted, significant blood loss does not usually occur.

• **Fig. 12.92 Hemangioma.** Infant with two red, nodular masses on the posterior scalp and neck ("strawberry" hemangioma).

• **Fig. 12.93 Hemangioma.** Nodular, red mass on the upper lip vermilion in a 4-year-old child. (Courtesy of Dr. Lynn Wallace.)

Hemangiomas that occur in crucial areas can be associated with significant morbidity. Periocular tumors often result in amblyopia (dimness of vision), strabismus, or astigmatism. Patients with multiple cutaneous hemangiomas or large facial hemangiomas are at increased risk for concomitant visceral hemangiomas. Tumors in the neck and laryngeal region can lead to airway obstruction.

Large, segmental cervicofacial hemangioma can be a component of a well-recognized hemangioma syndrome—**PHACE (S) syndrome.** This acronym stands for the following:

- **P**osterior fossa brain anomalies (usually Dandy-Walker malformation)
- **H**emangioma (usually cervical segmental hemangioma)
- **A**rterial anomalies
- **C**ardiac defects and **C**oarctation of the aorta
- **E**ye anomalies
- **S**ternal cleft or **S**upraumbilical raphe

Kasabach-Merritt phenomenon is a serious coagulopathy that has been associated with two rare and potentially aggressive vascular tumors known as *tufted hemangioma* and *kaposiform hemangioendothelioma.* This disorder is characterized by severe thrombocytopenia and hemorrhage because of platelet trapping within the tumor. The mortality rate is as high as 20%–30%.

Vascular Malformations

Vascular malformations are present at birth and persist throughout life. Port wine stains are relatively common capillary malformations that occur in 0.3% of newborns.. They are most common on the face, particularly along the distribution of the trigeminal nerve. In Sturge-Weber syndrome, associated intracranial lesions are present (see page 551). Port wine stains are typically pink or purple macular lesions that grow commensurately with the patient. As the patient gets older, the lesion often darkens and becomes nodular because of vascular ectasia.

Low-flow **venous malformations** encompass a wide spectrum of lesions, from small isolated ectasias to complex growths that involve multiple tissues and organs. They are present at birth, although they may not always be immediately apparent. Typically, venous malformations are blue and are easily compressible (Fig. 12.94). They often grow

• **Fig. 12.94 Venous Malformation.** Blue-purple mass of the anterior tongue.

dentlearn.ir

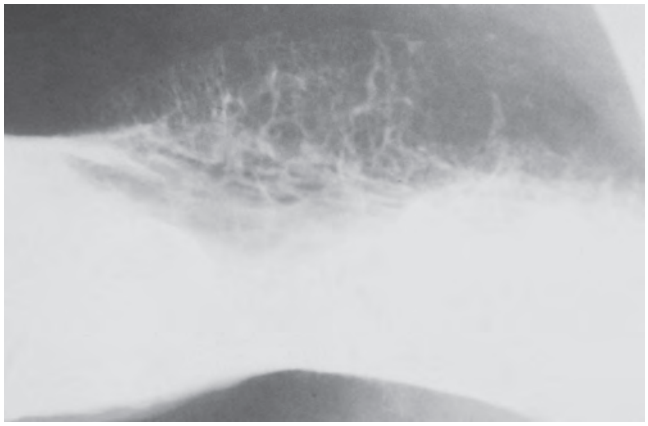
proportionately with the patient, but they may swell when dependent or with increased venous pressure. Secondary thrombosis and phlebolith formation can occur.

Arteriovenous malformations are high-flow lesions that result from persistent direct arterial and venous communication. Although they are present from birth, they may not become noticeable until later in childhood or adulthood. Because of the fast vascular flow through these lesions, a palpable thrill or bruit often is noticeable. The overlying skin typically feels warmer to touch. Presenting symptoms may include pain, bleeding, and skin ulceration.

Intrabony Vascular Malformations

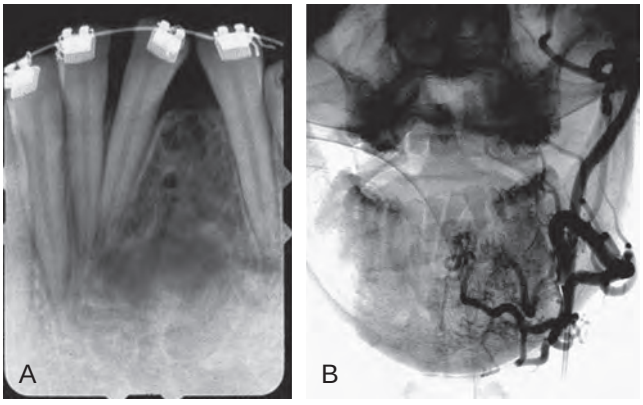
Intrabony "hemangiomas" also may occur and usually represent either venous or arteriovenous malformations. In the jaws, such lesions are detected most often during the first three decades of life. They are slightly more common in females than in males and occur three times more often in the mandible than the maxilla. The lesion may be completely asymptomatic, although some examples are associated with pain and swelling. Mobility of teeth or bleeding from the gingival sulcus may occur. A bruit or pulsation may be apparent on auscultation and palpation.

The radiographic appearance of intrabony vascular malformations is variable. Most commonly, the lesion shows a multilocular radiolucent defect. The individual loculations may be small (honeycomb appearance) or large (soap bubble appearance). In other cases the lesion may present as an ill-defined radiolucent area or a well-defined, cystlike radiolucency (Fig. 12.95). Large malformations may cause cortical expansion, and occasionally a "sunburst" radiographic pattern is produced (Fig. 12.96). Angiography can be helpful in demonstrating the vascular nature of the lesion (Fig. 12.97).



Histopathologic Features

Early infantile hemangiomas are characterized by numerous plump endothelial cells and often-indistinct vascular lumina (Figs. 12.98 and 12.99). At this stage, such lesions often are known microscopically as *juvenile* or *cellular* hemangiomas. Because of their cellular nature, these lesions also have been called **juvenile hemangioendothelioma,** although this term should be avoided because hemangioendothelioma also is used to designate other vascular tumors of intermediate malignant potential. As the lesion matures, the endothelial cells become flattened, and the small, capillary-sized vascular spaces become more evident (Fig. 12.100). As the hemangioma undergoes involution, the vascular spaces become less prominent and are replaced by fibrofatty connective tissue.



Vascular malformations do not show active endothelial cell proliferation, and the channels resemble the vessels of origin. Therefore, capillary malformations may be similar to the capillary stage of hemangioma, whereas venous malformations may show more dilated vessels (Fig. 12.101). Because of their similar features, many vascular malformations are incorrectly categorized as *hemangiomas.* Arteriovenous malformations demonstrate a mixture of thick-walled arteries and veins, along with capillary vessels.

• **Fig. 12.95 Intrabony Venous Malformation.** Well-circumscribed radiolucency that contains fine trabeculations.

GLUT1 is an immunohistochemical marker that is consistently positive in infantile hemangiomas. In contrast, this marker is negative in other developmental vascular tumors and anomalies listed in Box 12.2 (RICH, NICH, PICH, tufted angioma, kaposiform hemangioendothelioma, pyogenic granuloma, and vascular malformations).

Treatment and Prognosis

Because most hemangiomas of infancy undergo involution, management often consists of "watchful neglect." It is important to educate parents that although rapid growth may be seen, regression will occur. For problematic or life-threatening hemangiomas, pharmacologic therapy with the beta blocker propranolol has become the first-line treatment in recent years. Systemic corticosteroids also may help to reduce the size of the lesion, but this approach is associated with a greater risk potential than propranolol therapy. Intralesional and topical corticosteroids sometimes have been used for smaller localized, problematic lesions. Topical timolol maleate may be effective for thin or superficial infantile hemangiomas.

Surgical removal rarely is warranted for infantile hemangiomas, although excision may be effective for localized, pedunculated tumors that demonstrate ulceration or recurrent bleeding. Surgical management early in childhood also might be a consideration in situations where eventual surgical repair would be required anyway and the scar can be easily hidden. Upper eyelid tumors that can affect vision also may be candidates for surgery.

Flashlamp pulsed dye lasers can be effective in the treatment of port wine stains. The management of venous malformations depends on the size, location, and associated complications of the lesion. Small, stable malformations may not require treatment. Larger, problematic lesions may be treated with a combination of sclerotherapy and surgical excision. Sclerotherapy involves the injection of sclerosing agents, such as 95% ethanol, sodium tetradecyl sulfate, or ethanolamine oleate, directly into the lesion to induce fibrosis. Sclerotherapy alone may be sufficient for smaller lesions; for larger lesions, subsequent surgical resection can be accomplished with less risk of bleeding after sclerotherapy.

dentlearn.ir

The treatment of arteriovenous malformations is more challenging and also depends on the size of the lesion and degree of involvement of vital structures. For cases that require resection, radiographic embolization often is performed 24–48 hours before surgery to minimize blood loss.

Vascular malformations of the jaws are potentially dangerous lesions because of the risk of severe bleeding, which may occur spontaneously or during surgical manipulation. Needle aspiration of any undiagnosed intrabony lesion before biopsy is a wise precaution to rule out the possibility of a vascular malformation. Severe and even fatal hemorrhages have occurred after incisional biopsy or extraction of teeth in the area of such lesions.

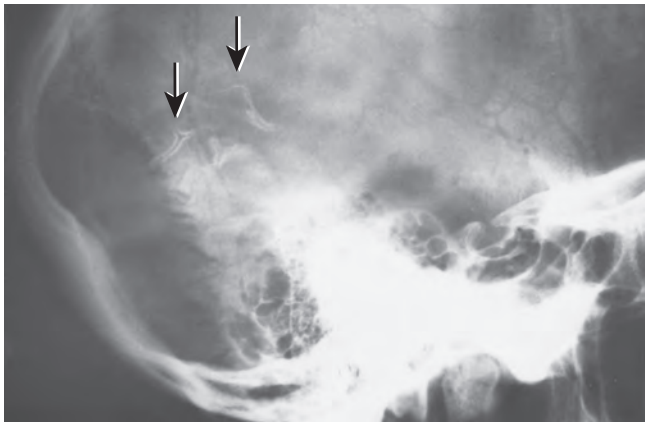
• **Fig. 12.102 Port Wine Stain.** Nevus flammeus of the malar area in a patient without Sturge-Weber syndrome. Unless the vascular lesion includes the region innervated by the ophthalmic branch of the trigeminal nerve, usually the patient does not have central nervous system (CNS) involvement.

◆ STURGE-WEBER SYNDROME (ENCEPHALOTRIGEMINAL ANGIOMATOSIS; STURGE-WEBER ANGIOMATOSIS)

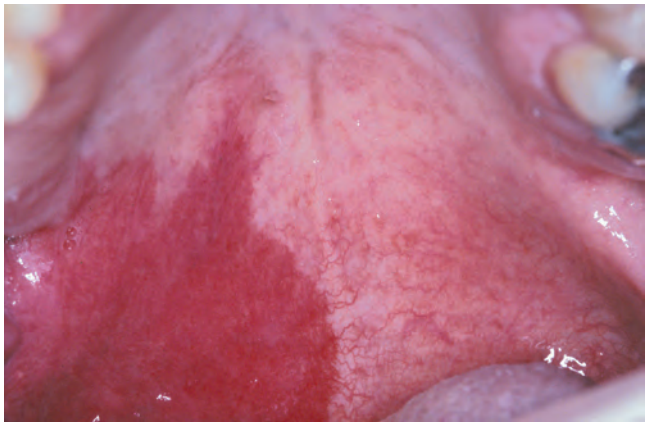
Sturge-Weber syndrome is a rare, nonhereditary developmental condition that is characterized by a hamartomatous vascular proliferation involving the tissues of the brain and face. The capillary malformation associated with this syndrome has been shown to be related to somatic mutations of the *GNAQ* and *PI3K* genes, resulting in aberrant activation of MAPK and/or PI3K.. It has been suggested that these embryologic mutations result in failure of the primitive cephalic venous plexus to regress and mature properly during the first trimester of pregnancy. The incidence of Sturge-Weber syndrome is estimated to be 1 in every 20,000 – 50,000 live births.

Clinical and Radiographic Features

Patients with Sturge-Weber syndrome are born with a dermal capillary vascular malformation of the face known as a **port wine stain** or **nevus flammeus** because of its deep-purple color. This port wine stain usually has a unilateral distribution along one or more segments of the trigeminal nerve. Occasionally, patients have bilateral involvement or additional port wine lesions elsewhere on the body. Risk for the condition occurs primarily in patients with involvement along the distribution of the ophthalmic branch of the trigeminal nerve (V1) (Figs. 12.102 and 12.103). Approximately 15%–20% of children with port-wine stains involving the distribution of V1 will have Sturge-Weber syndrome.



In addition to the facial port wine nevus, individuals with Sturge-Weber syndrome have leptomeningeal angiomas that overlie the ipsilateral cerebral cortex. This meningeal angiomatosis usually is associated with a convulsive disorder and often results in intellectual disability or contralateral hemiplegia. Other potential problems include migraine headaches, stroke-like episodes, growth hormone deficiency, and central hypothyroidism. Imaging studies of the brain may reveal gyriform "tramline" calcifications on the affected side (Fig. 12.104). Ocular involvement may be manifested by glaucoma and vascular malformations of the conjunctiva, episclera, choroid, and retina.



• **Fig. 12.103 Sturge-Weber Syndrome.** Port wine stain of the left face, including involvement along the ophthalmic branch of the trigeminal nerve. The patient also was intellectually disabled and had a seizure disorder.

Intraoral involvement in Sturge-Weber syndrome is common, resulting in hypervascular changes to the ipsilateral mucosa (Fig. 12.105). The gingiva may exhibit slight vascular hyperplasia or a more massive hemangiomatous proliferation that can resemble a pyogenic granuloma. Such gingival

dentlearn.ir

• **Fig. 12.105 Sturge-Weber Syndrome.** Unilateral vascular involvement of the soft palate.

hyperplasia may be attributable to the increased vascular component, anticonvulsant therapy used to control the epileptic seizures, or both. Destruction of the underlying alveolar bone has been reported in rare instances.

Histopathologic Features

The port wine nevus is characterized by excessive numbers of dilated blood vessels in the middle and deep dermis. The intraoral lesions show a similar vascular dilatation. Proliferative gingival lesions may resemble a pyogenic granuloma.

Treatment and Prognosis

The treatment and prognosis of Sturge-Weber syndrome depend on the nature and severity of the possible clinical features. Usually, facial port wine nevi can be improved by using flashlamp pulsed dye lasers. Cortical excision of angiomatous meningeal lesions may be necessary in some cases. Patients with intractable epilepsy and progressive intellectual disability eventually may require more extensive neurosurgical treatment, including lobectomy or hemispherectomy.

Port wine nevi that affect the gingiva can make flossing and dental prophylaxis difficult. Great care must be taken when performing surgical procedures in affected areas of the mouth because significant hemorrhage may be encountered. Lasers also may be helpful in the removal of hyperplastic oral lesions.

◆ NASOPHARYNGEAL ANGIOFIBROMA

The **nasopharyngeal angiofibroma** is a rare vascular and fibrous tumor-like lesion that occurs only in the nasopharynx. Although microscopically benign, it frequently exhibits locally destructive and aggressive behavior. It may represent a vascular malformation rather than a true neoplasm.

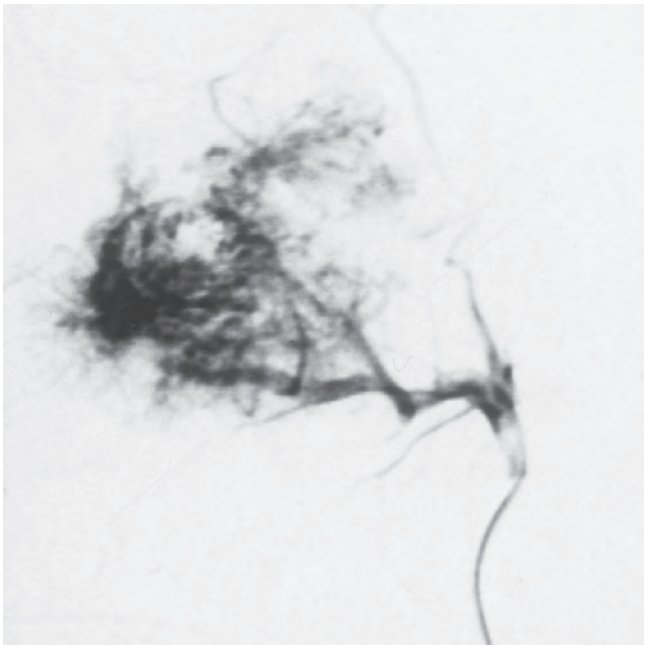
Clinical and Radiographic Features

Nasopharyngeal angiofibromas occur almost exclusively in males. The tumor is exceedingly rare in females—so much so that the diagnosis in a female patient should be viewed with skepticism and closely scrutinized. The lesion also shows a striking predilection for adolescents between the ages of 10 and 17 and often has been called the *juvenile nasopharyngeal angiofibroma.* However, rare examples also have been reported in slightly younger and older patients. Because of its almost exclusive occurrence in adolescent boys, a hormonal influence seems likely, although no definite endocrine abnormalities have been detected. Occasional examples of nasopharyngeal angiofibroma have been described in patients with familial adenomatous polyposis.

Unilateral nasal obstruction (80%) and epistaxis (60%) are common early symptoms. The lesion appears to arise in the pterygopalatine fossa and expands medially into the nasal cavity via the sphenopalatine foramen. Some cases show extension into the paranasal sinuses, orbits, cavernous sinus, or middle cranial fossa. Invasion into the oral cavity or cheek rarely has been reported. Computed tomography (CT) scans and magnetic resonance imaging (MRI) studies are helpful adjuncts in visualizing the extent of the lesion and degree of adjacent tissue destruction. Anterior bowing of the posterior wall of the maxillary sinus (Holman-Miller sign) is a characteristic feature (Fig. 12.106). Angiograms can be used to confirm the vascular nature of the lesion (Fig. 12.107).

Histopathologic Features

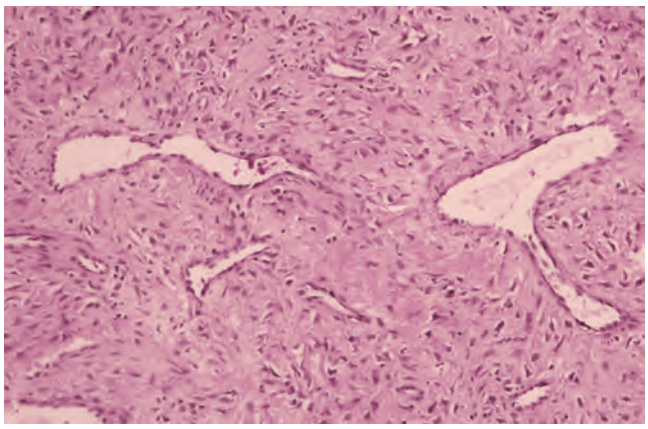
The nasopharyngeal angiofibroma consists of dense fibrous connective tissue that contains numerous dilated, thin-walled blood vessels of variable size (Fig. 12.108). Typically, the vascular component is more prominent at the periphery of the tumor, especially in lesions from younger patients.



Treatment and Prognosis

The primary treatment of nasopharyngeal angiofibroma usually consists of surgical excision. Depending on the extent of the lesion, this may be accomplished via endoscopic surgery,

dentlearn.ir



• **Fig. 12.106 Nasopharyngeal Angiofibroma.** A contrasted computed tomography (CT) scan showing a tumor of the nasopharynx and pterygopalatine fossa, with characteristic anterior bowing of the posterior wall of the right maxillary sinus (*arrow*). (Courtesy of Dr. Pamela Van Tassel.)

• **Fig. 12.107 Nasopharyngeal Angiofibroma.** A digital subtraction angiogram of the external carotid artery showing the intense vascular blush of the tumor. (Courtesy of Dr. Pamela Van Tassel.)

lateral rhinotomy, midfacial degloving procedure, infratemporal fossa approach, or combined craniofacial resection. Preoperative embolization of the tumor is helpful in controlling blood loss. Radiation therapy usually is reserved for recurrent lesions and extensive tumors with unusual vascular supplies or intracranial extension.

• **Fig. 12.108 Nasopharyngeal Angiofibroma.** Moderately cellular fibrous connective tissue with prominent blood vessels.

The recurrence rate varies from 20% to 40% in most studies. Such recurrences usually are retreated with further surgery or radiation therapy. Malignant transformation into fibrosarcoma rarely has been reported and probably is associated with prior radiation therapy.

◆ LYMPHATIC MALFORMATIONS (LYMPHANGIOMA; CYSTIC HYGROMA)

Lymphatic malformations are benign, hamartomatous tumor-like growths of lymphatic vessels. Like other vascular malformations, it is doubtful that they are true neoplasms; instead, they most likely represent developmental anomalies that arise from sequestrations of lymphatic tissue that do not communicate normally with the rest of the lymphatic system.

Lymphatic malformations can be classified into three types:

1. **Macrocystic**—composed of cystlike spaces measuring 2 cm or greater in diameter
2. **Microcystic**—composed of smaller vascular channels measuring less than 2 cm in diameter
3. **Mixed**—composed of a combination of macrocystic and microcystic spaces

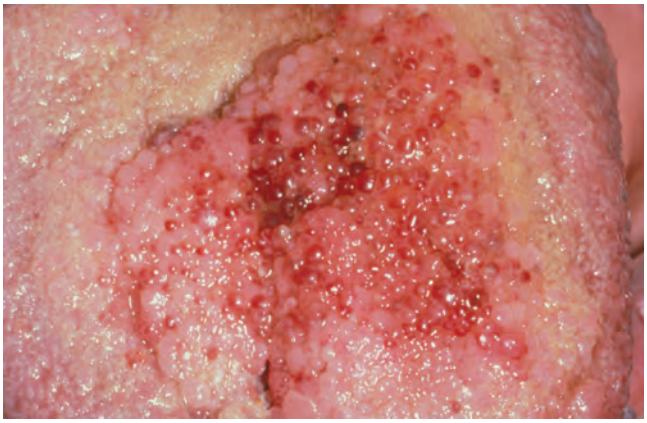
The subtypes are probably variants of the same pathologic process, and the size of the vessels may depend on the nature of the surrounding tissues. Macrocystic lymphatic malformations ("cystic hygroma") often occur in the neck, where the loose adjacent connective tissues allow for more expansion of the vessels. Microcystic lesions are more frequent in the mouth, where the denser surrounding connective tissue and skeletal muscle limit vessel expansion.

Clinical Features

Lymphatic malformations have a marked predilection for the head and neck, which accounts for 50%–75% of all cases (Fig. 12.109). About half of all lesions are noted at birth, and around 90% develop by 2 years of age.

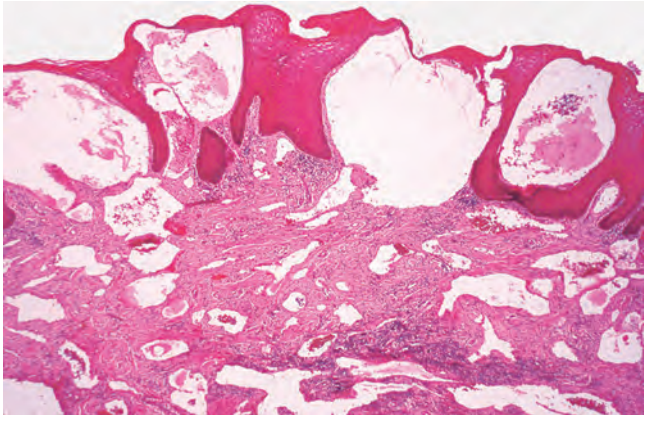
dentlearn.ir

• **Fig. 12.109 Lymphatic Malformation.** Young boy with a cystic hygroma primarily involving the right side of the face. (Courtesy of Dr. Frank Kendrick.)



Cervical lymphatic malformations are more common in the posterior triangle and are typically soft, fluctuant masses. They occur less frequently in the anterior triangle, although lesions in this location are more likely to result in respiratory difficulties or dysphagia if they grow large. Occasionally, cervical lesions will extend into the mediastinum or upward into the oral cavity. Such growths can become massive and can measure 15 cm or greater in size. Rapid enlargement may occur secondary to an upper respiratory tract infection, presumably because of increased lymph production, blocked lymphatic drainage, or secondary infection of the tumor.

Oral lymphatic malformations may occur at various sites but are most frequent on the anterior two-thirds of the tongue, where they often result in macroglossia (Figs. 12.110 and 12.111). Usually, the lesion is superficial in location and demonstrates a pebbly surface that resembles a cluster of translucent vesicles. The surface has been likened to the appearance of frog eggs or tapioca pudding. Secondary hemorrhage into the lymphatic spaces may cause some of these "vesicles" to become purple. Deeper tumors present as soft, ill-defined masses.

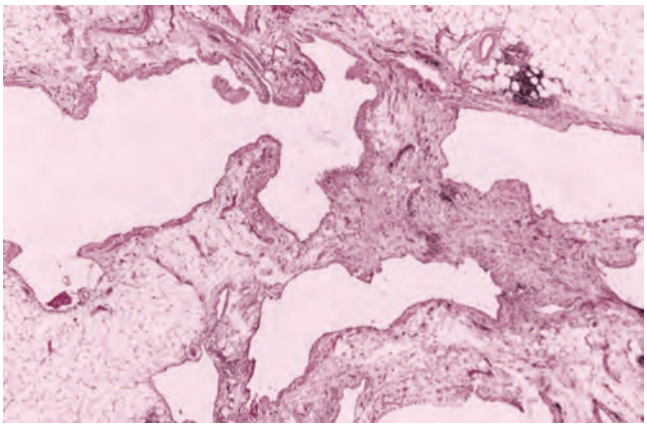


Small lymphatic anomalies less than 1 cm in size occur on the alveolar ridge in around 4% of black neonates. These lesions often occur bilaterally on the mandibular ridge and show a 2:1 male-to-female distribution. Most of these alveolar lymphangiomas apparently resolve spontaneously because they are not observed in older people.

• **Fig. 12.110 Lymphatic Malformation.** Pebbly, vesicle-like appearance of a tumor of the right lateral tongue.

• **Fig. 12.111 Lymphatic Malformation.** Dorsal tongue lesion demonstrating a purple color, which can be caused by secondary hemorrhage or an associated hemangiomatous component.

• **Fig. 12.112 Microcystic Lymphatic Malformation.** Lesion of the tongue showing dilated lymphatic vessels beneath the epithelium and in the deeper connective tissues.



Histopathologic Features

Lymphatic malformations are composed of lymphatic vessels that may show mild dilatation (microcystic) (Figs. 12.112 and 12.113) or macroscopic cystlike structures (macrocystic)

dentlearn.ir

• **Fig. 12.113 Microcystic Lymphatic Malformation.** High-power photomicrograph showing dilated, lymph-filled vessels immediately below the atrophic surface epithelium.

• **Fig. 12.114 Macrocystic Lymphatic Malformation.** Lesion from the neck showing markedly dilated lymphatic vessels.

(Fig. 12.114). The vessels often diffusely infiltrate the adjacent soft tissues and may demonstrate lymphoid aggregates in their walls. The lining endothelium is typically thin, and the spaces contain proteinaceous fluid and occasional lymphocytes. Some channels also may contain red blood cells, which creates uncertainty as to whether they are lymphatic or blood vessels. Although many of these likely represent secondary hemorrhage into a lymphatic vessel, some actually may be examples of mixed vascular malformations composed of both lymphatic and blood vessels.

In intraoral tumors, the lymphatic vessels are characteristically located just beneath the epithelial surface and often replace the connective tissue papillae. This superficial location results in the translucent, vesicle-like clinical appearance. However, extension of these vessels into the deeper connective tissue and skeletal muscle also may be seen.

Treatment and Prognosis

The treatment of lymphatic malformations of the head and neck depends on the size, location, and subtype of the anomaly. Smaller lesions not associated with significant functional or cosmetic problems may be managed best by observation alone. For example, some clinicians do not recommend treatment for nonenlarging lesions of the tongue because of the difficulty in removal and high recurrence rate. Spontaneous regression of lymphatic malformations is rare but has been reported in about 3% of cases.

When required, treatment usually consists of surgical excision, percutaneous sclerotherapy, or a combination of both. Total surgical removal may not be possible in all cases because of large size or involvement of vital structures. Recurrence after surgery is common, especially for microcystic lymphatic malformations of the oral cavity, because of their infiltrative nature. Macrocystic lesions of the cervical region are often well circumscribed and have a lower rate of recurrence.

In recent years, percutaneous sclerotherapy has proven to be a successful alternative to surgery for many lymphatic malformations. The most widely used sclerosants include doxycycline, OK-432, and bleomycin. Sclerotherapy is most successful in the management of macrocystic lesions, with over 80% of patients showing complete resolution or substantial response. A lower success rate is achieved in mixed and microcystic subtypes.

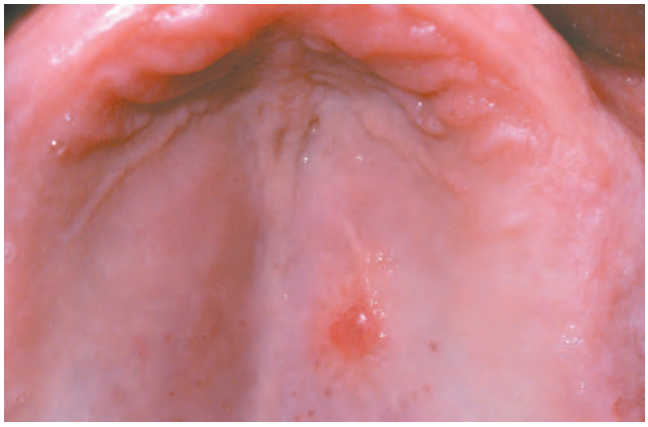
The prognosis is good for most patients, although large tumors of the neck or tongue may result in airway obstruction and death.

◆ LEIOMYOMA

Leiomyomas are benign tumors of smooth muscle that most commonly occur in the uterus, gastrointestinal tract, and skin. Leiomyomas of the oral cavity are rare. Most of these probably have their origin from vascular smooth muscle.

The three types are as follows:

1. Solid leiomyomas
2. Vascular leiomyomas (angiomyomas or angioleiomyomas)
3. Epithelioid leiomyomas (leiomyoblastomas)



Almost all oral leiomyomas are either solid or vascular in type; angiomyomas account for nearly 75% of all oral cases. Rare examples of developmental hamartomas composed primarily of smooth muscle (leiomyomatous hamartoma) also have been described in the oral cavity.

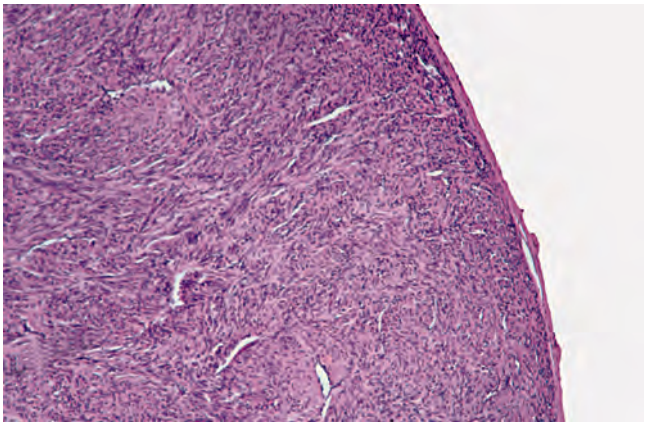
Clinical and Radiographic Features

The oral leiomyoma can occur at any age and is usually a slow-growing, firm, mucosal nodule (Fig. 12.115). Most lesions are asymptomatic, although occasional tumors can be painful. Solid leiomyomas are typically normal in color, although angiomyomas may exhibit a bluish hue. The most common sites are the lips, tongue, palate, and cheek, which together account for 80% of cases. Extremely rare intraosseous examples may present as unilocular radiolucencies of the jaws.

Oral leiomyomatous hamartomas occur most frequently on the anterior palatal gingiva in the incisive papilla region or on the midline dorsal tongue (Fig. 12.116). If the lesion is present at birth, then it may be mistaken for a congenital epulis (see page 546). Most other examples are discovered

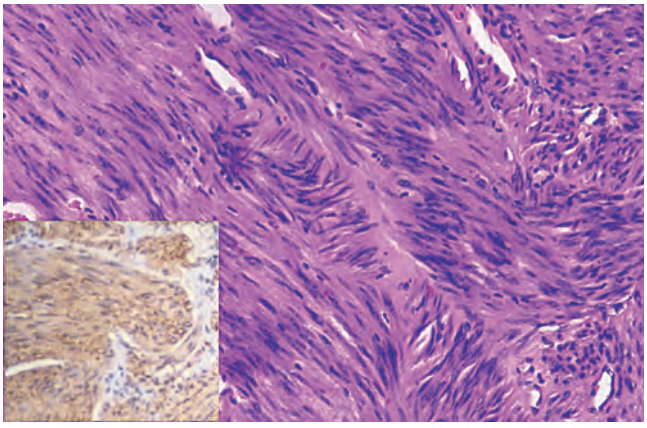
dentlearn.ir

• **Fig. 12.115 Leiomyoma.** Small, pink-red nodule on the posterior hard palate lateral to the midline.



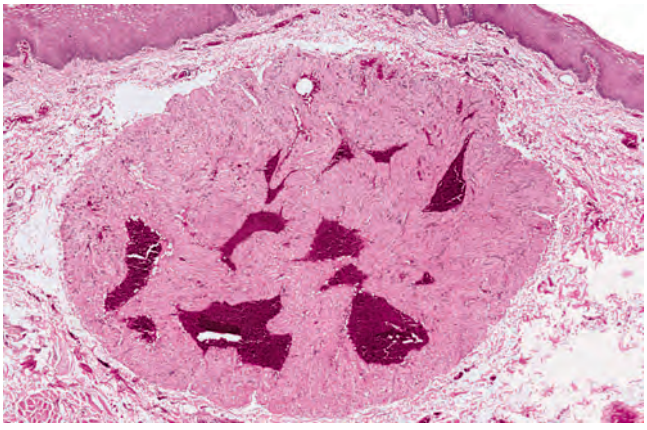
• **Fig. 12.116 Oral Leiomyomatous Hamartoma.** Small, papular growth on midline anterior maxillary alveolar ridge in a 7-year-old male. (Courtesy of Dr. Lon Doles.)

during early childhood or adolescence. The lesion appears as a smooth, sessile or pedunculated nodule that usually is less than 1 cm in diameter.



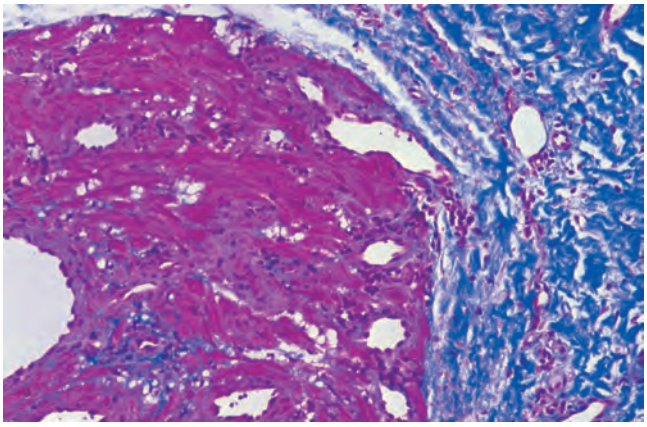
Histopathologic Features

Solid leiomyomas are well-circumscribed tumors that consist of interlacing bundles of spindle-shaped smooth muscle cells (Figs. 12.117 and 12.118). The nuclei are elongated, pale staining, and blunt ended. Mitotic figures are uncommon. Rare examples with extensive ossification have been reported.



Angiomyomas also are well-circumscribed lesions that demonstrate multiple tortuous blood vessels with thickened walls caused by hyperplasia of their smooth muscle coats (Fig. 12.119). Intertwining bundles of smooth muscle may be found between the vessels, sometimes with intermixed adipose tissue. As its name implies, the epithelioid leiomyoma is composed primarily of epithelioid cells rather than spindle cells. Leiomyomatous hamartomas consist of interlacing fascicles of eosinophilic spindle cells that may blend into the surrounding collagen.

• **Fig. 12.117 Leiomyoma.** Low-power view showing a well-circumscribed cellular mass of spindle-shaped smooth muscle cells.



• **Fig. 12.118 Leiomyoma.** High-power view showing spindle-shaped cells with blunt-ended nuclei. Immunohistochemical analysis shows strong positivity for smooth muscle actin (*inset*).

• **Fig. 12.119 Angiomyoma.** Well-circumscribed tumor exhibiting prominent blood vessels surrounded by smooth muscle.

Special stains and immunohistochemistry may be helpful to confirm the smooth muscle differentiation if the diagnosis is in doubt. The smooth muscle stains bright red with the Masson trichrome stain (Fig. 12.120). Immunohistochemical analysis usually reveals the tumor cells to be positive for

dentlearn.ir

• **Fig. 12.120 Angiomyoma.** Masson trichrome stain demonstrating bundles of smooth muscle (*red*) with adjacent normal collagen (*blue*).

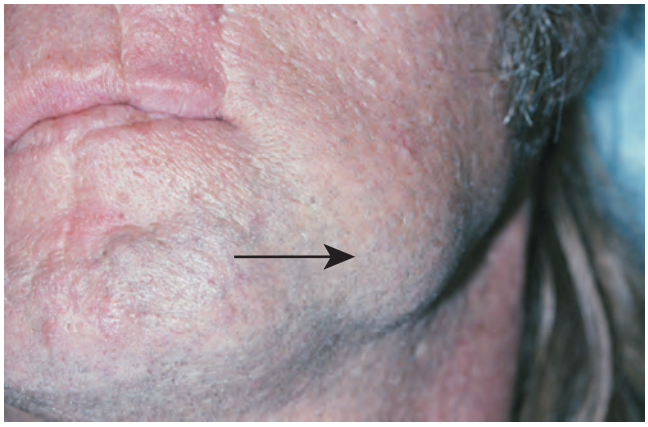
vimentin, smooth muscle actin, and muscle-specific actin; desmin positivity also may be seen.

Treatment and Prognosis

Oral leiomyomas are treated by local surgical excision. The lesion should not recur.

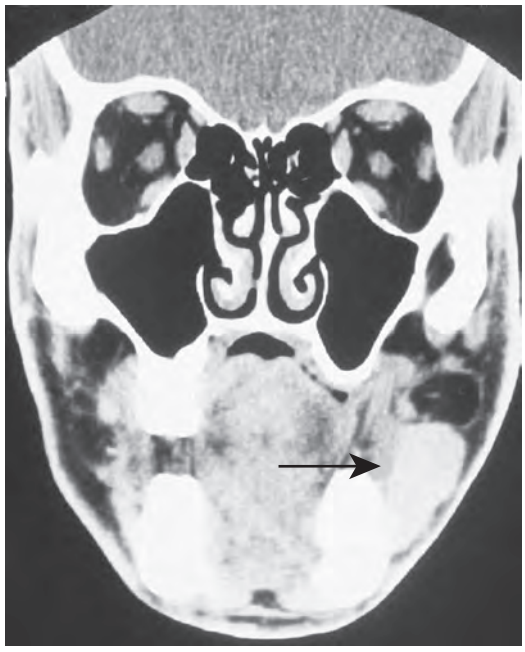
◆ RHABDOMYOMA

Benign neoplasms of skeletal muscle are called **rhabdomyomas.** The term *rhabdomyoma* also is used to describe a hamartomatous lesion of the heart that often is associated with tuberous sclerosis (see page 762). Despite the great amount of skeletal muscle throughout the body, benign skeletal muscle tumors are extremely rare. However, these extracardiac rhabdomyomas show a striking predilection for the head and neck. Rhabdomyomas of the head and neck can be subclassified into two major categories: (1) adult rhabdomyomas and (2) fetal rhabdomyomas.



Clinical Features

Adult Rhabdomyomas

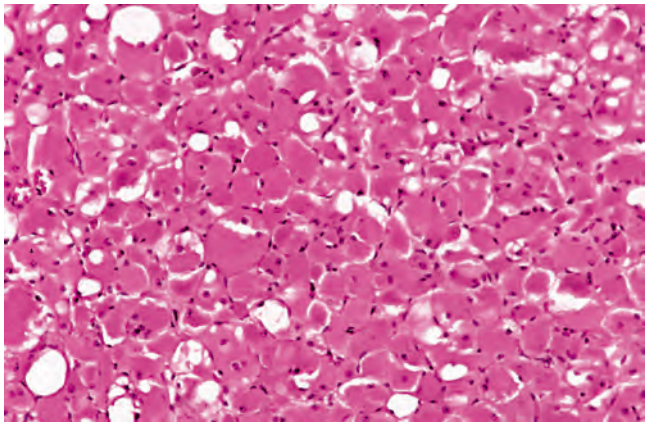


Adult rhabdomyomas of the head and neck occur primarily in middle-aged and older patients, with about 80% of cases found in men. The most frequent sites are the pharynx, oral cavity, and larynx; intraoral lesions are most common in the floor of the mouth, soft palate, and base of tongue. The tumor appears as a nodule or mass that can grow many centimeters before discovery (Figs. 12.121 and 12.122). Laryngeal and pharyngeal lesions often lead to airway obstruction. Sometimes, the tumor is multinodular in nature, with two or more discrete nodules found in the same anatomic location. From 3% to 15% of adult rhabdomyomas are multicentric, with separate, distinct tumors at different sites.

Fetal Rhabdomyomas

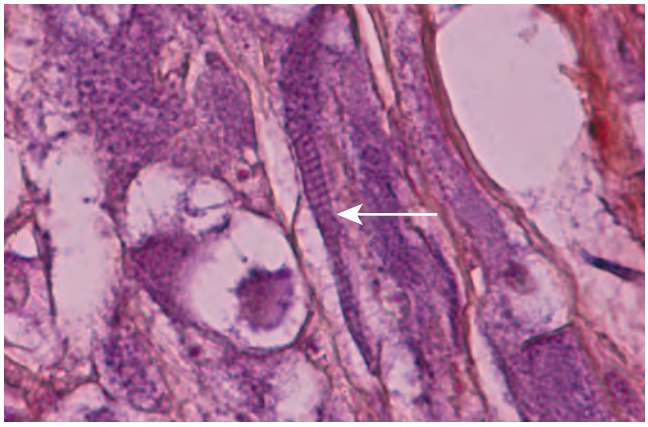
Fetal rhabdomyomas usually occur in young children, although some also develop in adults. A similar male predilection is noted. The most common locations are the face and periauricular region.

• **Fig. 12.121 Adult Rhabdomyoma.** Nodular mass (*arrow*) in the left cheek. (Courtesy of Dr. Craig Little.)



• **Fig. 12.122 Adult Rhabdomyoma.** Computed tomography (CT) scan of the same tumor depicted in Fig. 12.121. Note the mass *(arrow)* lateral to the left body of the mandible. (Courtesy of Dr. Craig Little.)

Histopathologic Features



Adult Rhabdomyomas

The adult rhabdomyoma is composed of well-circumscribed lobules of large, polygonal cells, which exhibit abundant granular, eosinophilic cytoplasm (Fig. 12.123). These cells often demonstrate peripheral vacuolization that results in a "spider web" appearance of the cytoplasm. Focal cells with cross striations can be identified in most cases (Fig. 12.124). Although rarely necessary for the diagnosis, immunohistochemical examination will show the tumor cells to be positive for myoglobin, desmin, and muscle-specific actin.

dentlearn.ir

• **Fig. 12.123 Adult Rhabdomyoma.** Medium-power view showing a uniform tumor composed of rounded and polygonal cells with focal vacuolization.

• **Fig. 12.124 Adult Rhabdomyoma.** Phosphotungstic acid hematoxylin (PTAH) stain that demonstrates focal cross striations in some cells (*arrow*).

Fetal Rhabdomyomas

The fetal rhabdomyoma has a less mature appearance and consists of a haphazard arrangement of spindle-shaped muscle cells that sometimes are found within a myxoid stroma. Some tumors may show considerable cellularity and mild pleomorphism, which makes them easily mistaken for rhabdomyosarcomas.

Treatment and Prognosis

The treatment of both variants of rhabdomyoma consists of local surgical excision. Recurrence has been reported in 10%–42% of cases, but this largely may be due to incomplete removal.

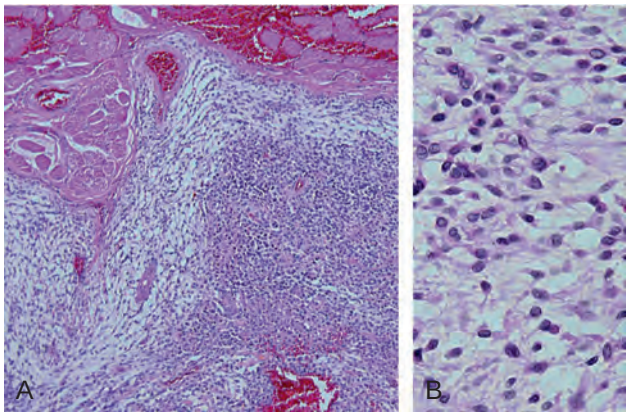
◆ ECTOMESENCHYMAL CHONDROMYXOID TUMOR

The **ectomesenchymal chondromyxoid tumor** is a rare benign intraoral neoplasm that was first identified in 1995. The histogenesis of this tumor is uncertain, although it has been suggested that it may arise from an uncommitted ectomesenchymal cell of neural crest origin or from a soft tissue myoepithelial cell. The vast majority of these lesions have been related to *RREB1::MKL2* fusion genes; a much smaller subset have shown *EWSR1* gene rearrangements.

• **Fig. 12.125 Ectomesenchymal Chondromyxoid Tumor.** Nodular mass on the right dorsal tongue. (From Kannan R, Damm DD, White DK, et al: Ectomesenchymal chondromyxoid tumor of the anterior tongue: a report of three cases, *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 82:417–422, 1996.)

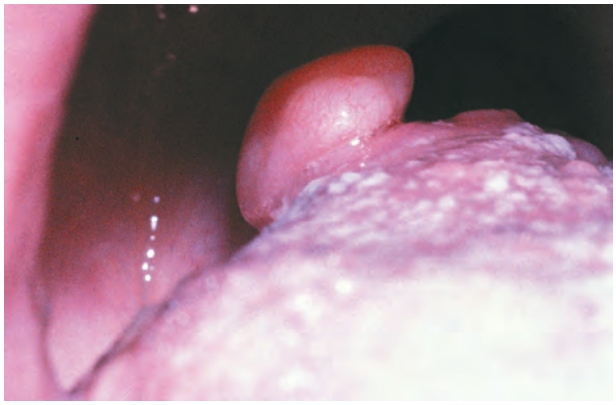
Clinical Features

Over 90% of ectomesenchymal chondromyxoid tumors occur on the anterior dorsal tongue, although rare examples also have been reported at the base of tongue, other oral soft tissue sites, and the mandible. The tumor shows a wide age range, most commonly being diagnosed in the third through the sixth decades of life. No sex predilection has been identified. The lesion usually presents at a painless nodular mass that may measure from less than 1 cm to several cm in diameter (Fig. 12.125).



Histopathologic Features

The ectomesenchymal chondromyxoid tumor can show a highly variable microscopic appearance. At low power, the tumor typically demonstrates a circumscribed, lobular growth pattern, although some cases may demonstrate focal infiltration into adjacent skeletal muscle. The cells can be polygonal to spindled or stellate in shape, with ovoid nuclei and pale eosinophilic to lightly basophilic cytoplasm. Varying degrees of cellularity are noted, including dense sheets of cells intermixed with zones of loosely arranged cells showing a myxoid appearance (Fig. 12.126). Focal hyalinized or chondroid stromal changes may be found. Immunohistochemistry usually shows the tumor cells to be positive for glial fibrillary acid protein (GFAP) and S100 protein.



Treatment and Prognosis

Treatment should consist of conservative surgical excision. Recurrence rarely has been reported.

dentlearn.ir

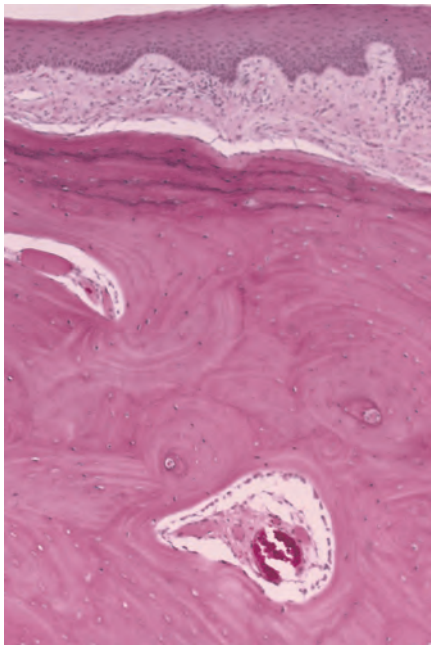
• **Fig. 12.127 Osseous Choristoma.** Hard pedunculated nodule on the posterior dorsum of the tongue. (Courtesy of Dr. Michael Meyrowitz.)

◆ OSSEOUS AND CARTILAGINOUS CHORISTOMAS

A **choristoma** is a tumor-like growth of microscopically normal tissue in an abnormal location. Several different tissue types may occur in the mouth as choristomas. These include gastric mucosa, glial tissue, and tumor-like masses of sebaceous glands. However, the most frequently observed choristomas of the oral cavity are those that consist of bone, cartilage, or both. These lesions sometimes have been called **soft tissue osteomas** or **soft tissue chondromas,** but *choristoma* is a better term because they do not appear to be true neoplasms.

Clinical Features



Osseous and cartilaginous choristomas show a striking predilection for the tongue, which accounts for 85% of cases. The most common location is the posterior tongue near the foramen cecum, although rare examples also have been reported elsewhere on the tongue and at other oral locations. The lesion is usually a firm, smooth-surfaced, sessile or pedunculated nodule between 0.5 and 2.0 cm in diameter (Fig. 12.127). Many patients are unaware of the lesion, although some complain of gagging or dysphagia.

Histopathologic Features

Microscopic examination of choristomas shows a well-circumscribed mass of dense lamellar bone or mature cartilage that is surrounded by dense fibrous connective tissue (Fig. 12.128). Sometimes a combination of bone and cartilage is formed. The bone has a well-developed Haversian canal system and occasionally demonstrates central fatty or hematopoietic marrow.

Treatment and Prognosis

Osseous and cartilaginous choristomas are best treated by local surgical excision. Recurrence has not been reported.

• **Fig. 12.128 Osseous Choristoma.** Mass of dense lamellar bone beneath the surface epithelium.

Soft Tissue Sarcomas

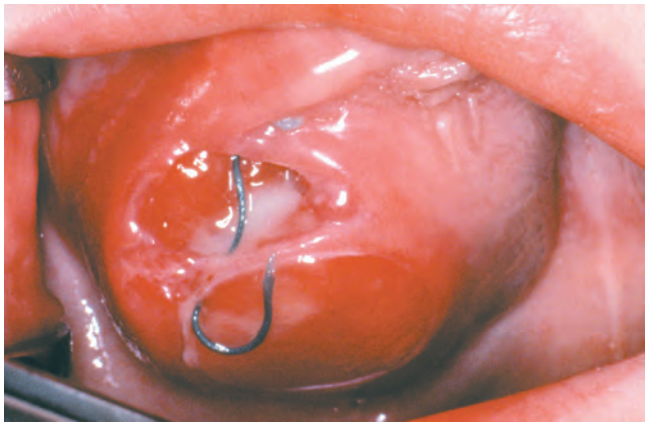
Fortunately, soft tissue sarcomas are rare in the oral and maxillofacial region and account for less than 1% of the cancers in this area. Because of their relative rarity, it is beyond the scope of this book to give a complete, detailed discussion of each of these tumors. However, a review of these entities is included in the following section.

◆ FIBROSARCOMA

The **fibrosarcoma** is a malignant tumor of fibroblasts. At one time, it was considered one of the most common soft tissue sarcomas. However, the diagnosis of fibrosarcoma rarely is made today because many spindle cell tumors with similar

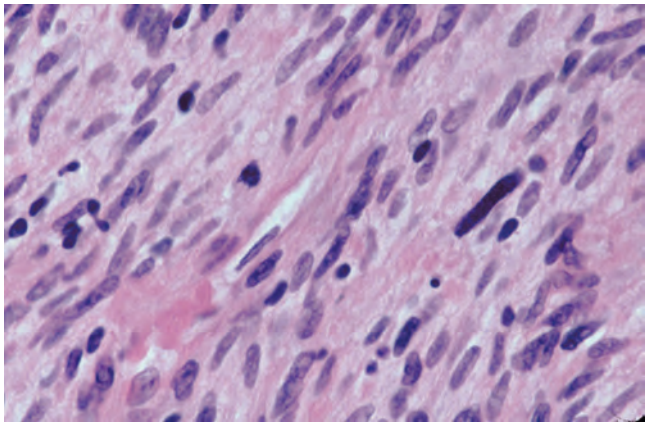
dentlearn.ir

microscopic features have now been reclassified into separate, distinct categories. Fibrosarcomas are most common in the extremities; only 10%–19% occur in the head and neck region.



Clinical Features

Fibrosarcomas most often present as slow-growing masses that may reach considerable size before they produce pain (Fig. 12.129). They can develop at any age and occur anywhere in the head and neck region. A number of cases have been reported in the nose and paranasal sinuses, where they often result in obstructive symptoms. Development of fibrosarcoma following radiation therapy to the head and neck also has been described.



Histopathologic Features

Adult-type fibrosarcoma is often a diagnosis of exclusion, being used for spindle cell sarcomas that do not fit microscopically into other recognized categories. Well-differentiated examples consist of fascicles of spindle-shaped cells that classically form a "herringbone" pattern (Fig. 12.130). The cells often show little variation in size and shape, although variable numbers of mitotic figures usually can be identified. In more poorly differentiated tumors, the cells are less organized and may appear rounder or ovoid. Mild pleomorphism along with more frequent mitotic activity may be seen. Higher grade tumors tend to produce less collagen than do well-differentiated tumors. Immunohistochemical markers should be negative except for vimentin and minimal smooth muscle actin.

In addition to classic adult-type tumors, the classification of "fibrosarcoma" includes a number of variants, including *myxofibrosarcoma*, *low-grade fibromyxoid sarcoma*, *sclerosing epithelioid fibrosarcoma*, and *juvenile/infantile fibrosarcoma*.

• **Fig. 12.129 Fibrosarcoma.** Child with a large mass of the hard palate and maxillary alveolar ridge. (Courtesy of Dr. John McDonald.)

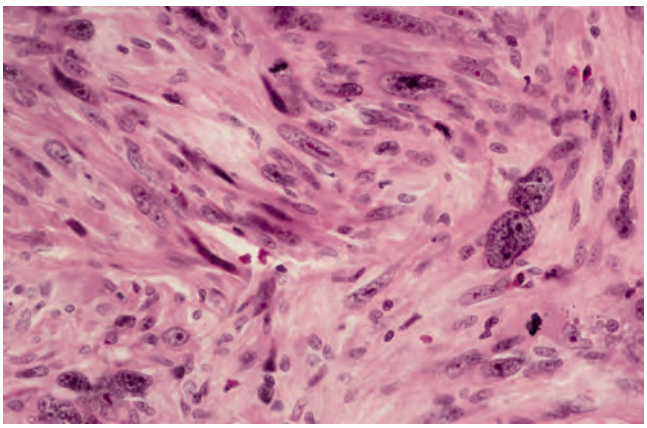
• **Fig. 12.130 Fibrosarcoma.** Cellular mass of spindle-shaped cells demonstrating mild pleomorphism.

Treatment and Prognosis

The treatment of choice is usually surgical excision, including a wide margin of adjacent normal tissue. Recurrence is noted in about half of cases, and 5-year survival rates range from 40% to 70%.

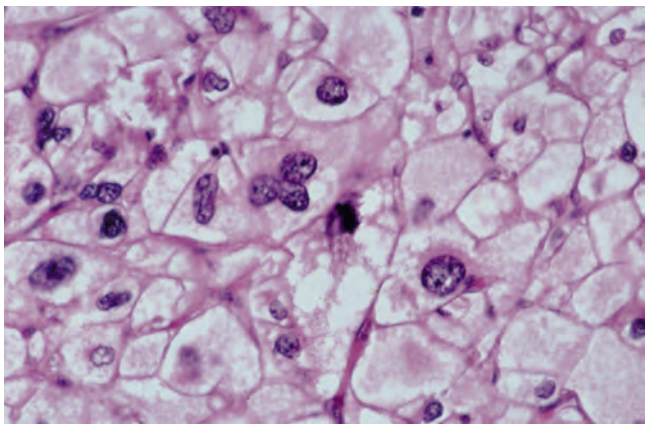
◆ UNDIFFERENTIATED PLEOMORPHIC SARCOMA (MALIGNANT FIBROUS HISTIOCYTOMA)

The term **malignant fibrous histiocytoma** was introduced in the 1960s to describe a group of sarcomas that were considered to show both fibroblastic and histiocytic features. This concept rapidly gained acceptance and malignant fibrous histiocytoma soon became the most commonly diagnosed soft tissue sarcoma in adults. However, experts today have questioned this concept because, with the help of immunohistochemistry and molecular studies, most tumors formerly diagnosed as malignant fibrous histiocytoma can now be reclassified into other categories, such as liposarcoma, leiomyosarcoma, rhabdomyosarcoma, myxofibrosarcoma, melanoma, and anaplastic carcinoma. However, there still remains a heterogeneous group of tumors from this former family, whose line of differentiation cannot be determined. The term **undifferentiated pleomorphic sarcoma** is now recommended for these lesions.



Clinical Features

Undifferentiated pleomorphic sarcomas occur primarily in older age groups. The most common complaint is an expanding mass that may or may not be painful or ulcerated. The extremities and deep tissues of the trunk are the most frequent locations. Tumors of the nasal cavity and paranasal sinuses produce obstructive symptoms.



Histopathologic Features

Several histopathologic patterns have been described. The most classic variety is the storiform-pleomorphic type, which is characterized by short fascicles of plump spindle cells arranged in a storiform pattern, admixed with areas of pleomorphic giant cells (Fig. 12.131).

dentlearn.ir

• **Fig. 12.131 Undifferentiated Pleomorphic Sarcoma.** Spindle cell neoplasm demonstrating marked pleomorphism and scattered mitoses.

• **Fig. 12.132 Liposarcoma.** High-power view showing vacuolated lipoblasts with pleomorphic nuclei.

Treatment and Prognosis

Undifferentiated pleomorphic sarcoma is considered to be an aggressive tumor that is usually treated by radical surgical resection. Approximately 40% of patients with head and neck tumors will have local recurrence, and almost 30% will develop metastases. The overall 5-year survival rate is 52%–55%.

◆ LIPOSARCOMA

The **liposarcoma** is a malignant neoplasm of fatty origin. It currently is considered to be the most common soft tissue sarcoma and accounts for 15%–25% of all soft tissue malignancies in adults. The most common sites are the thigh, retroperitoneum, and inguinal region. Liposarcomas of the head and neck are rare, comprising only 3% of all such tumors.

Clinical Features

Liposarcomas are seen primarily in adults; the mean age for head and neck tumors is 57 years. The tumor is typically a soft, slow-growing, ill-defined mass that may appear normal in color or yellow. Pain or tenderness is uncommon; when present, it is usually a late feature. The neck is the most common site for liposarcomas of the head and neck region. The most frequent intraoral locations are the tongue and cheek.

Histopathologic Features

Most liposarcomas can be divided into several major categories:

1. Well-differentiated liposarcoma/atypical lipomatous tumor
2. Myxoid/round cell liposarcoma
3. Pleomorphic liposarcoma
4. Dedifferentiated liposarcoma

The most common of these variants in the oral cavity is the **well-differentiated liposarcoma,** which accounts for 67% of all cases. These tumors resemble benign lipomas but demonstrate scattered lipoblasts and atypical, hyperchromatic stromal cells (Fig. 12.132). Because well-differentiated liposarcoma in superficial soft tissue exhibits such low-grade behavior, these lesions often are referred to as *atypical lipomatous tumors*. Positive immunostaining for CDK4 and MDM2 can help to distinguish well-differentiated liposarcoma/atypical lipomatous tumor from benign lipomatous lesions. In more difficult cases, demonstration of *MDM2* gene amplification by fluorescence *in situ* hybridization (FISH) can help to confirm the diagnosis.

Myxoid liposarcomas demonstrate proliferating lipoblasts within a myxoid stroma that contains a rich capillary network. The **round cell liposarcoma** is a more aggressive form of myxoid liposarcoma with less differentiated, rounded cells.

Pleomorphic liposarcomas exhibit extreme cellular pleomorphism and bizarre giant cells. **Dedifferentiated liposarcomas** are characterized by the combination of well-differentiated liposarcoma with poorly differentiated, nonlipogenic sarcomatous changes. These features may coexist in the same neoplasm, or the dedifferentiated changes may develop in a recurrent tumor or metastasis.

Treatment and Prognosis

Radical excision is the treatment of choice for most liposarcomas throughout the body. In spite of this, at least 50% of all tumors recur. The overall 5-year survival rate ranges from 59% to 70%. There is a 10-year survival rate of approximately 50%. The histopathologic subtype is extremely important in predicting the prognosis; the outlook for pleomorphic liposarcomas is much worse than for myxoid and well-differentiated tumors.

In contrast, the prognosis for oral liposarcoma is more favorable because of the predominance of well-differentiated subtypes and because most tumors are small when diagnosed. Local recurrence has been reported in 15%–20% of cases, but metastasis and death as a result of tumor is rare.

dentlearn.ir

◆ MALIGNANT PERIPHERAL NERVE SHEATH TUMOR (MALIGNANT SCHWANNOMA; NEUROFIBROSARCOMA; NEUROGENIC SARCOMA)

The principal malignancy of peripheral nerve origin is preferably called a **malignant peripheral nerve sheath tumor.** These tumors account for approximately 5%–10% of all soft tissue sarcomas, with one-fourth to one-half of such cases occurring in patients with neurofibromatosis type I (see page 537). The lesion is most common on the proximal portions of the extremities and the trunk; about 15% of cases occur in the head and neck region.

Clinical and Radiographic Features

Malignant peripheral nerve sheath tumors are most common in young adults. The mean age in patients with neurofibromatosis (29–36 years) is about one decade younger than in those without this condition (40–46 years). The tumor is an enlarging mass that sometimes exhibits rapid growth. Associated pain or a nerve deficit is common.

Oral tumors may occur anywhere, but the most common sites are the jaws, lips, and buccal mucosa (see Figs. 12.70 and 12.71, page 539). Radiographic examination of intraosseous tumors of the mandible may reveal widening of the mandibular canal or the mental foramen, with or without irregular destruction of the surrounding bone.

Histopathologic Features

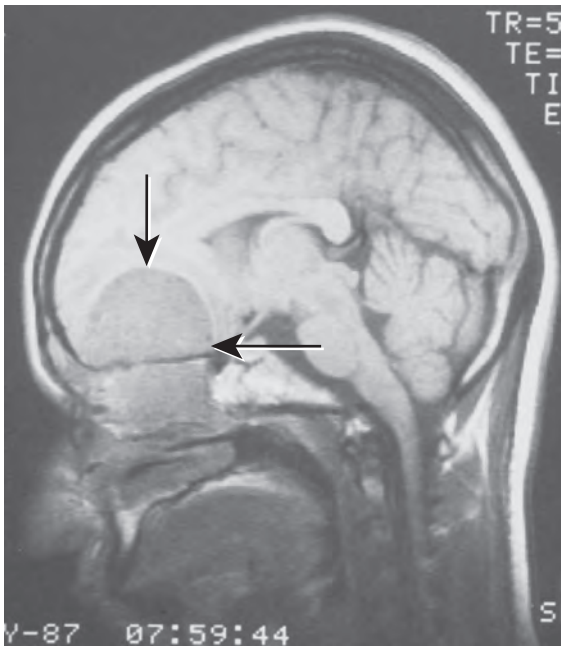
The malignant peripheral nerve sheath tumor shows fascicles of atypical spindle-shaped cells, which often resemble the cells of adult-type fibrosarcoma (see Fig. 12.72, page 540). However, these cells frequently are more irregular in shape with wavy or comma-shaped nuclei. In addition to streaming fascicles, less cellular myxoid areas also may be present. With some tumors, there can be heterologous elements, which include skeletal muscle differentiation **(malignant Triton tumor)**, cartilage, bone, or glandular structures.

A definitive diagnosis of neural origin often is difficult, especially in the absence of neurofibromatosis. Positive immunostaining for S-100 protein or SOX10 can be a helpful clue, but these are found in only about 50%–60% of all cases and may be focal. Also, these markers are not specific for neural origin, and sometimes they can be demonstrated in other spindle cell malignancies.

Treatment and Prognosis

The treatment of malignant peripheral nerve sheath tumors consists primarily of radical surgical excision, possibly along with adjuvant radiation therapy and chemotherapy. The prognosis is generally poor, with disease-specific survival ranging from 39% to 60% at 5 years, and 26% to 45% at 10 years. Some studies have suggested that patients with neurofibromatosis type I have a worse prognosis than sporadic cases, although other studies have shown no significant difference between these two groups. Tumors that are negative for S-100 protein have been reported to have a significantly worse prognosis.

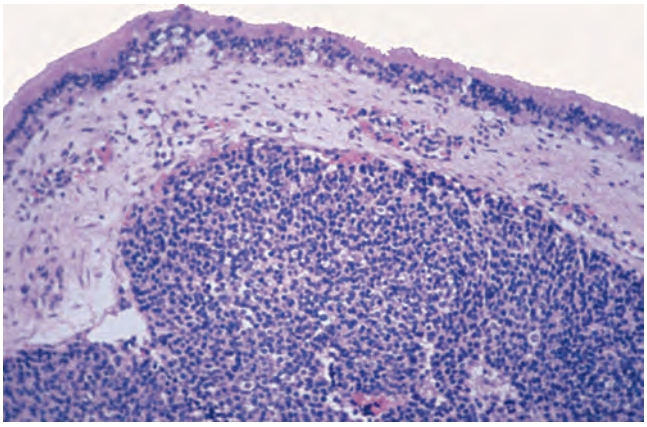
◆ OLFACTORY NEUROBLASTOMA (ESTHESIONEUROBLASTOMA)



The **olfactory neuroblastoma** is a rare neuroectodermal neoplasm of the upper nasal vault that shows some similarities to neuroblastomas seen elsewhere in the body. It is believed to arise from sensory olfactory neuroepithelial cells.

Clinical and Radiographic Features

Unlike the usual neuroblastoma, the olfactory neuroblastoma is rare in patients younger than the age of 10 years. Instead, it is more common in adults, with a mean age at diagnosis of 45–56 years. The tumor arises high in the nasal cavity close to the cribriform plate. From there it may extend into the adjacent paranasal sinuses (especially the ethmoid sinus), the orbit, and the anterior cranial fossa (Fig. 12.133). The most common symptoms are nasal obstruction, epistaxis, pain, and anosmia.



Histopathologic Features

Olfactory neuroblastomas consist of small, round to ovoid basophilic cells that are arranged in sheets and lobules (Fig. 12.134). Rosette and pseudorosette formation and

• **Fig. 12.133 Olfactory Neuroblastoma.** A T1-weighted sagittal magnetic resonance image (MRI) showing a tumor filling the superior nasal cavity and ethmoid sinus, with extension into the anterior cranial fossa (*arrows*). (Courtesy of Dr. Pamela Van Tassel.)

dentlearn.ir

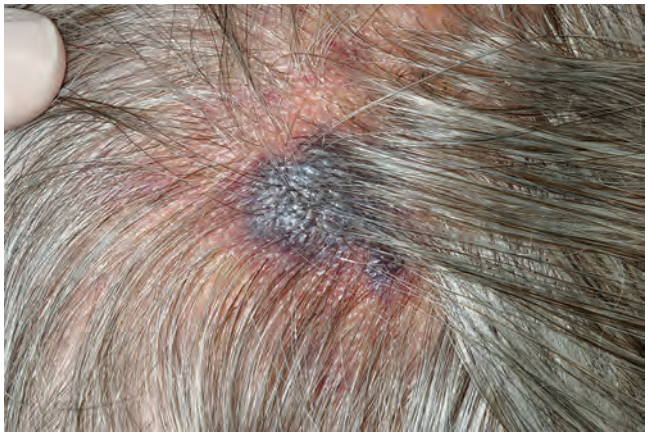
• **Fig. 12.134 Olfactory Neuroblastoma.** Sheet of small, basophilic cells adjacent to the sinonasal epithelium (*top*).

areas of delicate neurofibrillary material may be seen. The tumor cells typically will express neuroendocrine markers, such as chromogranin, synaptophysin, and CD56.

Treatment and Prognosis

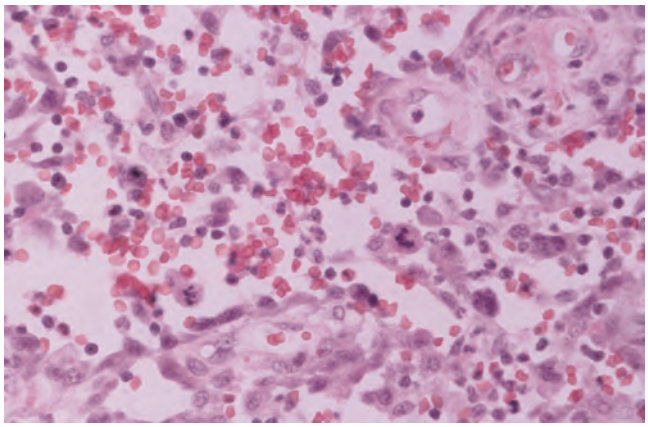
The treatment of olfactory neuroblastoma consists of surgical excision, often with adjuvant radiation therapy. A combined craniofacial surgical approach frequently is used. Adjuvant chemotherapy also has been shown to improve survival.

The prognosis depends on the histopathologic grade and clinical stage of the tumor. The overall 5-year survival is approximately 75%, and disease-free survival is 60%. At 10 years, these survival rates decrease to 60% and 40% respectively. Death is usually a result of local recurrence; metastasis occurs in approximately 20% of cases and is associated with an extremely poor prognosis.



◆ ANGIOSARCOMA

Angiosarcoma is a rare malignancy of vascular endothelium, which may arise from either blood or lymphatic vessels. Although it accounts for only 1% of all sarcomas, about half of all cases occur in the head and neck region, with the scalp and forehead being the most common sites. However, intraoral examples are exceedingly rare.



The term **hemangioendothelioma** is used to describe vascular tumors with microscopic features intermediate between those of hemangiomas and angiosarcomas. Such tumors also are rare and are considered to be of intermediate malignancy.

Clinical Features

Cutaneous angiosarcomas of the head and neck are most common in older adult patients. Early lesions often resemble a simple bruise, which may lead to a delay in diagnosis. However, the lesion continues to enlarge, which results in an elevated, nodular, or ulcerated surface (Fig. 12.135). Many examples appear multifocal in nature. Oral angiosarcomas have been reported in various locations; the gingiva and tongue are the most common sites.

• **Fig. 12.135 Angiosarcoma.** Slightly elevated, bluish purple lesion on the scalp. (Courtesy of Dr. Terry Day.)

• **Fig. 12.136 Angiosarcoma.** Sinusoidal vascular spaces lined by pleomorphic endothelial cells.

Histopathologic Features

Angiosarcoma is characterized by an infiltrative proliferation of endothelium-lined blood vessels that form an anastomosing network (Fig. 12.136). The endothelial cells appear hyperchromatic and atypical; they often tend to pile up within the vascular lumina. Increased mitotic activity may be seen. Immunohistochemical studies show the tumor cells to be positive for CD31 and ERG in most cases, whereas CD34 positivity is observed less consistently.

Treatment and Prognosis

Treatment usually consists of radical surgical excision, radiation therapy, or both. The prognosis for angiosarcoma of the head and neck is poor, with reported 5- and 10-year overall survival rates of only 26.5% and 16.9%, respectively. However, angiosarcomas of the oral cavity and salivary glands may have a somewhat better outcome. One recent

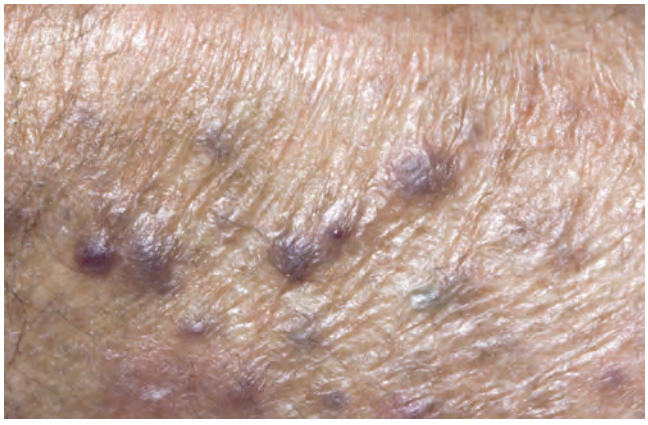
dentlearn.ir

review showed that 50% of patients with intraoral angiosarcoma died from their disease.

KAPOSI SARCOMA

Kaposi sarcoma is an unusual vascular neoplasm that was first described in 1872 by Moritz Kaposi, a Hungarian dermatologist. Before the advent of the acquired immunodeficiency syndrome (AIDS) epidemic, it was a rare tumor; however, beginning in the early 1980s, Kaposi sarcoma became quite common because of its propensity to develop in individuals infected by HIV. Since the introduction of combination antiretroviral therapy (ART) in the mid- to late 1990s, the prevalence of AIDS-related Kaposi sarcoma in the Western world has declined.

Kaposi sarcoma is caused by infection with human herpesvirus 8 (HHV-8; Kaposi sarcoma-associated herpesvirus [KSHV]). The lesion most likely arises from endothelial cells, which may express markers for both lymphatic and blood vessel differentiation. Four clinical presentations are recognized:



1. Classic
2. Endemic (African)
3. Iatrogenic (transplant-associated)
4. AIDS-related

The first three forms are discussed here; AIDS-related Kaposi sarcoma is covered in the section on HIV disease (see page 254).

Clinical Features

Classic Type

Classic Kaposi sarcoma is primarily a disease of late adult life, and 90% of cases occur in men. Because HHV-8 exposure occurs with much greater frequency in some areas of the world, the prevalence of Kaposi sarcoma also is much higher in these regions, such as the Mediterranean, eastern Europe, and central equatorial Africa. Multiple blue-purple macules and plaques are present on the skin of the lower extremities (Fig. 12.137). These lesions grow slowly over many years and develop into painless tumor nodules. Oral lesions are rare and most frequently involve the palate. Some studies have suggested that patients with classic Kaposi sarcoma have an increased prevalence of lymphoreticular malignancies, but other reports have questioned any significant association.

• **Fig. 12.137 Kaposi Sarcoma.** Classic Kaposi sarcoma in an older man presenting as multiple purple macules and plaques on the lower leg.

Endemic Type

Prior to the advent of HIV/AIDS, endemic Kaposi sarcoma was already recognized as a relatively common neoplasm of younger adults and children in sub-Saharan Africa. The course of the disease can vary widely; some patients develop indolent skin lesions similar to the pattern observed in classic Kaposi sarcoma, whereas others exhibit more aggressive tumors that involve deeper tissues, bone, and viscera. A particularly aggressive lymphadenopathic form also is recognized in young children, which is characterized by rapidly growing tumors of the lymph nodes, occasional visceral organ lesions, and sparse skin involvement. Although endemic Kaposi sarcoma used to be the most common form of the disease seen in Africa, AIDS-related Kaposi sarcoma is seen more frequently now.

Iatrogenic Type

Iatrogenic (transplant-associated) Kaposi sarcoma occurs in recipients of solid organ transplants. It affects 0.5% of renal transplant patients, usually several months to a few years after the transplant. It is probably related to the loss of cellular immunity from immunosuppressive therapy given to prevent organ rejection. Like classic Kaposi sarcoma, iatrogenic cases are more common in individuals of Mediterranean and eastern European ancestry; however, the disease may run a more aggressive course.

Histopathologic Features

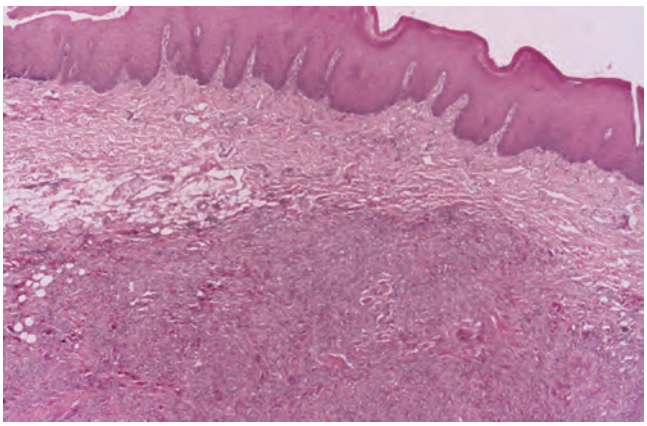
Kaposi sarcoma typically evolves through three stages:

1. Patch (macular)
2. Plaque
3. Nodular

A proliferation of miniature vessels characterizes the **patch stage.** This results in an irregular, jagged vascular network that surrounds preexisting vessels. Sometimes normal structures, such as hair follicles or preexisting blood vessels, may appear to protrude into these new vessels (promontory sign). The lesional endothelial cells have a bland appearance and may be associated with scattered lymphocytes and plasma cells.

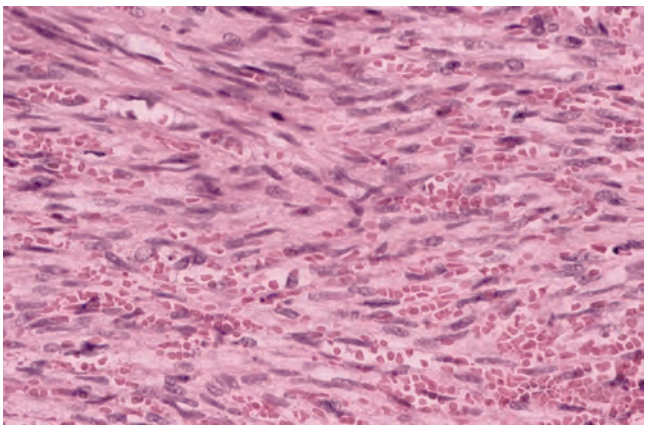
The **plaque stage** demonstrates further proliferation of these vascular channels along with the development of a significant spindle cell component. Tiny hyaline globules may be observed within or adjacent to the tumor cells.

In the **nodular stage,** the spindle cells increase to form a nodular tumor-like mass that may resemble a fibrosarcoma or other spindle cell sarcomas (Figs. 12.138 and 12.139). However, numerous extravasated erythrocytes are present, and slitlike vascular spaces may be discerned.



Other microscopic variants of Kaposi sarcoma include lymphangioma-like, telangiectatic, desmoplastic, lymphangiectatic, ecchymotic, and anaplastic subtypes.

dentlearn.ir



Treatment and Prognosis

The treatment of Kaposi sarcoma depends on the clinical subtype and stage of the disease. For skin lesions in the classic form of the disease, radiation therapy (such as electron beam) may be used. Radiation therapy for oral lesions must be approached with caution, because an unusually severe mucositis can develop. Surgical excision can be performed for the control of individual lesions of the skin or mucosa. Systemic chemotherapy also may be helpful. Intralesional injection of vinblastine is used to control individual lesions.

The prognosis is variable, depending on the form of the disease and the patient's immune status. The classic form of the disease is slowly progressive; only 10%–20% of patients develop disseminated lesions. The mean survival time is 10–15 years, and patients often die from unrelated causes. Some patients with the endemic form of the disease develop indolent lesions similar in behavior to classic non-African Kaposi sarcoma. However, the other endemic African forms are more aggressive and the prognosis is poorer. The lymphadenopathic form runs a particularly fulminant course, usually resulting in the death of the patient within 2–3 years. In transplant patients, the disease also may be somewhat more aggressive; however, the tumors may regress if the patient's immunosuppressive therapy can be switched from cyclosporine to rapamycin, which is thought to have antitumor activity.

• **Fig. 12.138 Kaposi Sarcoma.** Low-power photomicrograph showing a cellular spindle cell tumor within the connective tissue.

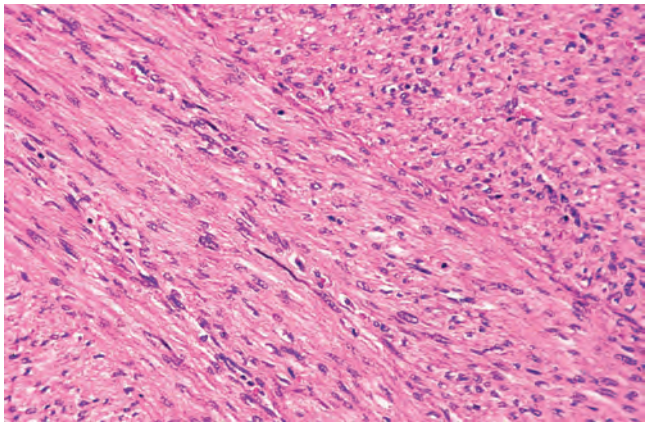
• **Fig. 12.139 Kaposi Sarcoma.** High-power photomicrograph showing spindle cells and poorly defined vascular slits.

◆ LEIOMYOSARCOMA

The **leiomyosarcoma** is a malignant neoplasm of smooth muscle differentiation, which accounts for 5%–10% of all soft tissue sarcomas. The most common sites are the uterine wall and gastrointestinal tract. Leiomyosarcomas of the oral cavity are rare.

Clinical Features

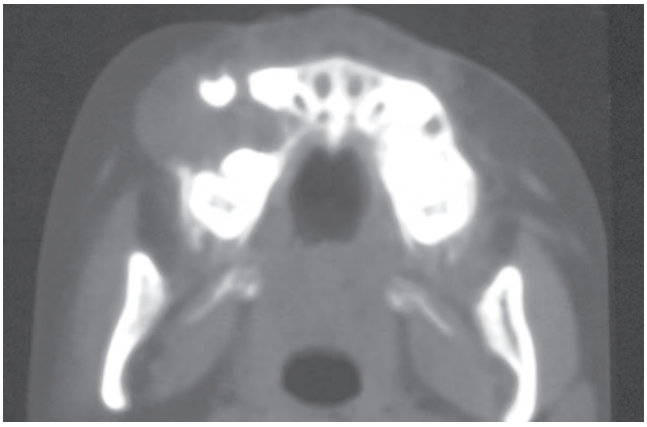
In general, leiomyosarcomas are most common in middle-aged and older adults. However, tumors in the oral and maxillofacial region occur over a wide age range without a predilection for any age group. They have been reported at various sites, but about one-third of all oral cases arise in the mandible. The clinical appearance is nonspecific; there is usually an enlarging mass that may or may not be painful (Fig. 12.140). Secondary ulceration of the mucosal surface may occur.



Histopathologic Features

The microscopic examination of a leiomyosarcoma shows fascicles of spindle-shaped cells with abundant eosinophilic cytoplasm and blunt-ended, cigar-shaped nuclei (Fig. 12.141). Some tumors may be composed primarily of rounded epithelioid cells that have either eosinophilic or clear cytoplasm (epithelioid leiomyosarcoma). The degree of pleomorphism varies from one tumor to the next, but smooth muscle tumors with the presence of five or more mitoses per ten high-power fields should be considered potentially malignant. Glycogen usually can be demonstrated within the cells with a periodic acid-Schiff (PAS) stain, and the cell cytoplasm appears bright red with a Masson trichrome stain. Immunohistochemical analysis usually reveals the presence of one or more of the following

• **Fig. 12.140 Leiomyosarcoma.** Ulcerated mass of the anterior maxillary alveolar ridge. (Courtesy of Dr. Jim Weir.)



dentlearn.ir

• **Fig. 12.141 Leiomyosarcoma.** Medium-high–power view of a pleomorphic spindle cell proliferation.

myogenic markers: smooth muscle actin, muscle-specific actin (HHF 35), desmin, smooth muscle myosin (SMMS), and h-caldesmon.

Treatment and Prognosis

The treatment of leiomyosarcoma primarily consists of radical surgical excision, sometimes with adjunctive chemotherapy or radiation therapy. The prognosis for head and neck tumors depends on the degree of differentiation, with the potential for local recurrence and distant metastasis. A review of the Surveillance, Epidemiology, and End Results (SEER) database showed a 5-year disease-specific survival rate of 87.6% for patients with well-differentiated tumors, compared to 52.7% for patients with poorly differentiated tumors.

◆ RHABDOMYOSARCOMA

Rhabdomyosarcoma is a malignant neoplasm that is characterized by skeletal muscle differentiation. These tumors are much more common in young children, accounting for 50% of soft tissue sarcomas in childhood. In contrast, rhabdomyosarcoma comprises only 2%–5% of soft tissue sarcomas in adults. The most frequent site is the head and neck, which accounts for 26% of all cases. The genitourinary tract is the second most common location.

Four major subtypes of rhabdomyosarcoma are recognized:

- Embryonal
- Alveolar
- Pleomorphic
- Spindle/sclerosing

The discussion here will be limited primarily to the embryonal and alveolar subtypes, which comprise the vast majority of cases.

Clinical Features

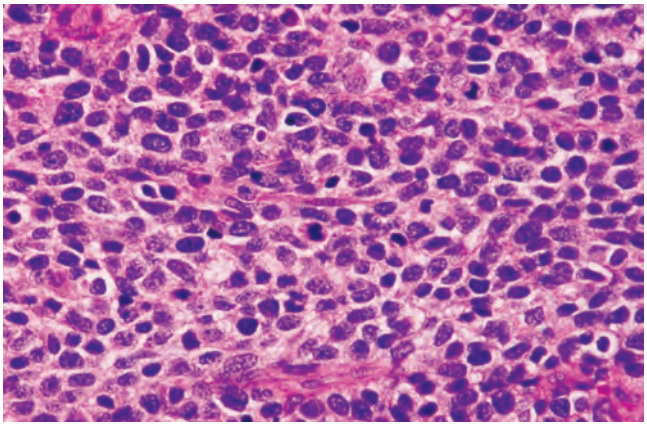
Rhabdomyosarcoma primarily occurs during the first decade of life but also may occur in teenagers and young adults. It is rare in people older than 45 years, and approximately 60% of all cases occur in males. Embryonal rhabdomyosarcomas are most common in the first 10 years of life and account for about 60% of all cases. Alveolar rhabdomyosarcomas occur most often in persons between 10 and 25 years of age; they account for approximately 30% of all tumors. Pleomorphic rhabdomyosarcomas represent less than 5% of all cases and show peak prevalence in patients older than 40 years of age. Spindle cell and sclerosing rhabdomyosarcomas formerly were classified as separate, distinct lesions. However, their overlapping microscopic and molecular features suggest that they are related entities. They represent 5%–10% of rhabdomyosarcomas.

Most head and neck lesions are embryonal or alveolar types; pleomorphic rhabdomyosarcomas primarily occur on the extremities. Spindle/sclerosing rhabdomyosarcomas in children are seen at a variety of sites, but adult cases show a predilection for the head and neck region.

The tumor is most often a painless, infiltrative mass that may grow rapidly (Figs. 12.142 and 12.143). In the head and neck region, the face and orbit are the most frequent locations, followed by the nasal cavity. The palate is the most

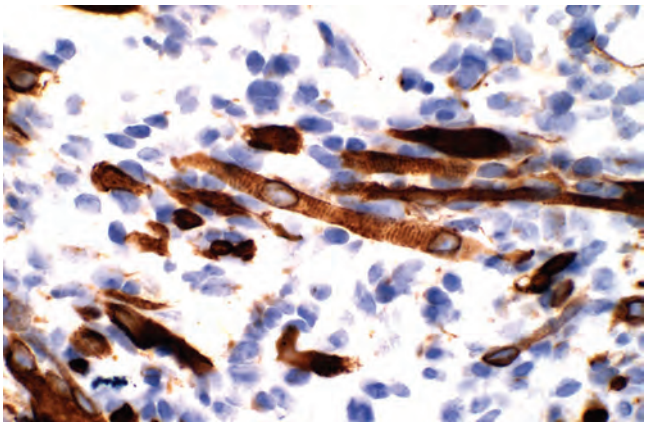
dentlearn.ir

frequent intraoral site, and some lesions may appear to arise in the maxillary sinus and break through into the oral cavity. Some embryonal rhabdomyosarcomas that arise within a cavity, such as the vagina or oropharynx, demonstrate an exophytic, polypoid growth pattern that resembles a cluster of grapes. The term *botryoid* (grapelike) *rhabdomyosarcoma* has been used for these lesions.



Histopathologic Features

Embryonal Type



The embryonal rhabdomyosarcoma resembles various stages in the embryogenesis of skeletal muscle. Poorly differentiated examples may be difficult to diagnose and consist of small round or oval cells with hyperchromatic nuclei and indistinct cytoplasm (Fig. 12.144). Alternating hypercellular and myxoid zones may be seen. Better-differentiated lesions show round to ovoid rhabdomyoblasts with distinctly eosinophilic cytoplasm and fibrillar material around the nucleus. Some tumors contain elongated, strap-shaped rhabdomyoblasts, but cross striations rarely are found (Fig. 12.145).

The **botryoid** subtype of embryonal rhabdomyosarcoma is sparsely cellular and has a pronounced myxoid stroma. Increased cellularity, or a so-called *cambium layer,* is usually seen just beneath the mucosal surface.

Immunohistochemical analysis for the presence of desmin, myogenin, MyoD1, and muscle-specific actin can be helpful in supporting the muscular nature of the tumor. However, the intensity of the immunostaining can vary depending on the degree of rhabdomyoblastic differentiation.

• **Fig. 12.144 Embryonal Rhabdomyosarcoma.** Medium-power view showing a sheet of small, round cells with hyperchromatic nuclei.

• **Fig. 12.145 Embryonal Rhabdomyosarcoma.** This tumor shows strap-shaped rhabdomyoblasts that are positive for desmin with immunohistochemical staining. Note the cross striations.

Alveolar Type

Both classic and solid variants of alveolar rhabdomyosarcoma are recognized. The classic pattern is characterized by aggregates of poorly differentiated round to oval cells separated by fibrous septa. These cells demonstrate a central loss of cohesiveness, which results in an alveolar pattern. The peripheral cells of these aggregates adhere to the septal walls in a single layer. The central cells appear to float freely within the alveolar spaces. Mitoses are common, and multinucleated giant cells also may be seen. In contrast, solid alveolar rhabdomyosarcoma demonstrates cellular fields of small round basophilic cells without fibrovascular septa.

Cytogenetic and molecular studies play an important role in the diagnosis of rhabdomyosarcoma. Two distinct chromosomal translocations have been identified in alveolar rhabdomyosarcoma: *PAX3::FOXO1* and *PAX7::FOXO1.* Embryonal rhabdomyosarcoma frequently shows loss of heterozygosity at loci of chromosome 11p15.5. Congenital/infantile forms of spindle cell/sclerosing rhabdomyosarcoma are characterized by gene fusions involving *VGLL2, SRF,* and *TEAD1,* whereas "sclerosing rhabdomyosarcoma" in adults often shows *MYOD1* mutations.

Treatment and Prognosis

Before 1960 the prognosis for a patient with rhabdomyosarcoma was extremely poor, with more than 90% of patients dying. With the advent of multimodal therapy, the prognosis has improved dramatically.

Treatment typically consists of local surgical excision combined with multiagent chemotherapy (vincristine, actinomycin D, and cyclophosphamide). Postoperative radiation therapy also is used, except for localized tumors that have been completely resected at initial surgery. The 5-year overall survival rate for embryonal rhabdomyosarcoma of the head and neck is 63%, although the figure for botryoid variants (95%) is much better. The 5-year overall survival rate for alveolar rhabdomyosarcoma of the head and neck is only 35%. Congenital/infantile forms of spindle/sclerosing rhabdomyosarcoma have 5-year overall survival rate of 75%; however, this survival figure falls to 30% for those with *MYOD1* mutations.

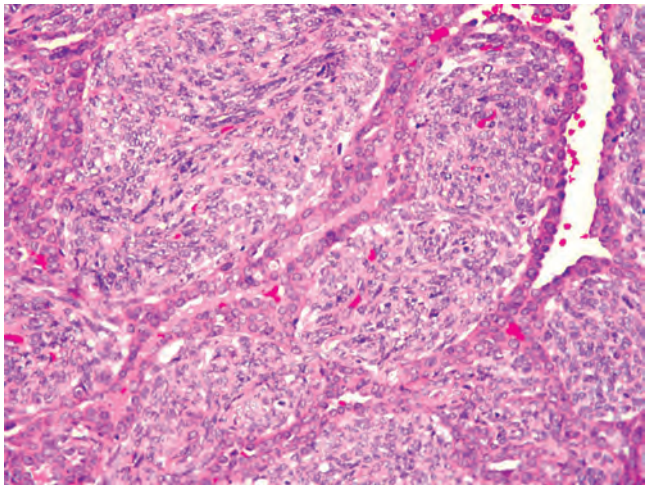
◆ SYNOVIAL SARCOMA

Synovial sarcoma is an uncommon malignancy that represents 5%–10% of all soft tissue sarcomas. The tumor occurs primarily near large joints and bursae, especially in the extremities, but authorities now agree that this lesion probably does not arise from the synovium. Although it is often

dentlearn.ir

para-articular in location, the tumor rarely occurs within the joint capsule. In some instances, it arises in areas without any obvious relationship to synovial structures. Synovial sarcomas of the head and neck are rare (only 1.9%–3.7% of all cases), and many of these are unrelated to joint areas.

Over 90% of synovial sarcomas exhibit a balanced reciprocal translocation involving fusion of the *SS18* gene on chromosome 18 with either the *SSX1* or *SSX2* gene (or, rarely, *SSX4*) on the X chromosome. Detection of this translocation can be helpful in making the diagnosis and confirming the presence of metastatic disease.



Clinical Features

Synovial sarcomas most frequently occur in teenagers and young adults (mean age = 33.5 years), and there is a slight male predilection. The most common presentation is a gradually enlarging mass that often is associated with pain or tenderness. Tumors in the head and neck region are most common in the paravertebral and parapharyngeal areas. Often, they produce symptoms of dysphagia, dyspnea, or hoarseness. Rare intraoral examples have been reported in the tongue, cheek, and other sites.

Histopathologic Features

Two major patterns of synovial sarcoma are recognized: biphasic and monophasic. Biphasic synovial sarcomas usually are associated with *SS18::SSX1* gene fusions and are characterized by a combination of spindle cells and epithelial cells. The spindle cells usually predominate and produce a pattern that is similar to fibrosarcoma. Within this spindle cell background are groups of cuboidal to columnar epithelial cells that surround glandlike spaces or form nests, cords, or whorls (Fig. 12.146). Calcifications are seen in around 30% of cases.

Monophasic synovial sarcomas typically show *SS18::SSX2* gene fusions and are more common than biphasic forms of the tumor. Microscopically, they consist primarily or entirely of spindle cells, which can make distinction from other spindle cell malignancies difficult. However, many examples will demonstrate focal cells with epithelioid features and/or positive immunostaining for cytokeratin and epithelial membrane antigen. Nuclear immunoreactivity for TLE1 is also a useful screening marker. However, molecular genetic testing for the *SS18::SSX2* fusion gene transcript often is necessary to confirm the diagnosis. Rare examples of monophasic epithelial-predominant synovial sarcomas also have been reported.

• **Fig. 12.146 Synovial Sarcoma.** Biphasic tumor consisting of spindle cells intermixed with cuboidal to columnar epithelial cells that line glandlike spaces.

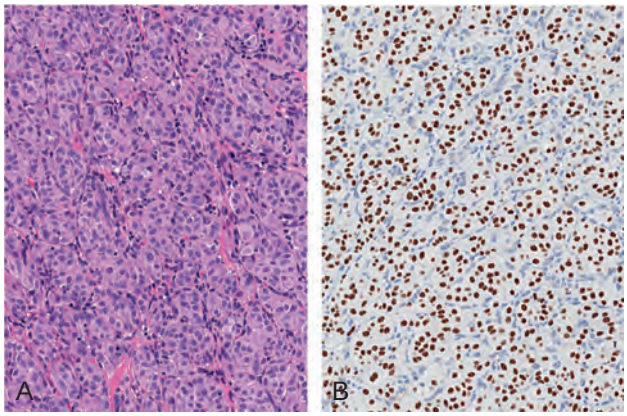
Treatment and Prognosis

Treatment of synovial sarcoma usually consists of radical surgical excision, often with adjunctive radiation therapy or chemotherapy. The prognosis is guarded because the tumor has a high rate of recurrence and metastasis. The reported 5-year overall survival rates range from 56% to 76%. One recent series of head and neck synovial sarcomas showed 5- and 10-year disease specific survival rates of 79% and 68%, respectively.

◆ ALVEOLAR SOFT-PART SARCOMA

The **alveolar soft-part sarcoma** is a rare neoplasm of uncertain histogenesis, which accounts for 0.5%–1% of all soft tissue sarcomas. Molecular analysis of this tumor shows a characteristic genetic translocation, der(17)t(X;17)(p11.2q25), which results in an *ASPSCR1::TFE3* fusion gene.

Clinical Features



The alveolar soft-part sarcoma is usually a slow-growing, painless mass that is most common in adolescents and young adults between 15 and 35 years of age. The lower extremity is the most frequent location, especially the anterior thigh. However, examples that develop in infants and young children are most common in the head and neck region; the orbit and tongue are the most common head and neck sites. During the first two decades of life, the tumor shows nearly a 2:1 female predilection. However, cases that develop after the age of 30 are more common in men.

Histopathologic Features

Alveolar soft-part sarcomas are composed of groups of large, polygonal cells that are arranged around central alveolar spaces (Fig. 12.147, *A*). These cells have abundant granular, eosinophilic cytoplasm and one to several vesicular nuclei. Mitoses are rare. Special stains will reveal PAS-positive, diastase-resistant crystals that are highly characteristic for this tumor. Under the electron microscope, these crystals appear as rhomboid, polygonal, or rod-shaped structures with a regular latticework pattern.

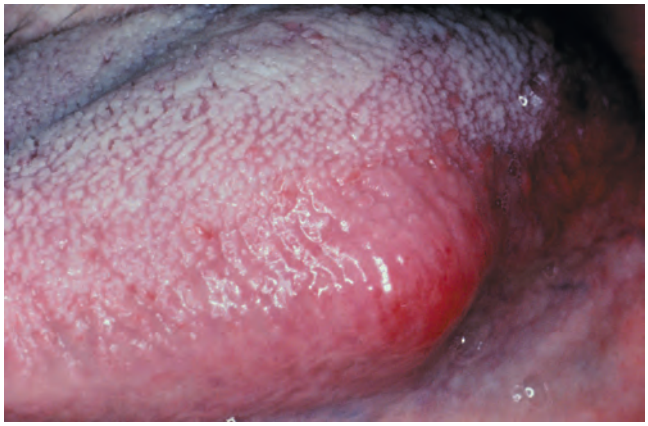
Immunohistochemical analysis will demonstrate strong positivity for TFE3 transcription factor in the tumor nuclei (see Fig. 12.147, *B*). The diagnosis can be confirmed by

dentlearn.ir

• **Fig. 12.147 Alveolar Soft-Part Sarcoma. A,** Alveolar collections of large, polygonal cells containing granular cytoplasm. **B,** Immunohistochemistry showing strong nuclear positivity for TFE3. (Courtesy of Dr. Mark Lingen.)

identification of the *ASPSCR1::TFE3* fusion gene with reverse-transcription polymerase chain reaction (RT-PCR) or fluorescence *in situ* hybridization (FISH).

Treatment and Prognosis

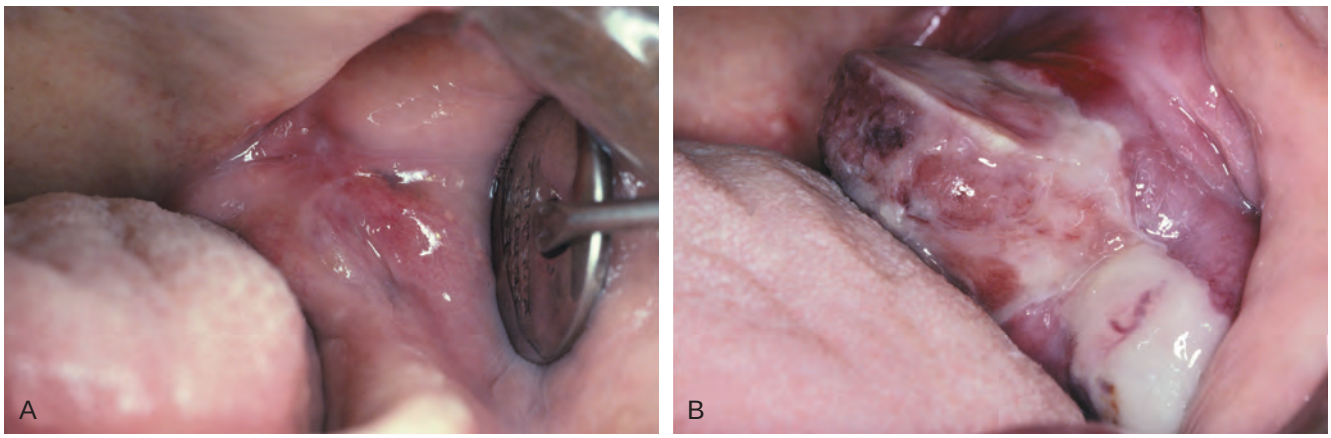


Most patients with alveolar soft-part sarcomas are treated by radical surgical excision, often in conjunction with radiation therapy and chemotherapy. The prognosis is generally poor, often as a result of late metastasis. One study reported a 5-year survival rate of 60%, but the 20-year survival rate dropped to only 15%. Another series showed a 5-year disease-free survival of 71% for patients with localized disease, compared with only 20% for patients who presented with metastatic disease. However, the prognosis for children appears to be better than for adults. Lingual and orbital tumors have much higher survival rates, possibly because of smaller tumor size at diagnosis and younger patient age.

◆ METASTASES TO THE ORAL SOFT TISSUES

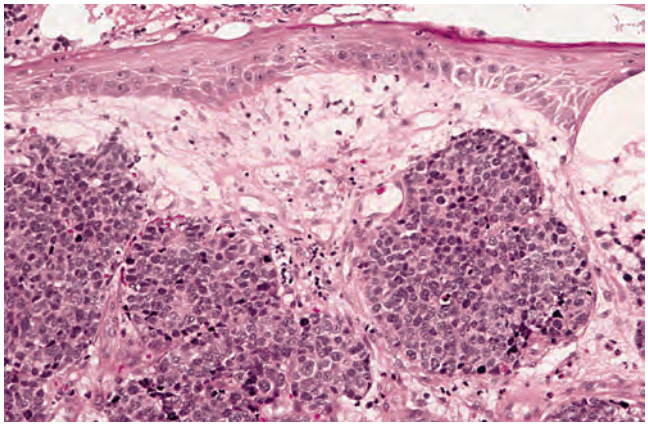
Metastatic tumors to the oral cavity are uncommon and represent approximately 1% of all oral malignancies. Such metastases can occur to bone (see page 673) or to the oral soft tissues. The mechanism by which tumors can spread to the oral cavity is poorly understood. Primary malignancies from immediately adjacent tissues might be able to spread by a lymphatic route; however, such a mechanism cannot explain metastases from tumors from lower parts of the body, which are almost certainly blood-borne and should be filtered out by the lungs. One possible explanation for blood-borne metastases to the head and neck, especially in the absence of pulmonary metastases, is **Batson plexus,** a valveless vertebral venous plexus that might allow retrograde spread of tumor cells, bypassing filtration through the lungs.

• **Fig. 12.148 Metastatic Melanoma.** Pigmented nodule of the mandibular gingiva.



• **Fig. 12.149 Metastatic Renal Carcinoma.** Nodular mass of the left lateral border of the tongue. (Courtesy of Dr. Mark Bowden.)

Clinical Features



The most common site for oral soft tissue metastases is the gingiva, which accounts for 54% of all cases. The next most common site is the tongue, which accounts for 22.5% of cases. The lesion usually appears as a nodular mass that often resembles a hyperplastic or reactive growth, such as a pyogenic granuloma (Figs. 12.148–12.150). Occasionally, the lesion appears as a surface ulceration. Adjacent teeth may become loosened by destruction of the underlying alveolar bone. The presence of teeth may play an important role in the preference of metastases for the gingiva. Once malignant cells reach the oral cavity, the rich vascular network of inflamed gingival tissues or an extraction site may serve as a fertile location for further growth.

Oral soft tissue metastases are more common in males and are seen most frequently in middle-aged and older adults. Almost any malignancy from any body site is capable of metastasis to the oral cavity, and a wide variety of tumors have been reported to spread to the mouth. (However, there is probably a bias in the literature toward reporting more unusual cases.) In the cases reported, lung cancer is responsible for nearly one-third of all oral soft tissue metastases in

dentlearn.ir

• **Fig. 12.150 Metastatic Adenocarcinoma of the Colon. A,** Focal swelling of the left retromolar pad area. **B,** Same patient 4 weeks later. Note the marked enlargement of the lesion.

• **Fig. 12.151 Metastatic Carcinoma of the Lung.** Aggregates of malignant epithelial cells below the surface epithelium.

men, followed by renal carcinoma and melanoma. Although prostate cancer is common in men, metastases from these tumors have an affinity for bone and rarely occur in soft tissues. For women, breast cancer accounts for almost 25% of all cases, followed by malignancies of the genital organs, kidney, lung, and bone.

In most cases the primary tumor already is known when the metastatic lesion is discovered. In 25% of patients, however, the oral lesion is the first sign of the malignant disease.

Histopathologic Features

The microscopic appearance of the metastatic neoplasm should resemble the tumor of origin (Fig. 12.151). Most cases represent carcinomas; metastatic sarcomas to the oral region are rare.

Treatment and Prognosis

The prognosis for patients with metastatic tumors is generally poor because other metastatic sites also are frequently present. Management of the oral lesion is usually palliative and should be coordinated with the patient's overall treatment.

13 Hematologic Disorders

LYMPHOID HYPERPLASIA

The lymphoid tissue of the body plays an important role in the recognition and processing of foreign antigens, such as viruses, fungi, and bacteria. In addition, the lymphoid tissue has a protective function through a variety of direct and indirect mechanisms. In responding to antigenic challenges, lymphoid cells proliferate, thus increasing their numbers, to combat the offending agent more effectively. This proliferation results in enlargement of the lymphoid tissue, which is seen clinically as **lymphoid hyperplasia.**

Clinical Features

Lymphoid hyperplasia may affect the lymph nodes, the lymphoid tissue of Waldeyer ring, or the aggregates of lymphoid tissue that are normally scattered throughout the oral cavity, particularly in the oropharynx, the soft palate, the lateral tongue, and the floor of the mouth. When lymphoid hyperplasia affects the lymph nodes, usually the site that the lymph node drains can be identified as a source of active or recent infection. In the head and neck region, the anterior cervical chain of lymph nodes is most commonly involved, although any lymph node in the area may be affected.

With acute infections, the lymphadenopathy appears as enlarged, tender, relatively soft, freely movable nodules. Chronic inflammatory conditions produce enlarged, rubbery firm, nontender, freely movable nodes. Sometimes these chronic hyperplastic lymph nodes may be difficult to distinguish clinically from lymphoma, and a history of a preceding inflammatory process and lack of progressive enlargement are helpful clues that are consistent with a reactive process. Another condition, however, that should be considered in the differential diagnosis of multiple, persistently enlarged, nontender lymph nodes is human immunodeficiency virus (HIV) infection (see page 256).

Tonsillar size is variable from one person to the next, but lymphoid tissue is normally more prominent in younger individuals, usually reaching its peak early during the second decade of life and gradually diminishing thereafter. Some patients have such large tonsils that it seems as if they would occlude the airway (so-called kissing tonsils). Often, however, these patients have no symptoms and are unaware of a problem. As long as the large tonsils are symmetrical and asymptomatic (Fig. 13.1), it is likely that they are normal for that particular patient. Tonsillar asymmetry is a potentially serious sign that should be evaluated further to rule out the presence of a metastatic tumor or lymphoma.

Hyperplastic intraoral lymphoid aggregates appear as discrete, nontender, submucosal swellings, usually less than 1 cm in diameter, which may appear normal or dark pink in color if the aggregate is deeper; they may have a creamy yellow-orange to amber hue if the collection of lymphocytes is closer to the surface (Figs. 13.2 and 13.3). Lymphoid hyperplasia commonly involves the posterior lateral tongue, where it may appear somewhat ominous. The enlargement is usually bilaterally symmetrical, however, which helps to distinguish the condition from a malignancy. The buccal lymph node may also become hyperplastic and appear as a nontender, solitary, freely movable nodule, usually less than 1 cm in diameter, within the substance of the cheek. Infrequently, a more diffuse lymphoid hyperplasia involves the posterior hard palate, producing a slowly growing, nontender, boggy swelling with an intact mucosal surface and little color change. These palatal lesions may be clinically impossible to distinguish from extranodal lymphoma and would, therefore, necessitate biopsy.

Histopathologic Features

The microscopic features of lymphoid hyperplasia include sheets of small, well-differentiated lymphocytes with numerous interspersed, sharply demarcated collections of reactive lymphoblasts called **germinal centers.** The cells that comprise the germinal centers are primarily transformed B lymphocytes that may demonstrate numerous mitoses. Macrophages can also be identified by the presence of phagocytized material **(tingible bodies)** in their cytoplasm as they engulf nuclear debris from the proliferating lymphocytes. In some instances, immunohistochemical studies and clonality assays must be performed to rule out the possibility of follicular lymphoma.

Treatment and Prognosis

Once the diagnosis of lymphoid hyperplasia is confirmed, no treatment is usually required because it is a completely benign process. For those patients with palatal lymphoid hyperplasia that may interfere with a dental prosthesis, complete excision of the lesion is recommended.

dentlearn.ir

HEMOPHILIA

Hemophilia (*hemo* = blood; *philia* = loving) represents a variety of bleeding disorders associated with a genetic deficiency of any one of the clotting factors of the blood (Table 13.1). This condition was common in certain European royal families, with the initial mutation of the gene for factor IX affecting Queen Victoria of England, who then passed it on to her descendants. DNA analysis of the remains of the Russian royal family (Tsarina Alexandra was a granddaughter of Queen Victoria) confirmed a factor IX gene mutation that resulted in hemophilia B. Because this is an X-linked hereditary condition, a significant proportion of the male members of these families had hemophilia.

In the days before blood transfusions and clotting factor replacement therapy, many of these patients died as a direct result of, or from the complications of, uncontrolled hemorrhage. Because **hemophilia A** (factor VIII deficiency) is the most significant and widely recognized form of hemophilia and accounts for 80%–85% of the bleeding diatheses associated with a specific clotting factor deficiency, most of this discussion centers on that entity. Its estimated prevalence in the United States is 1 in 10,000 persons (or 1 in 5000 males).

As previously mentioned, a deficiency of factor IX or **hemophilia B (Christmas disease)** also may be encountered. Hemophilia B is similar to hemophilia A in its presentation, being transmitted in an X-linked fashion. Hemophilia B is much less common than hemophilia A, occurring with a prevalence of 1 in 60,000 (or 1 in 30,000 males). The term *Christmas disease* was obtained from the surname of the first person, a Canadian boy, who was identified as having hemophilia B in 1952.

Another clotting disorder that is sometimes seen, **von Willebrand disease**, is the result of a genetic deficiency of a plasma glycoprotein called **von Willebrand factor**. This glycoprotein aids in the adhesion of platelets at a site of bleeding, and it also binds to factor VIII, acting as a transport molecule. von Willebrand disease is a genetically heterogeneous condition, with

• **Fig. 13.1 Lymphoid Hyperplasia.** The large tonsil observed in this patient represents a benign hyperplasia of the lymphoid cells. If significant asymmetry is observed, further investigation may be warranted to rule out the possibility of lymphoma.

• **Fig. 13.2 Lymphoid Hyperplasia.** The smooth-surfaced papule of the posterior lateral tongue represents an enlarged lymphoid aggregate. The lesion exhibits a lighter color as a result of the accumulation of lymphocytes, which are white blood cells. (Courtesy of Dr. Dean White.)

• **Fig. 13.3 Lymphoid Hyperplasia.** Multiple prominent lymphoid aggregates in the floor of the mouth.

TABLE 13.1 Comparison of the Most Commonly Encountered Inherited Bleeding Disorders

Type	Defect	Inheritance	Findings
Hemophilia A (classic hemophilia)	Factor VIII deficiency	X-linked recessive	Abnormal PTT
Hemophilia B (Christmas disease)	Factor IX deficiency	X-linked recessive	Abnormal PTT
von Willebrand disease	Abnormal von Willebrand factor, abnormal platelets	Autosomal dominant	Abnormal PFA, abnormal PTT

PFA, platelet function assay (replaces bleeding time test); *PTT*, partial thromboplastin time.

dentlearn.ir

several subtypes currently identified, and it may be transmitted in an autosomal dominant or recessive pattern. It is the most common of the inherited bleeding disorders, affecting an estimated 1 in 800–1000 persons. However, many cases of von Willebrand disease are mild and may be clinically insignificant.

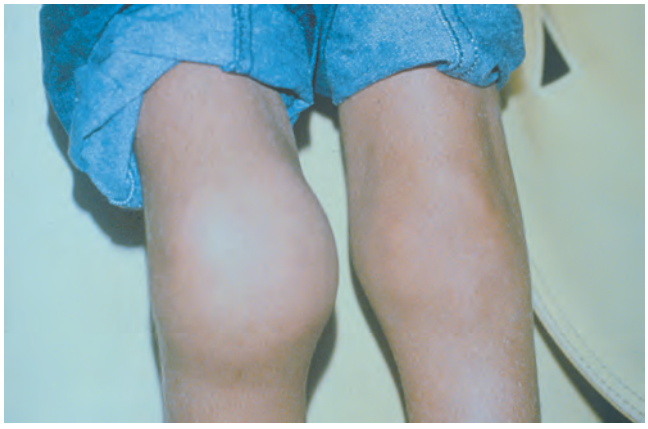
Clinical Features

Hemophilia A is an X-linked disorder. Females typically carry the trait, but it is expressed primarily in males. Approximately 1 in 5000 males is born with this genetic disease, with about 30% of the cases representing new mutations. Failure of normal hemostasis after circumcision is typically one of the first signs that a bleeding disorder is present.

The severity of the bleeding disorder depends on the extent of the clotting factor deficiency. Hemophilia A is a heterogeneous disorder that is caused by any one of a variety of mutations associated with the gene for factor VIII. Because the mutations occur at different sites in the factor VIII gene (more than 2000 different mutations have been identified), a clinical spectrum of deficiency of factor VIII is seen. This results in varying degrees of disease expression, with those mutations affecting more significant or larger portions of the factor VIII gene causing more severe clinical disease. Not all patients have an absolute lack of the particular clotting factor; rather, the deficiency may be a percentage of the normal value in a given patient. For example, a patient with only 25% of normal factor VIII levels may be able to function normally under most circumstances; one with less than 5% commonly manifests a marked tendency to bruise with only minor trauma.

In infants, oral lacerations and ecchymoses that involve the lips and tongue are a frequent occurrence as a result of the common falls and bumps experienced by this age group. If not treated appropriately, then such lacerations may result in significant blood loss in more severely affected patients. Sometimes deep hemorrhage occurs during normal activity and may involve the muscles, soft tissues, and weight-bearing joints **(hemarthrosis),** especially the knees (Fig. 13.4). The result of such uncontrolled bleeding is the formation of scar tissue as the body removes the extravasated blood. This often causes a crippling deformity of the knee joints secondary to arthritis and ankylosis. Sometimes the tissue hemorrhage results in the formation of a tumorlike mass, which has been called **pseudotumor of hemophilia.** Such lesions have been reported in the oral regions. In most instances, pseudotumors of hemophilia occur in patients affected with hemophilia A, but these lesions also have been described rarely in hemophilia B and von Willebrand disease.

An increased coagulation time (delay in blood clotting), of course, is the hallmark feature of this group of conditions. Uncontrollable or delayed hemorrhage may result from any laceration; this includes surgical incisions, dental extractions, and periodontal curettage (Fig. 13.5). Measurements of the platelet count, platelet function assay (PFA—an *in vitro* test of platelet function that has replaced the bleeding time test), prothrombin time (PT), and partial thromboplastin time (PTT) should be ordered as screening tests for any patient with a possible bleeding disorder.



Treatment and Prognosis

The treatment of clotting factor deficiencies essentially consists of replacement therapy with the appropriate clotting factor. Whether treatment is instituted depends on the severity of the clotting factor deficiency.

Patients who have greater than 25% of normal values of factor VIII may function normally. For patients with mild hemophilia (5%–40% of normal levels of factor VIII), no special treatment is typically required for normal activities. If surgery is to be performed, then clotting factor replacement therapy may be indicated.

For patients with severe deficiencies (less than 1% of normal levels of factor VIII), injections with the clotting factor must be performed as soon as a hemorrhagic episode occurs to prevent such complications as the crippling joint deformities of the knees.

The use of aspirin is strictly contraindicated because of its adverse effect on blood platelet function. Severe hemorrhage

• **Fig. 13.4 Hemophilia.** The enlargement of the knees of this patient with factor VIII deficiency is due to repeated episodes of bleeding into the joints (hemarthrosis). Inflammation and scarring have resulted.

• **Fig. 13.5 Hemophilia.** Hemorrhage in a patient with factor IX deficiency occurred after routine periodontal curettage.

dentlearn.ir

may result if these patients use aspirin-containing medications.

Genetic counseling should be provided to these patients and their families to help them understand the mechanism of inheritance. Using molecular techniques, women who are carriers can be confirmed. In addition, affected male fetuses can now be identified, and the severity of the factor VIII mutation can be assessed.

Optimal dental care is strongly encouraged for these patients to prevent oral problems that might require surgery. If oral or periodontal surgery is necessary, then consultation with the patient's physician is mandatory. The patient is usually prepared for the procedure by the administration of clotting factor just before the surgery. With an extensive surgical procedure, additional doses of clotting factor may be needed subsequently. In addition, epsilon-aminocaproic acid (EACA), an antifibrinolytic agent that inhibits clot degradation, should be given 1 day before the surgery and continued for 7–10 days afterward. Alternative therapy for patients who have levels of factor VIII greater than 5% of normal is desmopressin (1-deamino-8-D-arginine; DDAVP), which can be given just before surgery, either intravenously, subcutaneously, or intranasally. This drug causes the release of bound factor VIII, producing a temporary increase in the plasma levels of the clotting factor. Desmopressin may also be used to manage most patients affected by type 1 von Willebrand disease, which represents approximately 70%–80% of the cases of that disorder.

Although it saved many lives, clotting factor replacement therapy has also resulted in a tragic complication for many of these patients. Cryoprecipitation, the traditional method of concentrating clotting factors from the plasma, also resulted in the concentration of several viruses, including the hepatitis viruses and HIV. More than 40% of hemophilia A and B patients in the United States were estimated to be infected with hepatitis C virus. In addition, as many as 80%–90% of hemophiliac patients treated with multiple doses of factor VIII cryoprecipitate were infected with HIV, and many of these patients eventually developed acquired immunodeficiency syndrome (AIDS). The methods of preparing the clotting factors from pooled human plasma have been modified to eliminate or inactivate HIV; hepatitis A, B, and C; and parvovirus. Recombinant DNA technology also now provides a source of factor VIII that is manufactured by inserting the human factor VIII gene into bacteria that then synthesize the protein. Therefore, this product can now be manufactured without contamination by any viral organisms. Young people affected by hemophilia currently have minimal risk of contracting these infections as a result of their clotting factor replacement therapy.

Other problems must occasionally be confronted, however. Approximately 25%–30% of patients with severe hemophilia A may develop antibodies directed against factor VIII, and this is a very serious complication. Because the antibodies react with the factor VIII molecule, the result is an inhibition of the activity of the clotting factor, and these patients are once more faced with the prospect of uncontrolled bleeding. Patients with factor IX deficiency can develop similar inhibitory antibodies to factor IX, but this appears to occur much less frequently. Attempts to induce immune tolerance may help some individuals, although more immediate care has generally centered on bypassing the factor VIII–related portion of the clotting cascade by administration of recombinant factor VIIa or activated prothrombin complex. More recently, a bispecific monoclonal antibody, emicizumab, has been developed. Emicizumab essentially acts as a substitute for active factor VIII by forming a link between active factor IX and factor X, resulting in activation of factor X, which allows the clotting process to proceed. These methods that are necessary to bypass the inhibitory antibodies are expensive however. Hemophilia research centers are currently focused on developing gene therapy that will correct the condition at the molecular level.

◆ PLASMINOGEN DEFICIENCY (LIGNEOUS CONJUNCTIVITIS; HYPOPLASMINOGENEMIA)

Plasminogen deficiency is a rare autosomal recessive condition that is caused by any one of several mutations of the gene responsible for the production of plasminogen, the precursor to plasmin. In the clotting cascade, factors are activated that lead to the development of a clot; however, simultaneously serum proteins such as plasminogen are converted to plasmin, which is responsible for degrading the clot. Without the formation of plasmin, the clot tends to grow and persist despite having performed its original hemostatic function. The result of plasminogen deficiency is a buildup of fibrin, deposited as irregular plaques and nodules that primarily affect mucosal surfaces. Involvement of the conjunctival mucosa is characterized by the formation of thick, firm plaques, for which the term *ligneous conjunctivitis* has been used (*ligneous* means "woodlike"). Even though this condition was initially described in the 19th century, it was during the late 1990s that an explanation for the majority of these cases was provided. Similar lesions have been produced in mice that have been genetically manipulated to create knock-out mutations of the plasminogen gene.

Clinical Features

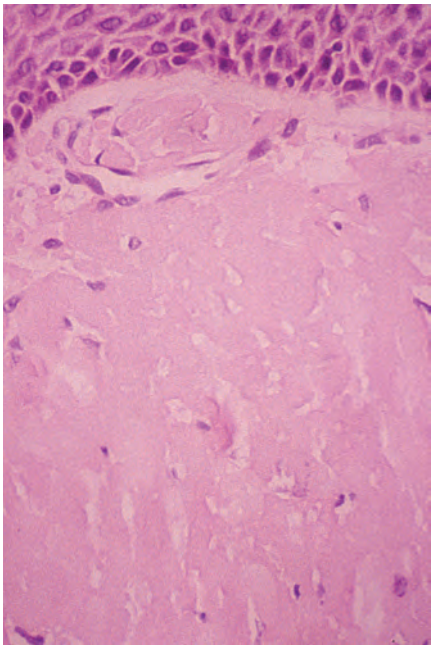
The most striking aspect of plasminogen deficiency is the development of thick, creamy yellow to erythematous, firm plaques and nodules involving primarily the conjunctival mucosa of the upper eyelid. Typically the condition is detected during the first decade of life, but lesions can develop later as well. Even though this is an autosomal recessive condition, there is a tendency for the disease to present more often in women, although the reason for this is unknown.

In addition to the conjunctival lesions, other mucosal surfaces can be affected, including the oral mucosa, laryngeal mucosa, and vaginal mucosa. In a recent series of 50 patients with this condition, ocular lesions were documented in 80%, gingival lesions in 34%, respiratory tract lesions in 16%, and vaginal lesions in 8%. Laryngeal mucosal involvement often includes the vocal cords, which typically results in a raspy,

dentlearn.ir

• **Fig. 13.6 Plasminogen Deficiency.** The ulcerated plaques and papules seen on the gingiva of this patient with plasminogen deficiency represent accumulations of fibrin. (Courtesy of Dr. Kenneth Rasenberger.)

hoarse voice. Occlusion of the airway by a fibrin mass has been described rarely.



Oral lesions of plasminogen deficiency primarily involve the gingivae, presenting as patchy ulcerated papules and nodules with a very irregular surface (Fig. 13.6). These lesions may be few in number or distributed diffusely in all quadrants, and they tend to wax and wane in severity.

Histopathologic Features

The microscopic features of the lesions associated with this condition can be very confusing for the pathologist who is not familiar with the disease. The accumulation of fibrin appears as diffuse sheets of acellular eosinophilic material that bears a close resemblance to amyloid (Fig. 13.7). Special stains for amyloid (such as Congo red) are negative, however, because this material represents fibrin. Confirmation that the eosinophilic material is fibrin can be done using the Fraser-Lendrum histochemical staining method. Variable numbers of inflammatory cells are seen, and granulation tissue is usually seen adjacent to the fibrin deposits.

Treatment and Prognosis

Treatment of plasminogen deficiency remains a problem. Damage to the mucosal tissues, including surgical trauma, should be minimized to reduce the likelihood of fibrin accumulation. Careful, thorough oral hygiene practices should be encouraged to diminish the effect of local inflammation. Sporadic reports describe resolution of the conjunctival lesions with either topical or systemic plasminogen; however, this agent is not available commercially. Some patients have experienced spontaneous regression of their lesions over time. Topical heparin combined with prednisone has helped control the gingival lesions in some patients. Alternatively, surgical excision of the gingival nodules, followed by low-dose systemic doxycycline, topical chlorhexidine mouth rinse, and systemic warfarin has also reportedly been effective in managing the lesions. Currently, these may be the two most

• **Fig. 13.7 Plasminogen Deficiency.** This high-power photomicrograph shows attenuated surface epithelium and a collection of relatively acellular eosinophilic material that superficially resembles amyloid, but is actually fibrin.

reasonable approaches for treating the oral lesions, although successful human trials using replacement plasminogen have been published, and this treatment awaits approval by the U.S. Food and Drug Administration. In the future, gene therapy may be feasible. Interestingly, these patients do not have any unusual problems with intravascular thrombus formation, and their lifespan does not appear to be shortened.

◆ ANEMIA

Anemia is a general term for either a decrease in the volume of red blood cells (hematocrit) or in the concentration of hemoglobin. This problem can result from a number of factors, including a decreased production of erythrocytes or an increased destruction or loss of erythrocytes. Laboratory studies, such as the red blood cell (RBC) count, hematocrit, hemoglobin concentration, mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC), can help indicate the probable cause of the anemia.

Rather than being a disease itself, anemia is often a sign of an underlying disease, such as renal failure, liver disease, chronic inflammatory conditions, malignancies, or vitamin or mineral deficiencies. The diverse causes and complexity of the problem of anemia are presented in Box 13.1.

Clinical Features

The symptoms of anemia are typically related to the reduced oxygen-carrying capacity of the blood, which is a result of the reduced numbers of erythrocytes. Symptoms such as tiredness, headache, shortness of breath, or lightheadedness are often present.

dentlearn.ir

• BOX 13.1 Causes of Anemia

Anemias With Disturbed Iron Metabolism

- Iron deficiency anemia
- Sideroblastic anemias

Megaloblastic Anemias

- Cobalamin (B_{12}) deficiency (pernicious anemia)
- Folic acid deficiency

Anemia Associated With Chronic Disorders

- Anemia of chronic infection (infective endocarditis, tuberculosis, osteomyelitis, lung abscess, and pyelonephritis)
- Anemia of inflammatory connective tissue disorders (rheumatoid arthritis, lupus erythematosus, sarcoidosis, temporal arteritis, and regional enteritis)
- Anemia associated with malignancy
  - Secondary to chronic bleeding
  - Myelophthisic anemia
- Anemia of uremia
- Anemia of endocrine failure
- Anemia of liver disease

Hemolytic Anemias

- Extrinsic causes
  - Splenomegaly
  - Red cell antibodies
  - Trauma in the circulation
  - Direct toxic effects (various microorganisms, copper salts, and venom of certain snakes)
- Membrane abnormalities
  - Spur cell anemia
  - Paroxysmal nocturnal hemoglobinuria
  - Hereditary spherocytosis
  - Hereditary elliptocytosis
- Disorders of the interior of the red cell
  - Defects in the Embden-Meyerhof pathway
  - Defects in the hexose monophosphate shunt

Disorders of Hemoglobin

- Sickle cell anemia
- Thalassemias

Pallor of the mucous membranes may be observed in severe cases of anemia. The palpebral conjunctiva is often the site where this paleness is most easily appreciated, but the oral mucosa may show similar signs.

Treatment and Prognosis

The treatment of anemia depends on determining the underlying cause of the anemia and correcting that problem, if possible.

◆ SICKLE CELL ANEMIA

Sickle cell anemia is one of the more severe genetic disorders of hemoglobin synthesis **(hemoglobinopathies).** Because of the mutational substitution of a thymine molecule for an adenine in DNA, the codon is altered to code for the amino acid valine rather than glutamic acid in the β-globin chain of hemoglobin. This results in a hemoglobin molecule that, in the deoxygenated state, is prone to molecular aggregation and polymerization. Consequently, the red blood cells (RBCs) of patients with sickle cell anemia have a marked tendency to undergo deformation from the normal biconcave disk shape to a rigid-and-curved (sickle) shape. Because the genes for hemoglobin synthesis are codominant, if only one allele is affected, then only 40%–50% of that patient's hemoglobin will be abnormal. Such a patient is simply a carrier and is said to have **sickle cell trait,** a condition that has no significant clinical manifestations in most everyday circumstances. Some sickling may be precipitated under certain conditions, such as dehydration or low-oxygen tensions related to either exercise or high altitudes.

This abnormal gene has persisted in the human race perhaps because it confers a degree of resistance to the malarial organism. As a result, the gene is seen most frequently in populations, such as African, Mediterranean, and Asian, who reside in areas where malaria is endemic. In the United States, nearly 2.5 million people (approximately 8% of the black population) carry this trait.

Unfortunately, in patients who inherit two alleles that code for sickle hemoglobin, the RBCs contain primarily sickle hemoglobin, which results in the condition called **sickle cell disease.** In the United States, about 1 of every 350–400 blacks is born with this disease. Such patients are often susceptible to the problems associated with abnormal RBC morphology. The sickled erythrocytes are more fragile than normal, lasting only 12–16 days in the circulation (about one-tenth of the lifespan of a normal RBC), and they tend to block the capillaries because of their shape and adherence properties. As a result, these patients have a chronic hemolytic anemia and many difficulties related to reduced blood flow to organs and tissues, which produces ischemia, infarction, and tissue death.

Clinical and Radiographic Features

Virtually any tissue or organ may be affected in sickle cell disease. The clinical spectrum of involvement can vary tremendously, with approximately one-third of patients exhibiting severe manifestations. Perhaps the most dramatic sign of this disease is the **sickle cell crisis,** a situation in which the sickling of the erythrocytes becomes severe. Hypoxia, infection, hypothermia, or dehydration may precipitate a crisis; however, for most crises there is no identifiable predisposing factor. Patients who experience a crisis suffer extreme pain from ischemia and infarction of the affected tissue. The long bones, lungs, and abdomen are among the most commonly affected sites, and each episode lasts 3–10 days. Pulmonary involvement, known as **acute chest syndrome,** is particularly serious, and one large study indicated that this is frequently precipitated by fat embolism or community-acquired pneumonia. Some patients may experience such crises monthly; others may go for 1 year or longer without problems. Often fever accompanies the crisis; therefore, infection must be considered in the differential diagnosis.

dentlearn.ir

Patients with sickle cell disease are susceptible to infections, especially those caused by *Streptococcus pneumoniae,* probably because of the destruction of the spleen at an early age by repeated infarctions. Such infections are the most common cause of death among children affected by sickle cell disease in the United States.

Other problems include delayed growth and development in most patients. Impaired kidney function and ocular abnormalities develop secondary to the damage caused by vaso-occlusive episodes in the capillary networks of those organs. If the patient lives long enough, then renal failure may eventually develop. In addition, approximately 5%–8% of these patients will experience central nervous system (CNS) damage in the form of a stroke, which occurs at an average age of about 8 years.

The oral radiographic features of sickle cell disease are relatively nonspecific. They consist of a reduced trabecular pattern of the mandible because of increased hematopoiesis occurring in the marrow spaces. Occasionally, a "hair-on-end" appearance is seen on the skull radiograph, although this is less prominent than that seen in thalassemia (Fig. 13.8). Other oral problems that have been reported include an increased prevalence of osteomyelitis of the mandible, mandibular bone infarction, prolonged paresthesia of the mandibular nerve, and asymptomatic pulpal necrosis.

Histopathologic Features

In homozygous sickle cell disease, a peripheral blood smear shows a peculiar curved distortion of the erythrocytes, resembling a sickle or boomerang shape.

Treatment and Prognosis

The patient experiencing a sickle cell crisis should be managed with supportive care, including fluids, rest, and appropriate analgesic therapy (usually narcotic preparations). It is important, but often difficult, to rule out the possibility of infection. Acute chest syndrome or cerebral infarct may require treatment with RBC transfusions.

• **Fig. 13.8 Sickle Cell Anemia.** Lateral skull radiograph reveals an altered trabecular pattern, including a slight degree of "hair-on-end" appearance of the cranial bones. (Courtesy of Dr. Reg Munden.)

All 50 states now screen for this hemoglobin disorder as part of their newborn infant health care system to identify affected individuals as soon as possible so that appropriate therapy can be instituted. For children with a diagnosis of sickle cell disease, continuous prophylactic penicillin therapy is indicated until at least 5 years of age. In addition, the child should be given polyvalent pneumococcal vaccinations. Situations that might precipitate a crisis, such as strenuous exercise, dehydration, or exposure to cold, should be avoided.

For nearly two decades, hydroxyurea that had been approved for treatment of adults with relatively severe disease. This drug increases the fetal form of hemoglobin (hemoglobin F), which may inhibit polymerization of hemoglobin S and may also reduce the adherence of erythrocytes to the vessel walls. Unfortunately, hydroxyurea has a number of potential side effects and should be used judiciously. In recent years, three new agents have been approved by the U.S. Food and Drug Administration for reduction of the number of crisis episodes in sickle cell disease patients. Each of these drugs has a different mechanism of action, and each is quite costly. Available in 2017, L-glutamine oral powder has to be mixed with water and taken twice daily by patients who are over 5 years of age. The mechanism of action is uncertain, but the medication may cause a decrease in oxidative damage in the sickled erythrocytes. Crizanlizumab-tmca and voxelotor were both approved in 2019. Crizanlizumab-tmca is a monoclonal antibody that is directed against P-selectin, a protein that is associated with the pathophysiologic mechanisms of the sickle cell crisis. This medication is given to patients over 15 years of age as a monthly intravenous infusion. Voxelotor can be given as a daily tablet to patients over 11 years of age, and it reduces sickling of the erythrocyte by inhibiting hemoglobin-S polymerization. Hemoglobin levels also increase in patients taking this medication.

Bone marrow transplantation is curative, but this is a procedure with multiple potential complications and is used primarily for severely affected patients having a histocompatibility antigen (HLA)-matched donor sibling. Only about 18% of sickle cell anemia patients currently meet these criteria. Gene therapy is another potential approach to curing sickle cell anemia, and several clinical trials are currently ongoing. To date, only one patient has been reported to have undergone successful lentivirus-mediated insertion of the corrected β-globin gene into the genome of his hematopoietic stem cells, resulting in resolution of the sickle cell disease. This treatment is not without risks, however, as illustrated by a recent report describing the development of acute myeloid leukemia in a woman who had undergone the same procedure. Although the insertion of the corrected gene itself was not thought to be responsible for the development of malignancy, other factors related to sickle cell anemia itself and the transplantation protocol could have played a role.

When surgery is necessary, local anesthesia, if possible, is usually preferred. If general anesthesia is indicated, then

dentlearn.ir

precautions should be taken to avoid conditions that might induce a crisis, such as hypoxia, vascular stasis, acidosis, infection, reduced body temperature, or dehydration.

For patients who have the sickle cell trait or the disease, genetic counseling is appropriate. DNA diagnostic techniques have been used for several years to assess whether a fetus is affected by sickle cell disease, permitting consideration of termination of the pregnancy. Molecular evaluation of the DNA from a single cell obtained from an embryo that was fertilized *in vitro* has allowed selection of a nonaffected embryo for uterine implantation. For parents who are carriers of the sickle cell trait, this is one method to ensure that their offspring do not have sickle cell disease.

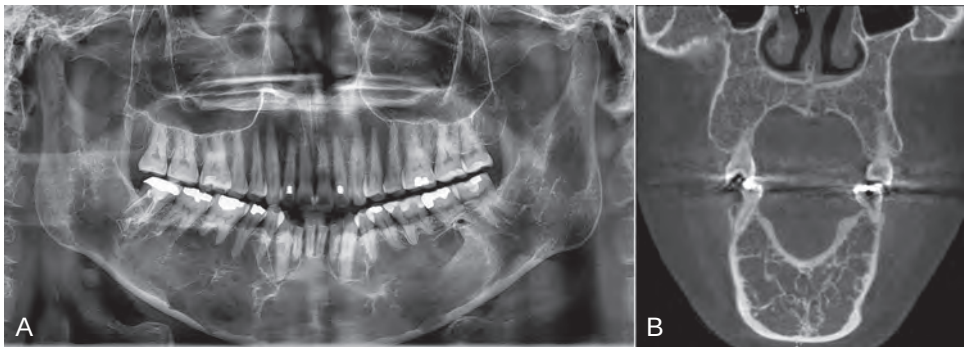
Although the mortality rate for sickle cell disease in developed countries has improved dramatically over the past few years, the prognosis is variable because of the wide spectrum of disease activity. Those who are severely affected, however, often are quite disabled because of the many complications of the disease and have a decreased lifespan.

◆ THALASSEMIA

Thalassemia represents a group of disorders of hemoglobin synthesis that are characterized by reduced synthesis of either the α-globin or β-globin chains of the hemoglobin molecule. As in those with sickle cell trait, people who carry the trait for one of the forms of thalassemia seem to be more resistant to infection by the malarial organism; an increased frequency of these genes is seen in Mediterranean, African, Indian, and Southeast Asian populations. Because the original cases were reported from the region of the Mediterranean Sea, the name *thalassemia* was given, derived from the Greek word *thalassa,* meaning "sea." The thalassemias are considered to be among the most common inherited conditions that affect humans.

An understanding of the structure and synthesis of hemoglobin is helpful in explaining the pathophysiology of these conditions. The hemoglobin molecule is a tetramer that is composed of two α chains and two β chains; if one of the chains is not being made in adequate quantities, then the normal amount of hemoglobin cannot be made. Furthermore, the excess globin chains accumulate within the erythrocyte, further compromising the structure and function of the cell. These abnormal erythrocytes are recognized by the spleen and selected for destruction **(hemolysis).** In addition, there is evidence of ineffective erythropoiesis caused by premature cell death of erythrocyte precursors in the bone marrow because of activation of apoptotic mechanisms. The net result is that the patient has hypochromic, microcytic anemia.

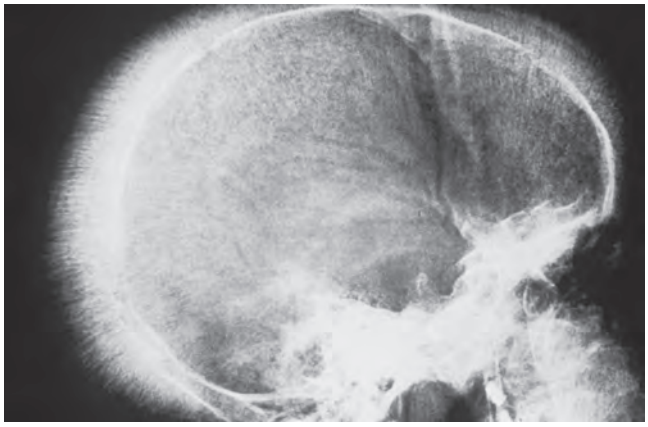
Because two genes code for the β chain and four genes code for the α chain, the degree of clinical severity in these conditions can vary considerably. The severity depends on which specific genetic alteration is present and whether it is heterozygous or homozygous. In the heterozygous state, an adequate amount of normal hemoglobin can be made and the affected patient experiences few signs or symptoms. In the homozygous state, however, the problems are often severe or even fatal. In addition, variations in the severity of the clinical presentation may be a reflection of the specific alteration in the genetic code, because more than 200 different mutations have been documented for β-thalassemia alone.



Clinical and Radiographic Features

β-Thalassemia

If only one defective gene for the β-globin molecule is inherited **(thalassemia minor)**, no significant clinical manifestations are usually present.



When two defective genes for the β-globin molecule are inherited, the patient typically is affected with **thalassemia major**, also called **Cooley anemia** or **Mediterranean anemia.** The disease is usually detected during the first year of life because a severe microcytic, hypochromic anemia develops when fetal hemoglobin synthesis ceases after 3–4 months of age. The red blood cells (RBCs) that are produced are extremely fragile and survive for only a few days in the peripheral circulation.

In an attempt to maintain adequate oxygenation, the rate of hematopoiesis (despite being ineffective) is greatly increased (up to 30 times normal), resulting in massive bone marrow hyperplasia, as well as hepatosplenomegaly and lymphadenopathy because of extramedullary hematopoiesis. The bone marrow hyperplasia may affect the jaws especially, producing an altered trabecular pattern and marked, painless enlargement of the mandible and maxilla (Fig. 13.9). This results in a characteristic "chipmunk" facies and causes

• **Fig. 13.9 Thalassemia. (Panel A: Courtesy of Dr. Nicole S. Pheifer. Panel B: Courtesy of Dr. Andrew P. Wightman.)

dentlearn.ir

• **Fig. 13.10 Thalassemia.** Lateral skull radiograph depicting the characteristic "hair-on-end" appearance in a patient with thalassemia.

reduced size or obliteration of the paranasal sinuses. Frontal bossing is also present, and a skull radiograph may show a prominent "hair-on-end" appearance of the calvaria (Fig. 13.10). Generalized maturational delay of the patient is typically seen. Delayed development of the dentition also has been described, with the teeth showing a mean delay of approximately 1 year compared with a matched population.

Without therapy, tissue hypoxia worsens and serious bacterial infections with pneumococcal organisms often develop. Eventually, high-output cardiac failure occurs; many patients die by 1 year of age as a result of infection or heart problems.

α-Thalassemia

Because four α-globin genes may be affected, **α-thalassemia** has a broader spectrum of involvement than does β-thalassemia. The condition is caused by deletion at the α-globin gene locus.

When only one deleted gene is inherited, no disease can be detected. With the inheritance of two deleted genes, the condition is known as **α-thalassemia trait**. These patients have a mild degree of anemia and microcytosis that is usually not clinically significant. With three deleted genes, the term **hemoglobin H (HbH) disease** is applied. Patients have problems with hemolytic anemia and splenomegaly. For patients with severe hemolysis, splenectomy may be indicated.

The homozygous state, in which all four genes are deleted, causes severe generalized fetal edema, a condition that has been termed **hydrops fetalis.** Hydrops fetalis is not specific for α-thalassemia and can be seen as a manifestation of other diseases, such as severe Rh incompatibility. Infants with α-thalassemia who are affected by this problem typically die within a few hours of birth.

Treatment and Prognosis

Thalassemia major is treated today primarily by means of blood transfusions. These should be administered every 2–3 weeks to simulate the normal hematologic state. Unfortunately, with repeated blood transfusions, iron overload inevitably develops because of the constant infusion of exogenous RBCs. This is a serious problem, and often death is due to **hemochromatosis,** an abnormal deposition of iron throughout the tissues of the body. The heart, liver, and endocrine glands are particularly affected by the toxic accumulation of iron. To combat this problem, an iron-chelating agent, deferoxamine (also known as *desferrioxamine*), must be given. If such therapy is used steadfastly, patients with β-thalassemia may have a relatively normal life span; however, problems may arise with patient compliance because this medication must be infused, either parenterally or subcutaneously, over several hours for at least 250 nights each year. If adequate control of iron levels is not obtained, the addition of an orally administered iron chelator, either deferiprone or deferasirox, is often considered. Deferiprone used alone is not as effective as deferoxamine, but the number of weekly infusions of the latter drug can be reduced when combined with deferiprone. Hematologic studies are done weekly due to agranulocytosis developing in 1% of patients taking deferiprone. Deferasirox does not seem to have significant side effects. All of these iron chelators are expensive, although the oral medications used in combination are more cost effective because patient compliance is better and infusion-related costs are eliminated. Hematopoietic stem cell transplantation has also been used with considerable success for individuals who are relatively young, have little organ damage, and have an HLA-matched donor.

Clinicians can now identify α-thalassemia, with its attendant hydrops fetalis (historically considered a fatal condition), *in utero* by molecular testing, and the fetus can be given intrauterine umbilical vein transfusions. An 80% survival rate has been reported for these infants, although they will require either lifelong transfusion therapy or hematopoietic stem cell transplantation. Prenatal diagnosis is also available for β-thalassemia.

For patients who have developed an abnormal facial appearance caused by thalassemia, surgical correction can be performed in many cases. Prevention of thalassemia also is desirable, either by screening for carriers of the genetic trait and providing genetic counseling, or by prenatal diagnosis.

◆ APLASTIC ANEMIA

Aplastic anemia is a rare, life-threatening hematologic disorder that is characterized by failure of the hematopoietic precursor cells in the bone marrow to produce adequate numbers of all types of blood cells (pancytopenia). A significant amount of evidence supports the concept that most cases of aplastic anemia represent an immune-mediated disease caused by cytotoxic T lymphocytes that target differentiating hematopoietic cells in the marrow. As a result, the hematopoietic stem cells do not seem to undergo normal maturation despite normal or increased levels of cytokines, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), which normally induce the production and maturation of several types of white blood cells.

Although the underlying trigger for the immune-mediated destruction of the hematopoietic cells is unknown, some cases of aplastic anemia are associated with exposure to certain environmental toxins (e.g., benzene), treatment with certain

dentlearn.ir

drugs (especially the antibiotic chloramphenicol), or infection with certain viruses (particularly non-A, non-B, non-C, or non-G hepatitis). It is possible that the abnormal immune response is perhaps initiated by such exogenous stimuli in certain instances. A few genetic disorders, such as **Fanconi anemia** and **dyskeratosis congenita** (see page 752), also are associated with an increased frequency of aplastic anemia.

Clinical Features

Because all of the formed elements of the blood are decreased in patients with aplastic anemia, the initial symptoms may be related to any one or several of the deficiencies. The erythrocyte deficiency produces signs and symptoms related to a decreased oxygen-carrying capacity of the blood; therefore, patients may experience fatigue, lightheadedness, tachycardia, or weakness. The platelet deficiency (thrombocytopenia) is seen as a marked tendency for bruising and bleeding, which affects a variety of sites. Retinal and cerebral hemorrhages are some of the more devastating manifestations of this bleeding tendency. Deficiency of white blood cells (neutropenia, leukopenia, or granulocytopenia) is the most significant complication of this disease, predisposing the patient to bacterial and fungal infections that often are the cause of death.

The oral findings related to thrombocytopenia include gingival hemorrhage (Fig. 13.11), oral mucosal petechiae, purpura, and ecchymoses. The oral mucosa may appear pale because of the decreased numbers of red blood cells (RBCs). Oral ulcerations associated with infection due to neutropenia, particularly those that involve the gingival tissues, may be present. Minimal erythema is usually associated with the periphery of the ulcers. Gingival hyperplasia has also been reported in association with aplastic anemia.

Histopathologic Features

A bone marrow biopsy specimen usually demonstrates a relatively acellular marrow with extensive fatty infiltration. The histopathologic features of an oral ulceration in a patient with aplastic anemia show numerous microorganisms in addition to a remarkable lack of inflammatory cells in the ulcer bed.

• **Fig. 13.11 Aplastic Anemia.** Diffuse gingival hyperplasia with sulcular hemorrhage.

Diagnosis

The diagnosis of aplastic anemia is usually established by laboratory studies. A pancytopenia is characterized by at least two of the following findings:

- Fewer than 500 granulocytes/μL
- Fewer than 20,000 platelets/μL
- Fewer than 20,000 reticulocytes/μL

Treatment and Prognosis

The course for patients with aplastic anemia is unpredictable. For the milder forms of the disease, spontaneous recovery of the marrow may occur in some instances; progression to severe aplastic anemia may be seen in others. Generally, in severe cases, the chances of spontaneous recovery are slim. If a particular environmental toxin or drug is associated with the process, then withdrawal of the offending agent may sometimes result in recovery.

The treatment is initially supportive. Appropriate antibiotics are given for the infections that develop, and transfusions of packed RBCs or platelets are administered for symptomatic treatment of anemia and bleeding problems, respectively.

Definitive therapy for aplastic anemia is to replace the defective marrow with normal marrow, either by bone marrow transplantation or peripheral blood stem cell transplantation from a matched donor. Patients must be carefully selected; patients younger than 50 years of age and those with an HLA-matched donor (usually a sibling) have the best prognosis, but unfortunately only about 30% of patients meet these criteria.

For those patients who would not be a good prospect for bone marrow transplantation because of their advanced age or no matched donor, immunosuppressive therapy is recommended. Antithymocyte globulin combined with cyclosporine produces a response in the majority of these patients. Compared with treatment results from only 35 years ago, the prognosis for this condition has markedly improved. In the past, for patients with severe aplastic anemia treated with only antibiotics and transfusions, the mortality rate was greater than 80% in the first year after the diagnosis. Currently, an overall long-term survival of 85% of these patients can be achieved with either bone marrow transplant or immunosuppressive therapy. However, even if the disease is controlled, then these patients remain at risk for recurrent marrow aplasia and are at increased risk for acute leukemia.

◆ NEUTROPENIA

Neutropenia refers to a decrease in the number of the circulating neutrophils below 1.5×10^9/L in an adult. It is often associated with an increased susceptibility of the patient to bacterial infections. Clinicians must be aware of this disorder because infection of the oral mucosa may be the initial sign of the disease. Interestingly, several ethnic groups, including patients of African and Middle Eastern background, will consistently have neutrophil counts that would qualify as

dentlearn.ir

neutropenia (as low as 1.2×10^9/L), yet these individuals are otherwise healthy. This finding has been termed **benign ethnic neutropenia,** and it appears to have no effect on the health of the patient because neutrophil counts respond to bacterial challenge.

A decrease in neutrophils may be precipitated by several mechanisms, most of which involve decreased production or increased destruction of these important inflammatory cells. When infections are noted in infancy and neutropenia is detected, the problem is usually the result of a congenital or genetic abnormality, such as **Schwachman-Diamond syndrome, dyskeratosis congenita** (see page 752), **cartilage-hair syndrome,** or **severe congenital neutropenia.** If the neutropenia is detected later in life, it usually represents one of the acquired forms. Many acquired neutropenia conditions have an unknown cause; however, others are clearly associated with various causes. A decreased production of neutrophils and the other formed elements of the blood may result from the destruction of the bone marrow by malignancies, such as leukemia (see page 593), or by metabolic diseases, such as Gaucher disease (see page 821), and osteopetrosis (see page 620). Several different types of malignancy, including Hodgkin and non-Hodgkin lymphoma, melanoma, renal cell carcinoma, and T-cell large granular lymphocyte leukemia (Fig. 13.12), have been reported to trigger destruction of neutrophils by various autoimmune mechanisms.

Many drugs may affect neutrophil production, either through direct toxic effects on the bone marrow progenitor cells or by triggering autoimmune mechanisms that destroy neutrophils. These drugs include the following:

- Anticancer chemotherapeutic agents (e.g., nitrogen mustard, busulfan, chlorambucil, and cyclophosphamide)
- Antibiotics (e.g., penicillins and sulfonamides)
- Phenothiazines
- Tranquilizers
- Diuretics

Neutropenia can also be a late manifestation of rituximab therapy, occurring 4–5 weeks after treatment on average. Nutritional deficiencies of vitamin B_{12} or folate, which may be a consequence of malabsorption syndromes, can inhibit neutrophil production as well.

A variety of viral and bacterial infections not only may reduce production of neutrophils but also seem to increase their destruction, typically at the sites of infection. Autoimmune mechanisms of neutrophil destruction may also be induced by viral or bacterial infections. Viral infections that have been implicated include the following:

- Hepatitis A and B
- Rubella
- Measles
- Respiratory syncytial virus
- Varicella
- HIV

Numerous bacterial infections, such as typhoid, tuberculosis, brucellosis, and tularemia, may also cause neutropenia. The increased destruction of neutrophils by an autoimmune mechanism also occurs in such disorders as systemic lupus erythematosus (SLE), in which autoantibodies directed against the neutrophil are produced.

• **Fig. 13.12 Neutropenia.** Palatal neutropenic ulceration that was seen in a patient with large granular lymphocyte leukemia, a rare form of leukemia that induces a severe decrease in neutrophils.

Clinical Features

Most patients with neutropenia have some form of bacterial infection rather than a viral or fungal infection, particularly if the other elements of the immune system (lymphocytes, plasma cells, and monocytes) are still intact. *Staphylococcus aureus* and gram-negative organisms seem to cause the most problems for patients with neutropenia. The suppuration and abscess formation normally associated with such infections may be markedly reduced because of the lack of neutrophils. The most common sites of infection include the middle ear, the oral cavity, and the perirectal area. When neutrophil counts drop below 0.5×10^9/L, however, pulmonary infections often develop.

The oral lesions of neutropenia consist of ulcerations that usually involve the gingival mucosa, probably because of the heavy bacterial colonization of this area and the chronic trauma that it receives. These ulcers characteristically lack an erythematous periphery (Fig. 13.12), although this finding has been variable. Premature periodontal bone loss with exfoliation of the deciduous dentition has been described.

Histopathologic Features

A biopsy specimen of neutropenic ulceration usually shows a reduced number or the absence of neutrophils. Bacterial invasion of the host tissue may be apparent in some instances.

Treatment and Prognosis

Infections related to neutropenia are managed with appropriate antibiotic therapy. The patient should be encouraged to maintain optimal oral hygiene to decrease the bacterial load in the oral cavity. Studies using recombinant human granulocyte colony-stimulating factor (G-CSF; filgrastim; pegfilgrastim), a cytokine that promotes the growth and differentiation of neutrophils, have shown remarkable

dentlearn.ir

results. Patients with severe neutropenia have a significant increase in neutrophil counts and resolution of infections after treatment with this agent. Prophylactic use of filgrastim or pegfilgrastim reduces the risk of febrile neutropenia in patients who are receiving certain antineoplastic chemotherapeutic regimens. Patients who do not respond to G-CSF may have to be considered for hematopoietic stem cell transplantation, depending on the severity of the neutropenia and subsequent infections.

AGRANULOCYTOSIS

Agranulocytosis is a condition in which the cells of the granulocytic series, particularly neutrophils, are absent. As in other disorders of the formed elements of the blood, agranulocytosis may occur as a result of decreased production or increased destruction or use of these cells. Although some cases are idiopathic, most are induced by exposure to one of several drugs. Some drugs, such as the anticancer chemotherapeutic agents, induce agranulocytosis by inhibiting the normal mitotic division and maturation of the hematopoietic stem cells. In other instances, the drugs trigger an immunologic reaction that results in the destruction of granulocytes. Rarely, agranulocytosis may be a congenital syndrome **(congenital agranulocytosis, Kostmann syndrome)** that results from a decreased level of the cytokine granulocyte colony-stimulating factor (G-CSF).

Clinical Features

Agranulocytosis typically develops within a few days after a person ingests the offending drug. Because of the lack of granulocytes (especially neutrophils), bacterial infections often develop and patients may show signs and symptoms of malaise, sore throat, swelling, fever, chills, bone pain, pneumonia, and shock. The erythrocyte and platelet counts are usually normal or only slightly depressed.

Oral lesions are common and include necrotizing, deep, punched-out ulcerations of the buccal mucosa, tongue, and palate. The gingivae are especially susceptible to infection, often resembling the pattern of necrotizing ulcerative gingivitis (NUG) (see page 151).

Histopathologic Features

Microscopic examination of a biopsy specimen from one of the oral ulcerations in agranulocytosis characteristically shows abundant bacterial organisms, both on the surface and within the tissue. The host inflammatory response is relatively sparse, with few granulocytes, particularly neutrophils, seen in the ulcer bed.

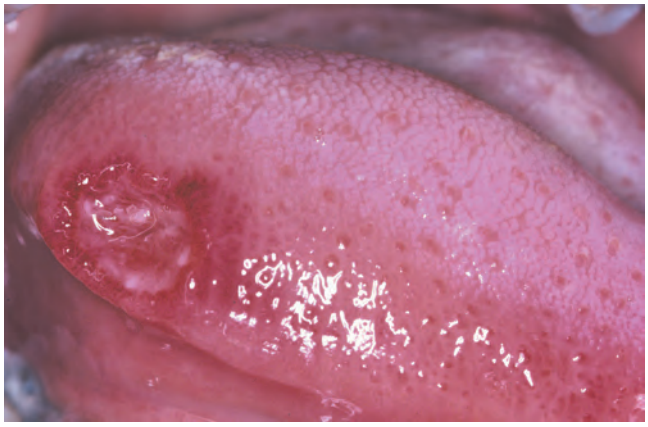
Treatment and Prognosis

If the clinician believes that a particular drug has caused the agranulocytosis, the medication should be discontinued as soon as is reasonably possible. In many instances, the granulocyte count returns to normal within 10–14 days after cessation of the offending agent. For patients who have agranulocytosis secondary to cancer chemotherapy, oral hygiene should be meticulous to foster an immaculate oral environment. In addition, the use of chlorhexidine-containing mouth rinses seems to reduce the severity of the oral lesions. Active infections are treated with appropriate antibiotic medications.

If the agranulocytosis is related to cancer treatment, the white blood cell count usually returns to normal after a period of weeks. For patients whose granulocyte counts do not recover, administration of G-CSF or granulocyte-macrophage colony-stimulating factor (GM-CSF) may be beneficial. The overall mortality rate for this condition in the past was 20%–30%, although cytokine therapy and the newer broad-spectrum antibiotics have improved the outlook for these patients.

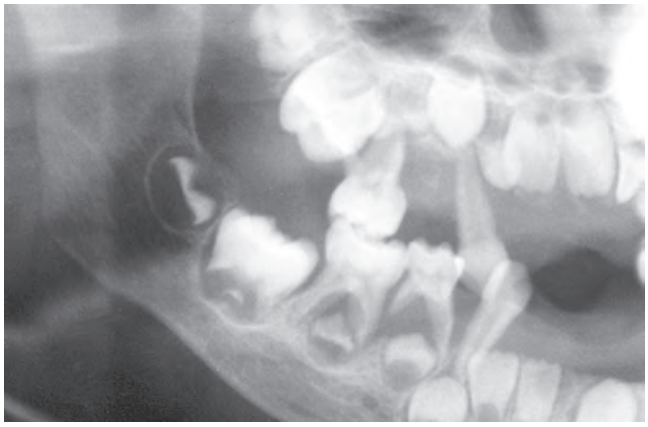
CYCLIC NEUTROPENIA (CYCLIC HEMATOPOIESIS)

Cyclic neutropenia is a rare idiopathic hematologic disorder that is characterized by regular periodic reductions in the neutrophil population of the affected patient. The underlying cause seems to be a mutation of the neutrophil elastase *(ELA-2* or *ELANE)* gene, resulting in arrested development of neutrophils at the promyelocyte stage within the marrow. This mutation is also associated with premature apoptosis of these myeloid precursor cells. The best estimated frequency of this disease in the population is about 1 in 1 million. Although an autosomal dominant pattern of inheritance has been described in a few cases, most examples of cyclic neutropenia are isolated.



Symptoms usually begin in childhood and tend to correlate with the neutrophil counts. When the neutrophil count is at its nadir (i.e., lowest point), the patient experiences problems with infection. As the neutrophil count rises toward normal, the signs and symptoms abate. Very low neutrophil counts usually are present for 3–6 days, and blood monocyte and eosinophil levels are typically increased when the neutrophil count is depressed. Even when the neutrophil count is at its peak, the levels are often less than normal.

Clinical and Radiographic Features



The signs and symptoms of cyclic neutropenia occur in rather uniformly spaced episodes, which usually have a 21-day cycle. Patients typically complain of recurrent episodes of fever, anorexia, cervical lymphadenopathy, malaise, pharyngitis, and oral mucosal ulcerations. Other gastrointestinal mucosal areas, including the colon, rectum, and anus, may be affected by recurrent ulcerations.

The oral ulcerations develop on any oral mucosal surface that is exposed to even minor trauma, particularly the lips, tongue, buccal mucosa, and oropharynx (Fig. 13.13). An erythematous halo is variably present at the periphery of the ulcers. The gingiva is the most severely affected region of the oral cavity. Severe periodontal bone loss with marked

dentlearn.ir

• **Fig. 13.13 Cyclic Neutropenia.** Ulceration of the lateral tongue is typical of the lesions associated with cyclic neutropenia. (From Allen CM, Camisa C: Diseases of the mouth and lips. In Sams WM, Lynch P, editors: *Principles and practice of dermatology,* ed 2, New York, 1996, Churchill Livingstone.)

• **Fig. 13.14 Cyclic Neutropenia.** Cyclic neutropenia is one of several conditions that may produce premature bone loss, as shown in the interradicular regions of the mandibular deciduous molar teeth.

gingival recession and tooth mobility also is characteristic (Fig. 13.14).

Diagnosis

The diagnosis of cyclic neutropenia should be established by sequential complete blood counts (typically three times per week for 6–8 weeks) to determine whether cycling of the neutrophil levels occurs. The neutrophil count should be less than 500/mm^3 for 3–5 days during each of at least three successive cycles to make this diagnosis.

Histopathologic Features

The histopathologic features of cyclic neutropenia are similar to those of the other neutropenic and granulocytopenic ulcerations if the biopsy is performed during the nadir of the neutrophil count.

Treatment and Prognosis

Supportive care for the patient with cyclic neutropenia includes antibiotic therapy for significant infections that might occur while the neutrophil count is at its lowest. Unfortunately, this approach cannot be considered a permanent treatment. Other methods that have been used with marginal success include splenectomy, corticosteroid therapy, and nutritional supplementation. Administration of the cytokine granulocyte colony-stimulating factor (G-CSF) several times weekly seems to correct the lack of production of neutrophils. This treatment results in a decrease in the time of neutropenia from 5 days to 1 day, which improves the clinical course of the disease. The cycles are reduced from 18 to 21 days to 11 to 13 days, and the severity of mucositis and infection are reduced.

Supportive care in the form of optimal oral hygiene should be maintained to reduce the number and severity of oral infections and improve the prognosis of the periodontal structures. Fortunately, for many of these patients, the severity of symptoms related to cyclic neutropenia seems to diminish after the second decade of life, despite the fact that the cycling of the neutrophils continues.

◆ THROMBOCYTOPENIA

Thrombocytopenia is a hematologic disorder that is characterized by a markedly decreased number of circulating blood platelets (formed elements derived from megakaryocyte precursors in the bone marrow). Platelets are necessary for hemostasis and clot formation. A platelet count of 200,000–400,000/mm^3 is considered normal. The decrease in platelets may be the result of the following:

- Reduced production
- Increased destruction
- Sequestration in the spleen

REDUCED PLATELET PRODUCTION

Reduced production of platelets may be the result of various causes, such as infiltration of the bone marrow by malignant cells or the toxic effects of cancer chemotherapeutic drugs. In such instances, decreases in the other formed elements of the blood are also seen.

INCREASED PLATELET DESTRUCTION

Increased destruction of platelets may be caused by an immunologic reaction, which is often precipitated by any one of more than 100 different drugs; heparin is one of the most common offending agents. This type of reaction is typically idiosyncratic and, therefore, not related to the dose of the drug. Similarly, autoantibodies directed against platelets, specifically certain surface glycoproteins, may on rare occasions be induced by viral infection or vaccination. In addition, certain systemic diseases may have thrombocytopenia as a component, such as systemic lupus erythematosus (SLE) and HIV infection. Increased

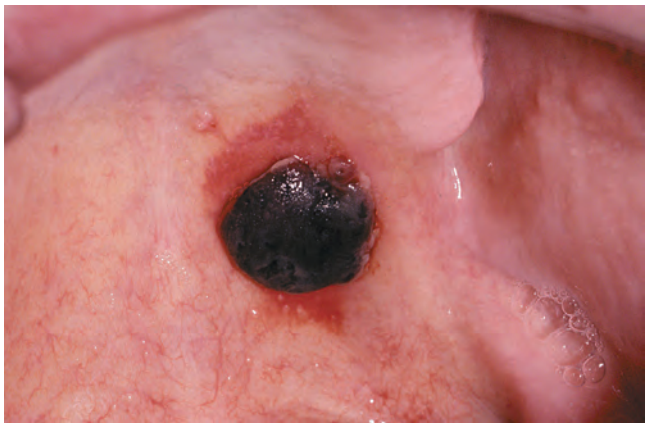
dentlearn.ir

destruction may also occur because of increased consumption of platelets associated with abnormal blood clot formation. This occurs in patients with conditions, such as **thrombotic thrombocytopenic purpura (TTP).** This serious disorder of coagulation is caused by a deficiency of a von Willebrand factor-cleaving metalloprotease (ADAMTS13), which triggers the formation of numerous thrombi within the small blood vessels of the body. The condition is usually caused by antibodies directed against ADAMTS13, but TTP can also rarely be inherited as an autosomal recessive condition when mutations of the ADAMTS13 gene are present.

SEQUESTRATION IN THE SPLEEN

Under normal conditions, one-third of the platelet population is sequestered in the spleen. Consequently, conditions that cause splenomegaly (e.g., portal hypertension secondary to liver disease, splenic enlargement secondary to tumor infiltration, and splenomegaly associated with Gaucher disease) also cause larger numbers of platelets to be taken out of circulation. Regardless of the cause, the result for the patient is a bleeding problem because normal numbers of platelets are not available for proper hemostasis.

Clinical Features



Clinical evidence of thrombocytopenia is not usually seen until the platelet levels drop below 100,000/mm^3. The severity of involvement is directly related to the extent of platelet reduction. The condition often is initially detected because of the presence of oral lesions. Minor traumatic events are continuously inflicted on the oral mucosa during chewing and swallowing of food. The small capillaries that are damaged during this process are normally sealed off with microscopic thrombi. In a patient with thrombocytopenia, however, the thrombi do not form properly. This results in a leakage of blood from the small vessels. Clinically, this usually produces pinpoint hemorrhagic lesions known as **petechiae.** If a larger quantity of blood is extravasated, then an **ecchymosis** or bruise results (Fig. 13.15). With even larger amounts of extravasated blood, a **hematoma** (*hemat* = blood; *oma* = tumor) will develop (Fig. 13.16). Spontaneous gingival hemorrhage often occurs in these patients, as does bleeding from sites of minor trauma.

Similar hemorrhagic events occur throughout the body. With severe thrombocytopenia (<10,000 platelets/mm^3), massive bleeding from the gastrointestinal or urinary tract may be fatal. Epistaxis is often present in these patients, and hemoptysis indicates significant pulmonary hemorrhage. Intracranial hemorrhage is also a potentially fatal complication of severe thrombocytopenia.

Immune thrombocytopenic purpura (ITP) or **immune thrombocytopenia**, which used to be known as idiopathic thrombocytopenic purpura or idiopathic thrombocytopenia, can present as either an acute or chronic process. Acute ITP usually occurs during childhood, classically after a nonspecific viral infection. The symptoms of thrombocytopenia appear quickly and may be severe. Most cases, however, resolve

• **Fig. 13.15 Thrombocytopenia.** The bruising (purpura) seen on this patient's forearm is a result of reduced platelet count secondary to myelodysplasia, a preleukemic bone marrow disorder.

• **Fig. 13.16 Thrombocytopenia.** This dark palatal lesion represents a hematoma caused by a lack of normal coagulation, characteristic of thrombocytopenia.

spontaneously within 4–6 weeks, and 90% of patients recover by 3–6 months. Chronic ITP most frequently affects women between 20 and 40 years. Autoantibodies directed against antigens on the platelet surface result in sequestration and destruction of the platelets in the spleen. Consequently many of these patients may respond to splenectomy.

Histopathologic Features

Gingival biopsy may be performed for diagnostic purposes in patients with suspected TTP. Approximately 30%–40% of such biopsy specimens show the presence of fibrin deposits in the small vessels. These deposits are more readily appreciated after staining the tissue section using the periodic acid-Schiff (PAS) method.

Treatment and Prognosis

If the clinician believes the thrombocytopenia to be drug-related, the drug should be discontinued immediately. In most instances, the platelet count returns to normal after

dentlearn.ir

several days. Platelet transfusions and corticosteroid therapy may be necessary if life-threatening hemorrhage occurs. As mentioned earlier, ITP often resolves spontaneously, but those cases that are more severe may require corticosteroid therapy or intravenous immunoglobulin (IVIG) therapy. Good success has been documented with rituximab (which targets B lymphocytes) or thrombopoietin-receptor agonists (which stimulate megakaryocytes to produce more platelets). Splenectomy is generally reserved for those cases of ITP that are refractory to medical treatment. For some forms of thrombocytopenia, such as TTP, the patient's prognosis is relatively guarded. In the past, the condition was almost uniformly fatal, although the outlook has greatly improved since therapy with plasma exchange transfusions, combined with corticosteroids or rituximab, became available. More than 70% of these patients now survive with proper treatment.

◆ POLYCYTHEMIA VERA (PRIMARY POLYCYTHEMIA; POLYCYTHEMIA RUBRA VERA; PRIMARY ACQUIRED ERYTHROCYTOSIS)

Polycythemia vera is a rare idiopathic hematologic disorder that is best thought of as an increase in the mass of the red blood cells (RBCs). Uncontrolled production of platelets and granulocytes, however, is often seen concurrently, and most authorities feel that this condition represents a relatively nonaggressive myeloproliferative disorder. Researchers believe the over-production is related to the abnormal behavior of a single progenitor marrow stem cell, which begins multiplying without regard to the normal regulatory hormones, such as erythropoietin. This gives rise to a group or clone of unregulated cells that then produce the excess numbers of these formed elements of the blood at two to three times the normal rate. These cells generally function in a normal fashion.

Clinical Features

Polycythemia vera typically affects older adults. The median age at diagnosis is 60 years. Only 5% of cases are diagnosed before the age of 40 years. No sex predilection is seen, and the annual incidence in the United States is estimated to be approximately 20 cases per million population. An acquired mutation of one of the tyrosine kinase genes, Janus kinase 2 *(JAK2),* plays a significant role in the development of this disorder, and more than 95% of patients with polycythemia vera have been shown to have this mutation.

The initial symptoms of the disease are nonspecific and include the following:

- Headache
- Weakness
- Dizziness
- Drowsiness
- Visual disturbances
- Sweating
- Weight loss
- Dyspnea
- Epigastric pain

A ruddy complexion may be evident on physical examination. One relatively characteristic complaint, described in about 40% of affected patients, is that of generalized pruritus (itching), particularly after bathing, without evidence of a rash.

The problems caused by thrombus formation, which would be expected with the increased viscosity of the blood and the increased platelet numbers, include transient ischemic attacks, cerebrovascular accidents, and myocardial infarctions. Hypertension and splenomegaly are also common.

A peculiar peripheral vascular event called **erythromelalgia** affects the hands and feet. Patients experience a painful burning sensation accompanied by erythema and warmth. This may eventually lead to thrombotic occlusion of the vessels that supply the digits. Digital gangrene and necrosis may result. Erythromelalgia is probably caused by excessive platelets, and its onset seems to be precipitated by exercise, standing, or warm temperatures.

Strangely enough, these patients may also have problems with excess hemorrhage. Epistaxis and ecchymoses are sometimes a problem, and gingival hemorrhage has been described.

Treatment and Prognosis

With the initial diagnosis of polycythemia vera, an immediate attempt is made to reduce the RBC mass. The first treatment is usually phlebotomy, with as much as 500 mL of blood removed every other day until a hematocrit of less than 45% is achieved. If thrombotic events are an immediate problem, then treatment with low-dose aspirin should be started. If difficulty in controlling the platelet levels is encountered, anagrelide hydrochloride, a selective inhibitor of megakaryocyte maturation and platelet production, may be prescribed. Antihistamines are used to help control the symptoms of pruritus.

Long-term management may include intermittent phlebotomy, as well as the relatively mild chemotherapeutic drug, hydroxyurea. Hydroxyurea is one chemotherapeutic agent that may not pose an increased risk of leukemia, however, because it acts as an antimetabolite and does not appear to have any mutagenic properties. If the patient cannot tolerate hydroxyurea, or if an inadequate response is seen, then treatment with recently developed medications that target the JAK2 pathway, such as pegylated interferon and ruxolitinib, may be appropriate. For resistant cases, myelosuppressive therapy has also been advocated, although an increased risk of leukemia is associated with some chemotherapeutic drugs. Nevertheless, in 2%–10% of patients with polycythemia vera, acute leukemia ultimately develops.

Overall, the prognosis is fair; patients with polycythemia vera survive an average of 10–12 years after the diagnosis, if treated. Given the fact that the median age at diagnosis is 60 years, the majority of affected patients do not seem to have a markedly higher death rate compared with their unaffected peers.

dentlearn.ir

LEUKEMIA

Leukemia represents several types of malignancies of hematopoietic stem cell derivation. The disease begins with the malignant transformation of one of the stem cells, which initially proliferates in the bone marrow and eventually overflows into the peripheral blood of the affected patient. Problems arise when the leukemic cells crowd out the normal defense cell and erythrocyte precursors. In the United States, approximately 3.4% of all cancers are leukemia, and 3.8% of deaths from cancer can be attributed to this disease.

Leukemias are usually classified according to their histogenesis and clinical behavior. Therefore, the broad categories would be **acute** or **chronic** (referring to the clinical course) and **myeloid** or **lymphocytic/lymphoblastic** (referring to the histogenetic origin). Myeloid leukemias can differentiate along several different pathways; thus they produce malignant cells that usually show features of granulocytes or monocytes, and less frequently, erythrocytes or megakaryocytes.

Acute leukemias, if untreated, run an aggressive course and often result in the death of the patient within a few months. Chronic leukemias tend to follow a more indolent course, although the end result is the same. One of the greatest successes in cancer treatment has been achieved in acute lymphoblastic leukemia of childhood, a condition that used to be uniformly fatal but now is often capable of being controlled.

Leukemias are probably the result of a combination of environmental and genetic factors. Certain syndromes are associated with an increased risk. These genetic disorders include the following:

- Down syndrome
- Bloom syndrome
- Neurofibromatosis type I
- Schwachman syndrome
- Ataxia-telangiectasia syndrome
- Klinefelter syndrome
- Fanconi anemia
- Wiskott-Aldrich syndrome

In addition, certain types of leukemia show specific chromosomal abnormalities. The first chromosomal abnormality to be detected was found in patients with **chronic myeloid leukemia,** and this malignancy was characterized by a genetic alteration called the **Philadelphia chromosome.** This abnormality represents a translocation of the chromosomal material between the long arms of chromosomes 22 and 9. This rearrangement of the genetic material occurs in such a fashion as to fuse the breakpoint cluster region *(BCR)* gene with the Abelson *(ABL)* oncogene, producing an entirely new gene: *BCR-ABL.* This gene is continuously transcribed, and the resulting protein product, a tyrosine kinase, causes the uncontrolled proliferation of the leukemic cells. Identifying such pathogenetic mechanisms has opened up an entirely new field of chemotherapy that targets specific molecular mechanisms of carcinogenesis. A variety of other genetic alterations in the bone marrow stem cells has been associated with the **myelodysplasia syndromes,** a group of disorders that appear to represent early stages in the evolution of **acute myeloid leukemia.** As the genetic alterations accumulate in the stem cells, the chances of the patient developing leukemia increase.

Some environmental agents are associated with an increased risk of leukemia, but their overall contribution to the leukemia problem is thought to be less than 5%. Exposure to pesticides, benzene, and benzene-like chemicals has been associated with an increased risk of developing leukemia. Ionizing radiation has also been implicated; this was documented by the increased frequency of chronic myeloid leukemia in the survivors of the atomic bomb blasts at Hiroshima and Nagasaki during World War II. Viruses have also been shown to produce leukemia, although this is not a common finding. The most thoroughly studied is the retrovirus known as *human T-cell leukemia/lymphoma virus type 1 (HTLV-1),* which is transmitted by contaminated blood from infected to uninfected individuals. This virus can cause a relatively rare form of malignancy of T lymphocytes, which may present as a leukemia or non-Hodgkin lymphoma (see page 600). Most cases have been identified in parts of the Caribbean, central Africa, and southwestern Japan.

As knowledge about this group of diseases increases, the fact that the leukemias are diverse and complex cannot be overlooked. For example, at least 11 distinct subtypes of acute myeloid leukemia have now been identified, and each subtype has a different treatment approach and prognosis. Because of the complexity of this area, the discussion is limited to those aspects of leukemia that are more directly related to the oral or head and neck region.

Clinical Features

If all types of leukemia are considered, this condition occurs at a rate of 13 cases per 100,000 population annually. Slightly more males than females are affected. The myeloid leukemias generally affect an adult population; **acute myeloid leukemia** affects a broader age range, which includes children. The median age of patients diagnosed with **chronic myeloid leukemia** is approximately 59 years. **Acute lymphoblastic leukemia,** in contrast, occurs predominantly in children and represents one of the more common childhood malignancies. **Chronic lymphocytic leukemia,** the most common type of leukemia, primarily affects older adults.

Many of the clinical signs and symptoms of leukemia are related to the marked reduction in the numbers of normal white and red blood cells, a phenomenon that results from the crowding out of the normal hematopoietic stem cells by the malignant proliferation **(myelophthisic anemia).** Because of the reduced red blood cell (RBC) count and subsequent reduction in oxygen-carrying capacity of the blood, patients complain of fatigue, easy tiring, and dyspnea on mild exertion. The malignant cells may also infiltrate other organs and often cause splenomegaly, hepatomegaly, and lymphadenopathy.

Leukemic patients may also complain of easy bruising and bleeding, problems that are caused by a lack of blood platelets

dentlearn.ir

(thrombocytopenia), the result of megakaryocytes being crowded out of the marrow. Petechial hemorrhages of the posterior hard palate and the soft palate may be observed, and these may be accompanied by spontaneous gingival hemorrhage, especially with platelet counts less than 10,000–20,000/mm^3. Because disturbances in stem cell differentiation accompany the myelodysplasia syndromes, thrombocytopenia is often present in these patients, and gingival hemorrhage has been reported in this setting. Serious hemorrhagic complications may result from bleeding into the CNS or the lungs.

A fever associated with infection may be the initial sign of the leukemic process. Perirectal infections, pneumonia, urinary tract infections, and septicemia are common infectious complications. The microorganisms that are typically involved include gram-negative bacteria, gram-positive cocci, and certain *Candida* species.

Ulceration of the oral mucosa is often present as a result of the impaired ability of the host to combat the normal microbial flora. Usually, the gingival mucosa is the most severely affected because of the abundant bacteria normally present around the teeth. The neutropenic ulcers that are produced are typically deep, punched-out lesions with a gray-white necrotic base. Oral candidiasis is often a complication of leukemia, involving the oral mucosa diffusely. Herpetic infections are the most common viral lesions, and these may involve any area of the oral mucosa rather than being confined to the keratinized mucosa, as in immunocompetent patients.

Occasionally, the leukemic cells infiltrate the oral soft tissues and produce a diffuse, boggy, nontender swelling that may or may not be ulcerated. This occurs most frequently with the myelomonocytic types of leukemia, and it may result in diffuse gingival enlargement (Figs. 13.17 and 13.18) or a prominent tumorlike growth (Fig. 13.19). The tumorlike collection of leukemic cells is known as **myeloid sarcoma,** a designation that has replaced the older terms, **granulocytic sarcoma** and **extramedullary myeloid tumor.** Historically the proliferation of leukemic cells was called *chloroma* because it is often greenish (*chlor* = green; *oma* = tumor) on fresh-cut sections. Other oral manifestations include infiltration of the periapical tissues, simulating periapical inflammatory disease both clinically and radiographically.

Histopathologic Features

Microscopic examination of leukemia-affected tissue shows diffuse infiltration and destruction of the normal host tissue by sheets of poorly differentiated cells with either myelomonocytic characteristics or lymphoid features.

Diagnosis

The diagnosis is usually established by confirming the presence of poorly differentiated leukemic cells in the peripheral blood and bone marrow. Bone marrow biopsy is normally performed in conjunction with the peripheral blood studies because some patients may go through an aleukemic phase in which the atypical cells are absent from

• **Fig. 13.18 Leukemia.** Extensive hemorrhagic enlargement of the maxillary and mandibular gingivae. (Courtesy of Dr. Michael Tabor.)

• **Fig. 13.17 Leukemia.** Diffuse gingival enlargement, as depicted in this photograph, may occur in leukemic patients, particularly in those with monocytic leukemia. (Courtesy of Dr. Spencer Shoff.)

• **Fig. 13.19 Leukemia.** The ulcerated soft tissue nodule of the hard palate represents leukemic cells that have proliferated in this area.

dentlearn.ir

the circulation. Classifying the type of leukemia requires establishing the immunophenotype by using immunohistochemical markers to identify cell surface antigens expressed by the tumor cells. Immunohistochemical confirmation of certain characteristic enzymes (e.g., myeloperoxidase and lysozyme) is necessary to identify and classify the myeloid leukemias. In addition, cytogenetic and molecular characterization of the lesional cells is typically necessary. In many cases, the results of these various studies will be significant because both the patient's treatment and the patient's prognosis are directly affected.

Treatment and Prognosis

Although a detailed discussion is beyond the scope of this text, the treatment of a patient with leukemia typically consists of various forms of chemotherapy; the type of leukemia dictates the chemotherapeutic regimen. In most cases the purpose of chemotherapy is to destroy as many of the atypical cells as possible in a short time, thus inducing a remission. For this reason, this technique has been termed **induction chemotherapy.** Usually, this phase of chemotherapy requires high doses of toxic chemotherapeutic agents; often, the patient experiences a number of unpleasant side effects during treatment. Once remission has been induced, this state must be maintained. This is the purpose of **maintenance chemotherapy,** which typically requires lower doses of chemotherapeutic drugs given over a longer period.

If the *BCR-ABL* fusion is identified in the leukemic cells of a patient with chronic myeloid leukemia, then treatment with a tyrosine kinase inhibitor is appropriate. The first tyrosine kinase inhibitor to be developed and marketed was imatinib mesylate, and at least half of these patients will respond dramatically to this therapy. Imatinib must be taken continuously, because relapses develop quickly if the drug is stopped. Unfortunately over 100 different mutations have been identified in this fused gene; consequently, 33% of chronic myelogenous leukemia patients will be resistant to imatinib. Additional BCR-ABL tyrosine kinase inhibitors, such as dasatinib, nilotinib, and bosutinib, have been developed and can be used as first-, second-, or third-line therapy. Chronic lymphocytic leukemia is considered curable only by treatment with allogeneic hematopoietic stem cell transplantation, a procedure that has its own risks and can be considered in patients less than 60 years of age. Most patients achieve a significant response when treated with traditional chemotherapeutic agents that are combined with monoclonal antibodies directed against one of the B-lymphocyte cell surface antigens. Rituximab, which is a CD20 antibody, has been effective in managing this disease; however, other monoclonal B-cell surface antibodies are being investigated. Drug therapy may be combined with radiation therapy to the CNS because the chemotherapeutic drugs often do not cross the blood-brain barrier effectively. Therefore, the leukemic cells may survive in this site and cause a relapse of the leukemia. Direct intrathecal infusion of the chemotherapeutic agent may be performed to circumvent the problem of the blood-brain barrier. If this strategy succeeds in inducing a remission, then a bone marrow transplant may be considered as a therapeutic option, particularly for the types of leukemia that tend to relapse. This option often is reserved for patients younger than 45 years of age because the success rate is less favorable in older patients.

Supportive care is often necessary if these patients are to survive their leukemia. For patients with bleeding problems, transfusions with platelets may be necessary. If severe anemia is present, packed RBCs may be required. Infections, of course, should be evaluated with respect to the causative organism, and appropriate antibiotics must be prescribed. Support must be maintained from an oral perspective because many of these patients experience infections of the oral mucosa during the course of their disease. Optimal oral hygiene should be encouraged, and aggressive investigation of any oral complaint should be performed as soon as possible to prevent potentially serious oral infectious complications.

The prognosis of a particular patient depends on a number of variables, including the type of leukemia, the age of the patient, and the cytogenetic alterations associated with the disease. In children with **acute lymphoblastic leukemia,** nearly 90% of these patients are now considered to be cured after appropriate treatment. In an adult with the same diagnosis, even though the rate of initial remission induction is 80%, the 5-year survival rate is generally much lower in most reported series.

Patients younger than 60 years of age with **acute myeloid leukemia** have a 5-year survival rate of approximately 40% today. This form of leukemia in a patient older than 60 years, however, has a much poorer prognosis, with less than a 10% chance of survival seen in that population. Similarly, patients with a previous history of myelodysplasia have an unfavorable prognosis.

Even though an indolent period is experienced with **chronic myeloid leukemia,** eventually the neoplastic cells undergo a process known as **blast transformation,** in which they become less differentiated, proliferate wildly, and cause the patient's death within 3–6 months. In the past, the 5-year survival rate for chronic myeloid leukemia was in the 20% range. Today, most centers are reporting 5-year survival rates of approximately 80%, a dramatic improvement presumably because of the effect of tyrosine kinase inhibitor therapy. Additional factors that may play a role in improved survival include diagnosis of the disease at an earlier stage and the availability of better supportive care. Attempts to control chronic myeloid leukemia by bone marrow transplantation from an HLA-matched donor have resulted in 5-year survival rates of 60%–70% in younger patients with this disease. This may be an option for those patients who do not respond to tyrosine kinase inhibitor therapy.

Chronic lymphocytic leukemia is considered to be incurable, but its course is highly variable and depends on the stage of the disease. Patients with limited disease have an average survival time of more than 10 years. Those with more advanced disease survive an average of only 2 years.

dentlearn.ir

◆ LANGERHANS CELL HISTIOCYTOSIS (HISTIOCYTOSIS X; LANGERHANS CELL DISEASE; IDIOPATHIC HISTIOCYTOSIS; EOSINOPHILIC GRANULOMA; LANGERHANS CELL GRANULOMA; LANGERHANS CELL GRANULOMATOSIS)

The term *histiocytosis X* was introduced as a collective designation for a spectrum of rare clinicopathologic disorders characterized by proliferation of histiocyte-like cells that are accompanied by varying numbers of eosinophils, lymphocytes, plasma cells, and multinucleated giant cells. The distinctive histiocytic cells present in this lesion have been identified as Langerhans cells, and the condition is now designated as **Langerhans cell histiocytosis.** In persons under 15 years of age, approximately 5 cases per million are diagnosed annually, however in adults the incidence drops to 1 in a million.

Langerhans cells are dendritic mononuclear cells normally found in the epidermis, mucosa, lymph nodes, and bone marrow. These cells process and present antigens to T lymphocytes. For many years, researchers have debated whether Langerhans cell histiocytosis represents a nonneoplastic condition or a true neoplasm. Studies examining the clonality of the lesional cells of this condition have shown this to be a monoclonal proliferation, a finding that is more consistent with a neoplastic process. *BRAF* or *MAP2K1* mutations have been identified in 40%–60% of Langerhans cell histiocytosis lesions, and these molecular alterations have been implicated in uncontrolled cell division related to several other neoplasms. Investigators have suggested that the varied clinical presentations of this condition may be related to the stage in the development of the Langerhans cell in which the *BRAF* or *MAP2K1* mutation occurs. When the mutation occurs early in the maturation process, a more aggressive, disseminated disease results; if the mutation happens in the later stages of maturation, a more localized, benign lesion develops.

Clinical and Radiographic Features

The clinicopathologic spectrum traditionally considered under the designation of Langerhans cell histiocytosis includes the following:

- Monostotic or polyostotic eosinophilic granuloma of bone—solitary or multiple bone lesions without visceral involvement
- Chronic disseminated histiocytosis—a disease involving bone, skin, and viscera **(Hand-Schüller-Christian disease)**
- Acute disseminated histiocytosis—a disease with prominent cutaneous, visceral, and bone marrow involvement occurring mainly in infants **(Letterer-Siwe disease)**

It is difficult to categorize many patients into one of these classic designations because of overlapping clinical features. The often-cited Hand-Schüller-Christian triad—bone lesions, exophthalmos, and diabetes insipidus—is present in only a few patients with chronic disseminated disease. It is widely believed that the traditional designations of Hand-Schüller-Christian and Letterer-Siwe disease serve no useful purpose and should be discontinued. Many cases reported as Letterer-Siwe disease in the older literature probably included obscure infections, immunodeficiency syndromes, and malignant histiocytic lesions. Pulmonary Langerhans cell histiocytosis has also been described, but this probably is unrelated to the condition that affects the jaws. Patients who develop pulmonary Langerhans cell histiocytosis are usually adults with a history of smoking, and clonality studies suggest that this is probably a reactive process. The Histiocyte Society, in order to better define prognostic categories of Langerhans cell histiocytosis, has proposed the following classification:

- Single organ involvement—typically bone or skin
  - Unifocal disease
  - Multifocal disease
- Multiorgan involvement
  - No organ dysfunction
  - Organ dysfunction
    - Low-risk (skin, bone, lymph nodes, and/or pituitary gland)
    - High-risk (lung, liver, spleen, and/or bone marrow)

Although Langerhans cell histiocytosis may be encountered in patients over a wide age range, more than 50% of all cases are seen in patients younger than age 15. Although some series have reported a male predilection, overall the sexes appear to be equally affected. Bone lesions, either solitary or multiple, are the most common clinical presentation. Lesions may be found in almost any bone, but the skull, ribs, vertebrae, and mandible are among the most frequent sites. Children younger than age 10 most often have skull and femoral lesions; patients older than age 20 more often have lesions in the ribs, shoulder girdle, and mandible. Adult patients with solitary or multiple bone lesions may have lymphadenopathy but usually do not have significant visceral involvement.

The jaws are affected in 10%–20% of all cases. Dull pain and tenderness often accompany bone lesions. Radiographically, the lesions often appear as sharply punched-out radiolucencies without a corticated rim, but occasionally an ill-defined radiolucency is seen. Bone involvement in the mandible usually occurs in the posterior areas, and a characteristic "scooped out" appearance may be evident when the superficial alveolar bone is destroyed. The resulting bone destruction and loosening of the teeth clinically may resemble severe periodontitis (Fig. 13.20). Extensive alveolar involvement causes the teeth to appear as if they are "floating in air" (Fig. 13.21).

Ulcerative or proliferative mucosal lesions or a proliferative gingival mass may develop if the disease breaks out of bone (Fig. 13.22). Occasionally, this process may involve only the oral soft tissues. Lesions also can occur within the body of the mandible or maxilla, where they may simulate a periapical inflammatory condition.

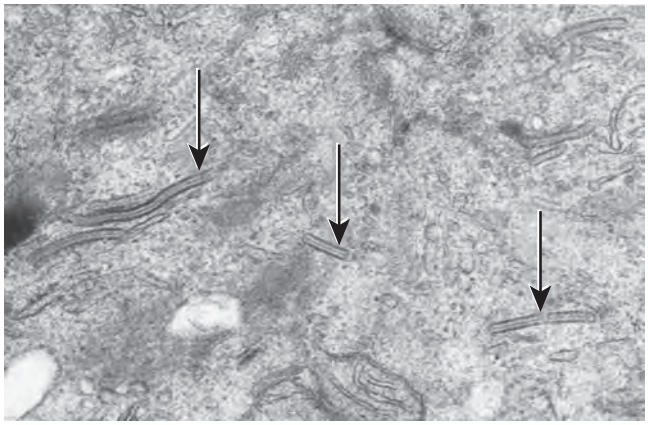
• **Fig. 13.22 Langerhans Cell Histiocytosis**. Clinical photograph of the same patient shown in Fig. 13.21. The lesion has broken out of bone and produced this soft tissue mass.

• **Fig. 13.21 Langerhans Cell Histiocytosis.** Periapical radiograph showing marked bone loss involving the mandibular teeth in a young girl, resulting in a "floating-in-air" appearance of the teeth.

• **Fig. 13.23 Langerhans Cell Histiocytosis.** There is a diffuse infiltrate of pale-staining Langerhans cells intermixed with numerous red granular eosinophils.

Histopathologic Features



The bone lesions of patients with Langerhans cell histiocytosis show a diffuse infiltration of large, pale-staining mononuclear cells that resemble histiocytes. These cells have indistinct cytoplasmic borders and rounded or indented vesicular nuclei. Varying numbers of eosinophils are typically interspersed among the histiocyte-like cells (Fig. 13.23). Plasma cells, lymphocytes, and multinucleated giant cells are often seen, and areas of necrosis and hemorrhage may be present.

The identification of lesional Langerhans cells is necessary to confirm the diagnosis. Because Langerhans cells cannot be differentiated from other histiocytes by routine histologic staining, additional diagnostic methods are required. Electron microscopic evaluation of lesional tissue was the gold standard for many years because, ultrastructurally, Langerhans cells contain rod-shaped cytoplasmic structures known as **Birbeck granules,** which differentiate them from other mononuclear phagocytes (Fig. 13.24). Immunohistochemical procedures are now used to identify the lesional Langerhans cells because of their immunoreactivity with antibodies directed against either CD-1a or CD-207 (langerin), and both markers are specific for Langerhans cell histiocytosis when seen in the correct clinical setting.

Treatment and Prognosis

Because this condition is relatively rare, treatment recommendations are often based on anecdotal experience, rather than randomized controlled trials. Most patients with oral involvement have single organ disease affecting the jaws, although other skeletal lesions may be present. Accessible bone lesions, such as those in the maxilla and mandible, are usually treated by curettage. Low doses of radiation

dentlearn.ir

• **Fig. 13.24 Langerhans Cell Histiocytosis.** Electron micrograph showing rod-shaped Birbeck bodies *(black arrows)* in the cytoplasm of a Langerhans cell. (Courtesy of Richard Geissler.)

may be used for less accessible bone lesions, although the potential for induction of malignancy secondary to this treatment is a concern in younger patients. Intralesional injection with corticosteroid agents has also been reported to be effective in some patients with localized bone lesions. Infrequently, the apparent spontaneous regression of localized Langerhans cell histiocytosis has been reported. The prognosis for bone lesions in the absence of significant visceral involvement is generally good; however, progression or dissemination of the disease may occur, particularly for patients who have three or more bones affected.

When multiple organs are involved, the low-risk pattern is often associated with considerable morbidity, but the mortality is much less than that of patients with high-risk organ involvement. Because of the relative rarity of disseminated cases, treatment protocols continue to be refined. Single-agent chemotherapy using prednisolone, etoposide, vincristine, or cyclosporine has produced a good response in a significant percentage of such patients, although recurrence is typically seen in over half of the cases. A combination of vincristine and prednisone, given over the period of a year, seems to reduce this risk of recurrence, particularly in children. Lesions in adults, however, respond much better to low-dose cytarabine (ara-C). Multiple high-risk organ involvement seen in infants and young children may not respond to these more conservative approaches, and multiple chemotherapeutic agents are given in that situation. In addition, hematopoietic stem cell transplantation may be an option. Patients who improve significantly with induction chemotherapy during the first 6 weeks have a much better prognosis (nearly 90% survival) compared to those who do not respond. In that group, only 20%–35% have survived historically. Drugs that specifically target the *BRAF* pathway, such as vemurafenib and dabrafenib, have shown promising initial results in experimental treatment trials examining their impact on multifocal high-risk Langerhans cell histiocytosis. In general, the prognosis is poorer for patients in whom the first sign of the disease develops at a very young age and somewhat better for patients who are older at the time of onset.

◆ HODGKIN LYMPHOMA (HODGKIN DISEASE)

Hodgkin lymphoma represents a malignant lymphoproliferative disorder, although for many years the exact nature of the process was poorly understood. The difficulty in comprehending the character of the condition is reflected in the relatively noncommittal term *Hodgkin disease*, which was used for decades and still may be heard today. Perhaps one reason why Hodgkin lymphoma was not easily understood is that, unlike most malignancies, the neoplastic cells **(Reed-Sternberg cells)** make up only about 0.1%–2% of the cells in the enlarged lymph nodes that characterize this condition. Current evidence regarding the histogenesis of the Reed-Sternberg cell points to a B-lymphocyte origin. Certainly, the disease can cause death if appropriate therapy is not instituted, although the treatment of this malignancy is one of the few major success stories in cancer therapy during the past 30 years. In the United States, Hodgkin lymphoma is about one-tenth as common as non-Hodgkin lymphoma; approximately 8500 cases are diagnosed annually. Although the cause of this disease is unknown, epidemiologic and molecular studies have linked Epstein-Barr virus (EBV) infection to a significant percentage of these lesions.

Clinical Features

Hodgkin lymphoma almost always begins in the lymph nodes, and any lymph node group is susceptible. The most common sites of initial presentation are the cervical and supraclavicular nodes (70%–75%) or the axillary and mediastinal nodes (5%–10% each). The disease initially appears less than 5% of the time in the abdominal and inguinal lymph nodes.

Overall, a male predilection is observed, and a bimodal pattern is noted with respect to the patient's age at diagnosis. One peak is observed between 15 and 35 years of age; another peak is seen after the age of 50.

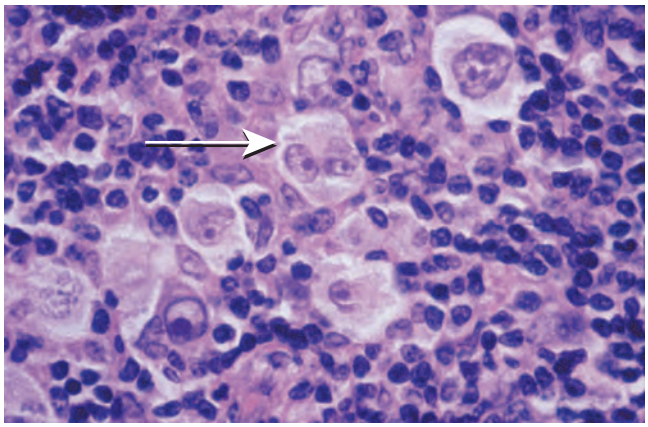
The usual presenting sign is the identification by the patient of a persistently enlarging, nontender, discrete mass or masses in one lymph node region (Fig. 13.25). In the early stages, the involved lymph nodes are often rather movable; as the condition progresses, the nodes become more matted and fixed to the surrounding tissues. If it is untreated, then the condition spreads to other lymph node groups and eventually involves the spleen and other extralymphatic tissues, such as bone, liver, and lung. Oral involvement has been reported, but it is rare. In about 30%–40% of patients with Hodgkin disease, other systemic signs and symptoms may be present, such as weight loss, fever, night sweats, and generalized pruritus (itching). The absence of these systemic signs and symptoms is considered to be better in terms of the patient's prognosis, and this information is used in staging the disease. Patients who have no systemic signs are assigned to category A and those with systemic signs to category B.

The staging of Hodgkin lymphoma is important for planning treatment and estimating the prognosis for a given

dentlearn.ir

• **Fig. 13.25 Hodgkin Lymphoma.** The prominent supraclavicular and cervical masses represent Hodgkin lymphoma.

patient. The staging procedure typically includes confirmation of the pathologic diagnosis, careful history and physical examination, abdominal and thoracic computed tomography (CT) scans or magnetic resonance imaging (MRI) studies, chest radiographs, and routine hematologic studies (e.g., complete blood count, serum chemistries, and erythrocyte sedimentation rate). Evaluation of the extent of disease involvement using (^{18}F)-fluorodeoxyglucose positron emission tomography (FDG PET/CT) scans is now part of the standard protocol, particularly at large institutions. The radiolabeled glucose is given intravenously, and the Hodgkin lymphoma cells metabolize this compound to a much greater extent than the normal tissues, thus identifying sites where tumor is present. Staging procedures that were used in the past, such as lymphangiography, gallium scan, bone marrow biopsy, exploratory laparotomy, and splenectomy, are often not necessary today. A summary of the staging system for Hodgkin lymphoma is presented in Table 13.2.



Histopathologic Features

Hodgkin lymphoma is recognized to comprise two main forms, (1) nodular lymphocyte–predominant Hodgkin lymphoma and (2) classical Hodgkin lymphoma, the latter of which is divided into five subtypes. Although this group of diseases has certain features in common, current immunohistochemical and molecular biologic techniques have allowed distinctions to be made among the various types. The common features include effacement of the normal nodal

TABLE 13.2 Ann Arbor System for Classification of Hodgkin Lymphoma

Stage	Defining Features
I	Involvement of a single lymph node region (I) or a single extralymphatic organ or site (I_E)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or one or more lymph node regions with an extralymphatic site (II_E)
III	Involvement of lymph node regions on both sides of the diaphragm (III), possibly with an extralymphatic organ or site (III_E), the spleen (III_S), or both (III_{SE})
IV	Diffuse or disseminated involvement of one or more extralymphatic organs (identified by symbols), with or without associated lymph node involvement
	A: Absence of systemic signs B: Presence of fever, night sweats, and/or unexplained loss of 10% or more of body weight during the 6-month period before diagnosis

Adapted from Gobbi PG, Ferreri AJM, Ponzoni M, et al: Hodgkin lymphoma, *Crit Rev Oncol Hematol* 85:216–237, 2013.

• **Fig. 13.26 Hodgkin Lymphoma.** This high-power photomicrograph shows the characteristic Reed-Sternberg cell *(arrow)* of Hodgkin lymphoma, identified by its "owl-eye" nucleus.

architecture by a diffuse, often mixed, infiltrate of inflammatory cells that is interspersed with large, atypical neoplastic lymphoid cells. In the case of classical Hodgkin lymphoma, this atypical cell is known as a **Reed-Sternberg cell** (Fig. 13.26). The Reed-Sternberg cell is typically binucleated ("owl-eye" nuclei), although it may be multinucleated ("pennies on a plate"), with prominent nucleoli. The malignant cell in nodular lymphocyte–predominant Hodgkin lymphoma is the "popcorn cell," which is so-named because of the resemblance of the nucleus to a kernel of popped corn. The pathologist must see one of these types of distinctive atypical cells to make a diagnosis of Hodgkin lymphoma, although

dentlearn.ir

their presence does not automatically imply that diagnosis, because similar cells may be seen in certain viral infections, especially infectious mononucleosis. To summarize, Hodgkin lymphoma is currently classified in the following manner:

- Nodular lymphocyte–predominant Hodgkin lymphoma, or
- Classical Hodgkin lymphoma (comprising five histopathologic subtypes):
  1. Lymphocyte rich
  2. Nodular sclerosis
  3. Mixed cellularity
  4. Lymphocyte depletion
  5. Unclassifiable

These names describe the most prominent histopathologic feature of each type, and specific epidemiologic and prognostic characteristics are associated with each type.

Nodular lymphocyte–predominant Hodgkin lymphoma constitutes 4%–5% of all cases of Hodgkin lymphoma in the United States. In the past, this form was probably combined with the lymphocyte-rich subtype, but the presence of the characteristic popcorn cells is a significant clue to the diagnosis.

Lymphocyte-rich classical Hodgkin lymphoma represents about 6% of all cases. Sheets of small lymphocytes with few Reed-Sternberg cells characterize this form.

The **nodular sclerosis** subtype makes up 60%–80% of cases and occurs more frequently in females during the second decade of life. This type gets its name from the broad fibrotic bands that extend from the lymph node capsule into the lesional tissue. Reed-Sternberg cells in the nodular sclerosis form appear to reside in clear spaces and, therefore, are referred to as *lacunar cells.*

The **mixed cellularity** form accounts for about 15%–30% of the cases and is characterized by a mixture of small lymphocytes, plasma cells, eosinophils, and histiocytes with abundant Reed-Sternberg cells.

The **lymphocyte depletion** subtype, the most aggressive type, makes up less than 1% of the cases in recent reports. Before modern immunohistochemical techniques, many examples of large cell lymphoma or anaplastic T-cell lymphoma were undoubtedly included in this category. In this form of Hodgkin lymphoma, numerous bizarre giant Reed-Sternberg cells are present, with few lymphocytes.

Occasionally, examples of Hodgkin lymphoma are encountered that really do not fit the criteria for any of the known subtypes, and these are designated as **unclassifiable.**

Treatment and Prognosis

The treatment of Hodgkin lymphoma depends on the stage of involvement. In the past, patients who had limited disease (stages I and II) often were managed by local radiation therapy alone. Recent treatment trends, however, combine less extensive radiotherapy fields with milder multiagent chemotherapy regimens to maximize disease control and minimize long-term complications of therapy. Patients with stage III or IV disease require chemotherapy; radiation therapy is used conjointly if significant mediastinal involvement or residual disease is detected. For many years a regimen known as **MOPP** (mechlorethamine, Oncovin, procarbazine, prednisone) was widely used to treat Hodgkin lymphoma. Because significant long-term side effects can be associated with this chemotherapy, other regimens, known as **ABVD** (Adriamycin, bleomycin, vinblastine, dacarbazine [DTIC]) and **BEACOPP** (bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine [Oncovin], procarbazine, prednisone), are now used most often because they have fewer complications.

Before modern cancer therapy was developed for Hodgkin lymphoma, the 5-year survival rate was only 5%. The prognosis for this disease is fairly good today; the best treatment results occur in those who present in the early stages. Patients with stage I and II disease often have an 80%–90% relapse-free 10-year survival rate; those with stage III and IV disease have a 55%–75% 10-year survival rate.

The histopathologic subtype of Hodgkin lymphoma appears to have minimal impact on the response to therapy. In the past, researchers believed that the lymphocyte depletion form had a poorer prognosis than the other subtypes. However, with newer immunohistochemical studies, clinicians now realize that many of these cases were misdiagnosed. In most instances, the stage of disease now plays a more important role in determining the patient's prognosis than does the histopathologic subtype.

After 15 years posttreatment, patient mortality is due more often to the complications of therapy: either secondary malignancy or cardiovascular disease. Currently, research is focused on the development of treatment regimens that continue to have a superior cure rate, while simultaneously decreasing the risk of treatment-related complications.

NON-HODGKIN LYMPHOMA

The **non-Hodgkin lymphomas** include a diverse and complex group of malignancies of lymphoreticular histogenesis and differentiation. In most instances, they initially arise within lymph nodes and tend to grow as solid masses. This is in contrast to lymphocytic leukemias (see page 593), which begin in the bone marrow and are characterized by a large proportion of malignant cells that circulate in the peripheral blood. The non-Hodgkin lymphomas most commonly originate from cells of the B-lymphocyte series, with an estimated 85% of European and American lymphoid neoplasms having this derivation. Tumors with a T-lymphocyte derivation are less common, whereas true histiocyte-derived lymphomas are even rarer.

The microscopic appearance of the lesional cells was used in the past to classify the tumors as either *lymphocytic* or *histiocytic.* With the development of modern immunologic techniques, however, it is now known that many of the lesions that had been classified as *histiocytic* were in fact neoplasms composed of transformed B lymphocytes. In the early 1980s, a group of American pathologists devised a classification scheme, known as the *Working Formulation for Clinical Use,* which may still be referred to in the United States. Based on this classification, lymphomas were broadly grouped into three categories:

dentlearn.ir

1. Low grade
2. Intermediate grade
3. High grade

Unfortunately, the Working Formulation has been shown to be somewhat limited in its utility and accuracy. Many lesions that have been recently defined are not included in this classification. For these reasons, an international study group in the early 1990s devised a new method of categorizing the lymphomas, known as the *REAL (revised European-American lymphoma) classification.* With this system, a combination of histopathologic features, immunologic cell surface markers, and gene rearrangement studies are used to organize this group of neoplasms. Further revisions to the World Health Organization (WHO) lymphoma classification system appear periodically as knowledge about this challenging area of pathology accumulates (Box 13.2).

• BOX 13.2 Classification of Hematopoietic and Lymphoid Neoplasms, Modified From the Revised European-American Lymphoma (REAL)/World Health Organization (WHO) Classification

B-Cell Neoplasms

I. Precursor B-cell neoplasm: Precursor B-acute lymphoblastic leukemia/LBL
II. Peripheral (mature) B-cell neoplasms
  A. B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma
  B. B-cell prolymphocytic leukemia
  C. Lymphoplasmacytic lymphoma/immunocytoma
  D. Mantle cell lymphoma
  E. Follicular lymphoma
  F. Extranodal marginal zone B-cell lymphoma of MALT type
  G. Nodal marginal zone B-cell lymphoma (± monocytoid B-cells)
  H. Splenic marginal zone lymphoma (± villous lymphocytes)
  I. Hairy cell leukemia
  J. Plasmacytoma/plasma cell myeloma
  K. Diffuse large B-cell lymphoma
  L. Burkitt lymphoma

T-Cell and Putative NK-Cell Neoplasms

I. Precursor T-cell neoplasm: Precursor T-acute lymphoblastic leukemia/LBL
II. Peripheral (mature) T-cell and NK-cell neoplasms
  A. T-cell chronic lymphocytic leukemia/prolymphocytic leukemia
  B. T-cell granular lymphocytic leukemia
  C. Mycosis fungoides/Sézary syndrome
  D. Peripheral T-cell lymphoma, not otherwise characterized
  E. Hepatosplenic gamma/delta T-cell lymphoma
  F. Subcutaneous panniculitis-like T-cell lymphoma
  G. Angioimmunoblastic T-cell lymphoma
  H. Extranodal T-/NK-cell lymphoma, nasal-type
  I. Enteropathy-type intestinal T-cell lymphoma
  J. Adult T-cell lymphoma/leukemia (HTLV 1+)
  K. Anaplastic large cell lymphoma, primary systemic type
  L. Anaplastic large cell lymphoma, primary cutaneous type
  M. Aggressive NK-cell leukemia

HTLV, human T-lymphotropic virus; *LBL*, lymphoblastic lymphoma; *MALT*, mucosa-associated lymphoid tissue; *NK*, natural killer.

This classification is more precise than the Working Formulation, and currently most pathologists in the United States categorize lymphomas according to the modified REAL system, although some of the more sophisticated molecular studies may not be available at smaller laboratories.

Approximately 77,000 cases of non-Hodgkin lymphoma are diagnosed in the United States annually; slightly more than one-fourth of this number will die of the disease each year. The incidence of this malignancy has been declining slightly in the United States over the past decade. The prevalence of lymphoma is increased in patients who have immunologic problems, such as congenital immunodeficiencies (e.g., Bloom syndrome, Wiskott-Aldrich syndrome, and common variable immunodeficiency), AIDS, organ transplantation, and autoimmune disease (e.g., Sjögren syndrome, systemic lupus erythematosus (SLE), and rheumatoid arthritis).

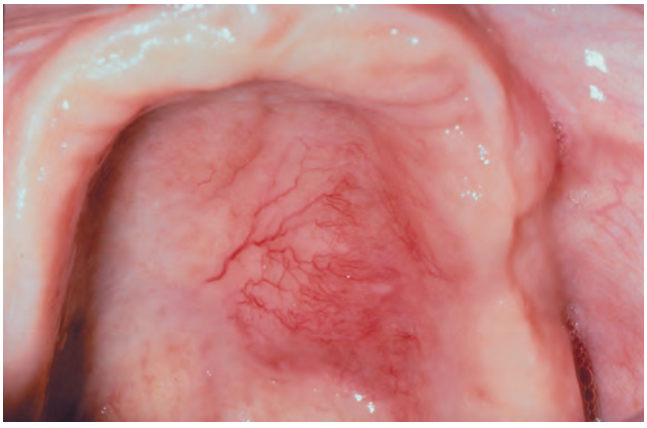
Viruses may play a role in the pathogenesis of at least some of these lesions. For example, Epstein-Barr virus (EBV) has been implicated, but not proven, to be an etiopathogenic agent in Burkitt lymphoma (see page 606), a type of high-grade, small, noncleaved B-cell lymphoma. EBV is more convincingly related to the development of various lymphoproliferative conditions (known as **EBV-associated lymphoproliferative disorders**) that range from benign, reactive processes through overt malignancies. Some of these occur in the setting of immune senescence (decreased function of the immune system with aging), whereas others are related to immunosuppressive medications (Fig. 13.27), immunosuppression after solid organ or bone marrow transplant, or in association with AIDS (see page 256). Human herpesvirus 8 (HHV-8) has not only been associated with Kaposi sarcoma but also with primary body cavity lymphoma and some cases of plasmablastic lymphoma. The blood-borne human retrovirus, human T-cell leukemia/lymphoma virus type I (HTLV-1), has been shown to cause an aggressive form of peripheral T-cell lymphoma among certain populations in the Caribbean, central Africa, and southwest Japan.

Even bacteria have been shown to induce the formation of so-called **mucosa-associated lymphoid tissue (MALT) lymphoma** of the stomach. Antibiotic treatment of *Helicobacter pylori* infection of the stomach lining often results in complete regression of this low-grade lymphoma.

Clinical and Radiographic Features

Non-Hodgkin lymphoma occurs primarily in adults, although children may be affected, particularly by the more aggressive intermediate- and high-grade lymphomas. The condition most commonly develops in the lymph nodes, but so-called extranodal lymphomas are also found. In the United States, approximately 20%–40% of lymphomas develop in an extranodal site, but in Asian countries such as Korea and Japan, nearly half of all lymphomas are extranodal.

With a nodal presentation, the patient usually is aware of a nontender mass that has been slowly enlarging for months. The lesion typically involves a local lymph node collection, such as the cervical, axillary, or inguinal nodes; one or two freely movable nodules are noticed initially. As the

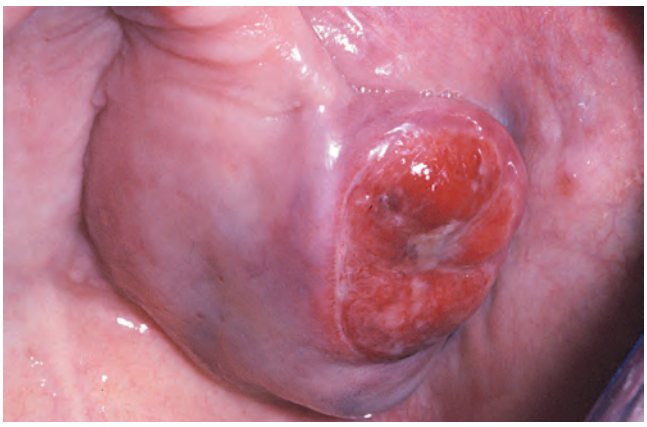


dentlearn.ir

• **Fig. 13.27 Epstein-Barr Virus (EBV)-Associated Lymphoproliferative Disorder. A,** This 42-year-old woman, treated for autoimmune hepatitis with mycophenolate mofetil, developed painful gingival ulcers. **B,** Resolution of the lesion after immune suppression was stopped and rituximab therapy was initiated.

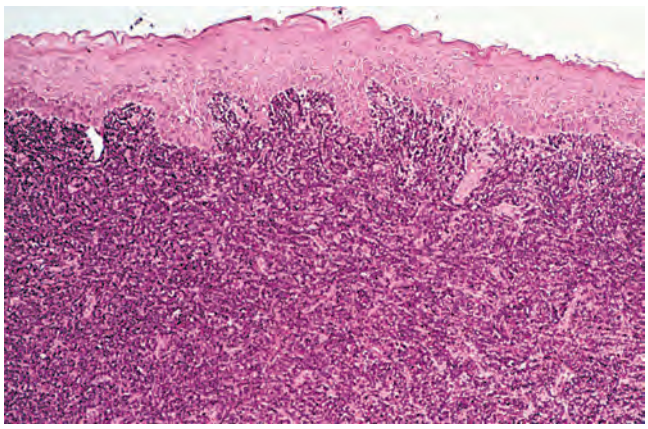
• **Fig. 13.28 Non-Hodgkin Lymphoma.** The matted, nontender lymph node enlargement in the lateral cervical region represents a common presentation of lymphoma.

• **Fig. 13.29 Non-Hodgkin Lymphoma.** One of the frequent locations of extranodal lymphoma in the head and neck area is the palate, where the tumor appears as a nontender, boggy swelling. Note the overlying telangiectatic blood vessels, a feature often seen with malignancy.



malignancy progresses, the nodes become more numerous and are fixed to adjacent structures or matted together (Fig. 13.28). Gradually, the process involves other lymph node groups, and invasion of adjoining normal tissues occurs.

In the oral cavity, lymphoma usually appears as extranodal disease. Although the oral lesions of lymphoma are often a component of more widely disseminated disease, at times the lymphoma begins in the oral tissues and has not spread to other sites. The malignancy may develop in the oral soft tissues or centrally within the jaws. Soft tissue lesions appear as nontender, diffuse swellings; they most commonly affect the buccal vestibule, posterior hard palate, or gingiva (Figs. 13.29 and 13.30). Such swellings characteristically have a boggy consistency. The lesion may appear erythematous or purplish, and it may or may not be ulcerated. Patients who wear a denture that contacts the lesional site often complain that their denture does not fit because it feels too tight.

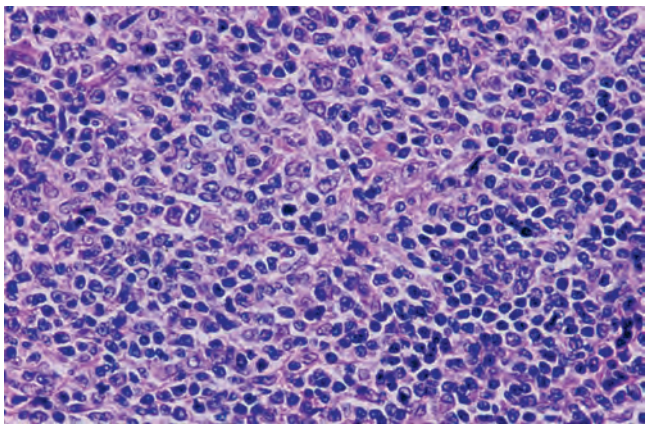


Lymphoma of bone may cause vague pain or discomfort, which might be mistaken for a toothache. The patient may complain of paresthesia, particularly with a mandibular lesion (so-called numb chin syndrome). Radiographs usually show an ill-defined or ragged radiolucency, although in the early stages, the radiographic changes may be subtle or nonexistent. If untreated, then the process typically causes expansion of the bone, eventually perforating the cortical plate and producing a soft tissue swelling. Such lesions have been mistaken for a dental abscess, although a significant amount of pain is not present in most cases.

Clinical staging to determine the extent to which the disease has spread is an important factor in assessing the prognosis for a particular patient. The staging evaluation should include a history, physical examination, complete blood

dentlearn.ir

• **Fig. 13.30 Non-Hodgkin Lymphoma.** Ulcerated mass of the left posterior maxilla.



• **Fig. 13.31 Non-Hodgkin Lymphoma.** This low-power photomicrograph shows a diffuse infiltration of the subepithelial connective tissue by lymphoma.

count, liver function studies, CT scans of the thoracic, pelvic and abdominal regions, and bone marrow biopsy. PET/CT scans are also very useful in staging, but this technique often is available only at larger medical centers. PET/CT is also employed to assess response to treatment, in addition to staging. Because of the information obtained with CT or PET/CT imaging, studies such as chest radiographs, lymphangiography, and staging laparotomy are not routinely performed today. The staging system for Hodgkin lymphoma (see Table 13.2) has been widely adopted for use with the non-Hodgkin lymphomas.

Histopathologic Features

Non-Hodgkin lymphomas are histopathologically characterized by a proliferation of lymphocytic-appearing cells that may show varying degrees of differentiation, depending on the type of lymphoma. Low-grade lesions consist of well-differentiated small lymphocytes. High-grade lesions tend to be composed of less differentiated cells. All lymphomas grow as infiltrative, broad sheets of relatively uniform neoplastic cells that usually show little or no evidence of lesional tissue necrosis (Figs. 13.31 and 13.32). In some lesions, particularly those of B-lymphocyte origin, a vague semblance of germinal center formation may be seen (i.e., a *nodular* or *follicular* pattern). Other lymphomas show no evidence of such differentiation, and this pattern is termed *diffuse.* If the lymphoma arises in a lymph node, then the tumor destroys the normal architecture of the node. An extranodal lymphoma destroys the normal adjacent host tissue by infiltrating throughout the area. In the oral cavity, diffuse large B-cell lymphoma, which is considered to be a high-grade lymphoma, is the most common diagnosis, comprising approximately 60% of the cases.

Standard of care demands that appropriate immunohistochemical and cytogenetic studies be performed for a tumor diagnosed as lymphoma. In general, these studies can become quite involved and, therefore, are beyond the scope of this text.

• **Fig. 13.32 Non-Hodgkin Lymphoma.** This high-power photomicrograph shows lesional cells of lymphoma, consisting of a population of poorly differentiated cells of the lymphocytic series with minimal cytoplasm.

Treatment and Prognosis

The treatment of a patient with non-Hodgkin lymphoma is based on several factors, including the type of lymphoma, the stage and grade of the lymphoma, the overall health of the patient, and the patient's pertinent past medical history. The patient's health must be considered because many of the chemotherapeutic regimens are quite debilitating. Surgical management is not usually indicated.

Because most non-Hodgkin lymphomas are of B-cell differentiation, many treatment strategies now incorporate monoclonal antibodies directed against CD20, a B-cell surface antigen, as part of the chemotherapeutic regimen for both low-grade and high-grade lymphomas. Rituximab is one of the more commonly used agents (see Fig. 13.27), although several others are now available. Novel monoclonal antibodies to CD20 and other lymphoid cell surface antigens are continually being developed and examined in clinical trials.

Low-grade (indolent) lymphomas are perhaps the most controversial in terms of treatment. Some authorities recommend no particular treatment because these tumors are slow

dentlearn.ir

growing and tend to recur despite chemotherapy. Given the fact that low-grade lymphomas arise in older adults and the median survival without treatment is 8–10 years, many oncologists in the past would opt for a "watch and wait" strategy, treating the patient only if symptoms develop. With the development of rituximab therapy, however, median survival in these patients is now 15 years. Unfortunately, approximately 40% of low-grade lymphomas eventually transform to a high-grade lymphoma, leading to the patient's demise. Because these low-grade lymphomas have been considered "incurable," new treatments are being investigated.

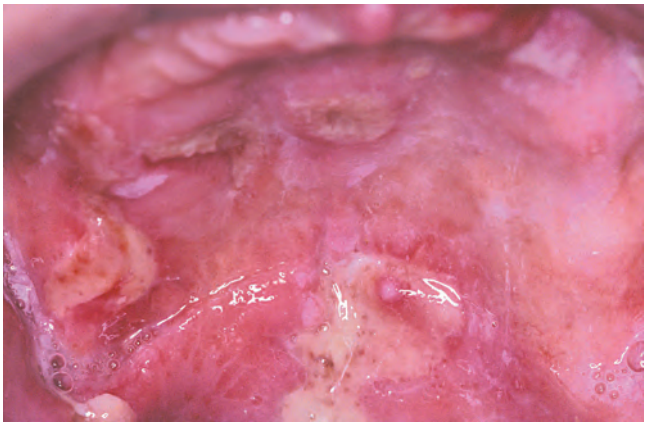
For **high-grade** (aggressive) lymphomas, the treatment of localized disease may consist of radiation plus chemotherapy. With more advanced and disseminated disease, chemotherapy alone usually is implemented. Multiagent chemotherapy is used routinely, and new combinations that include recently developed drugs, such as proteasome inhibitors and thalidomide analogues, are being evaluated continuously. Autologous hematopoietic stem transplantation or allogeneic bone marrow transplantation may also be used in some situations. In recent years, the response rate of many high-grade lymphomas has shown much improvement, although the cure rate generally is not high. Patients with some high-grade lymphomas may have a 60% survival rate at 5 years after diagnosis and treatment.

◆ MYCOSIS FUNGOIDES (CUTANEOUS T-CELL LYMPHOMA)

From its name, one might think that **mycosis fungoides** is a fungal infection. The early dermatologists who first recognized mycosis fungoides knew that this was not the case; however, they still thought the disease resembled a fungal condition. Thus this term has persisted. This condition, in fact, represents a lymphoma that is derived from T lymphocytes, specifically the T-helper (CD4+) lymphocyte. With modern diagnostic techniques, clinicians now know that there are several types of cutaneous lymphomas, each having specific T-lymphocyte or B-lymphocyte differentiation patterns. Even though mycosis fungoides is the most common of these cutaneous lymphomas, it is still a relatively rare malignancy; only about 1300 new cases are diagnosed in the United States annually. This condition exhibits a peculiar property called **epidermotropism** (i.e., a propensity to invade the epidermis of the skin). Oral involvement, although infrequent, may also be present.

Clinical Features

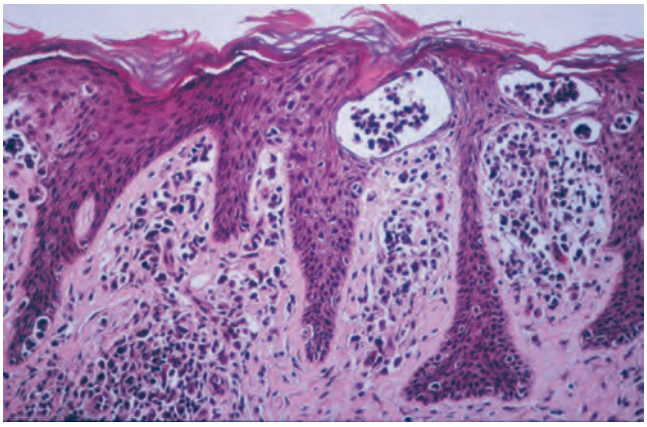
Mycosis fungoides is a condition that usually affects middle-aged adult men; there is a 2:1 male-to-female ratio and a mean age at diagnosis of 55–60 years. African-Americans appear to be affected approximately 1.5 times more frequently than other ethnic groups. The disease progresses through three stages, usually over the course of several years.



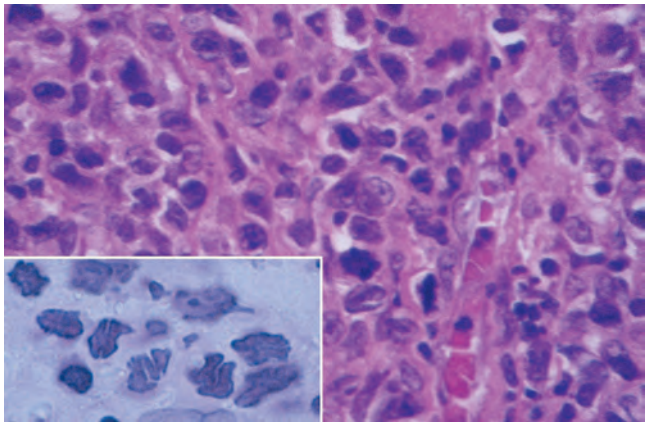
The first stage, known as the **eczematous (erythematous) stage,** is often mistaken for psoriasis of the skin because of the well-demarcated, scaly, erythematous patches that characterize these lesions. Patients may complain of pruritus. With time, the erythematous patches evolve into slightly elevated, red lesions **(plaque stage).** These plaques tend to grow and become distinct papules and nodules. At this time, the disease has entered the **tumor stage** (Fig. 13.33). Visceral involvement is also seen at this point.

Approximately 60 cases of mycosis fungoides with oral involvement have been reported. The most commonly affected sites are the tongue, palate, and gingiva (Fig. 13.34). The buccal mucosa, tonsils, lips, sinuses, and nasopharynx may also be affected. The oral lesions present as erythematous, indurated plaques or nodules that are typically ulcerated. Generally, these lesions appear late in the course of the disease and develop after the cutaneous lesions.

Sézary syndrome is an aggressive expression of mycosis fungoides that essentially represents a dermatopathic T-cell leukemia. The patient has a generalized exfoliative erythroderma, as well as lymphadenopathy, hepatomegaly, and splenomegaly.



• **Fig. 13.33 Mycosis Fungoides.** In the tumor stage of the disease, patients with mycosis fungoides have ulcerated nodules of the skin. (From Damm DD, White DK, Cibull ML, et al: Mycosis fungoides: initial diagnosis via palatal biopsy with discussion of diagnostic advantages of plastic embedding, *Oral Surg Oral Med Oral Pathol* 58:413–419, 1984.)



• **Fig. 13.34 Mycosis Fungoides.** The ulcerated palatal lesions represent a rare example of oral mucosal involvement by mycosis fungoides.

dentlearn.ir

• **Fig. 13.35 Mycosis Fungoides.** This medium-power photomicrograph of a cutaneous lesion of mycosis fungoides shows infiltration of the epithelium by the malignant infiltrate that forms Pautrier microabscesses.

• **Fig. 13.36 Mycosis Fungoides.** This high-power photomicrograph of an oral biopsy specimen reveals the atypical, malignant lymphoid cells of mycosis fungoides that exhibit cerebriform morphology *(inset)*.

The lung, kidneys, and CNS can also be involved. This condition follows a fulminant course and typically results in the patient's death within a short period of time; the median survival for this form of the disease is 2–3 years.

Histopathologic Features

Eczematous Stage

The early stages of mycosis fungoides may be difficult to diagnose histopathologically because of the subtle changes that characterize the initial lesions. A psoriasiform pattern of epithelial alteration is seen, with parakeratin production and elongation of the epithelial rete ridges. Scattered, slightly atypical lymphocytic cells may be seen in the connective tissue papillae, but such features are often mistaken for an inflammatory process.

Plaque Stage

With the development of the plaque stage, a more readily identifiable microscopic pattern emerges. Examination of the surface epithelium reveals infiltration by atypical lymphocytic cells, which are sometimes referred to as *mycosis cells* or *Sézary cells.* These atypical lymphocytes classically form small intraepithelial aggregates termed *Pautrier microabscesses* (Fig. 13.35). The lesional cells have an extremely unusual nucleus because of the marked infolding of the nuclear membrane, which results in what is termed a *cerebriform nucleus.* This feature can best be appreciated when viewed in special semithin, plastic-embedded microscopic sections (Fig. 13.36). The diagnosis of mycosis fungoides can be confirmed by demonstrating positivity for CD4 (a cell surface marker for T-helper cells) in the lesional cell population. In addition, T-cell receptor gene rearrangement analysis should identify a monoclonal population of T lymphocytes. A mixed infiltrate of eosinophils, histiocytes, and plasma cells may be observed in the subepithelial connective tissue.

Tumor Stage

As the condition progresses to the tumor stage, the diffuse infiltration of the dermis and epidermis by atypical lymphocytic cells makes it easier to identify as a malignant process. Other types of lymphoma would enter into the histopathologic differential diagnosis.

Immunohistochemical studies demonstrating a T-helper phenotype, combined with the T-cell receptor gene rearrangement studies, would help to distinguish the malignant infiltrate from other lymphomas and establish the diagnosis of mycosis fungoides. Examination of the peripheral blood of a patient with Sézary syndrome shows circulating atypical lymphoid cells.

Treatment and Prognosis

Topical nitrogen mustard, topical carmustine, superpotent topical corticosteroids, topical bexarotene (a synthetic retinoid), imiquimod, electron beam therapy, or photochemotherapy **(PUVA** [8-methoxy-**p**soralen + **u**ltra**v**iolet **A**]**)** are effective in controlling mycosis fungoides during the early stages. Ultimately, the topical forms of therapy fail, and aggressive chemotherapy is necessary, particularly if there is visceral involvement. Newer agents that may be added to the chemotherapy regimen include monoclonal antibodies (alemtuzumab; mogamulizumab), so-called HDAC-inhibitors (vorinostat and romidepsin), certain retinoid compounds (including systemic bexarotene), and specific interferon compounds. If Sézary syndrome develops, then extracorporeal photopheresis or chemotherapy is used as a treatment modality. Extracorporeal photopheresis involves removing of a small amount of the patient's blood and separating the red and white blood cells. The red blood cells are returned to the patient immediately. The white blood cells are mixed with the photoactive drug 8-methoxypsoralen, and are irradiated outside the body (extracorporeal) with ultraviolet A. These altered white cells are then infused back into the patient. Many of the altered white cells undergo apoptosis, but the procedure also may help generate an immunologic response to the patient's own abnormal lymphocytes. Allogeneic stem cell transplantation may also be an option for patients with advanced disease that has failed other treatments.

Although mycosis fungoides is not considered to be curable, the disease is usually slowly progressive. If the condition

dentlearn.ir

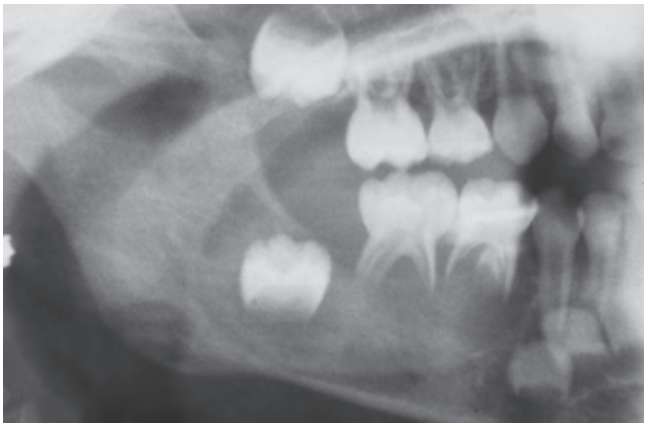
is identified in an early stage, the median overall survival can range from 20 to 35 years, and patients may die of causes unrelated to their lymphoma. Once the disease progresses beyond the cutaneous involvement, the course becomes much worse. In its later stages, the median overall survival rate typically ranges from 2 to 5 years, with the patient usually dying of organ failure or sepsis.

BURKITT LYMPHOMA

Burkitt lymphoma is a malignancy of B-lymphocyte origin that represents an undifferentiated lymphoma. It was named after the missionary doctor, Denis Burkitt, who first documented the process. In the original report, this type of lymphoma was described in young African children, and it seemed to have a predilection for the jaws. Because it was seen frequently in sub-Saharan Africa, the term **African Burkitt lymphoma** has been applied to the disease. It is now known to have increased prevalence in areas of the world where malaria is also seen, such as northeastern Brazil and New Guinea, and some investigators now refer to such tumors arising in these areas of increased prevalence as **endemic Burkitt lymphoma.** Examination of tumor tissue from the African cases led to the discovery of Epstein-Barr virus (EBV) by virologists in 1964. Although the mechanism is unknown, the pathogenesis of endemic Burkitt lymphoma is undoubtedly related to EBV because more than 90% of the tumor cells show expression of EBV nuclear antigen, and affected patients have elevated antibody titers to EBV. Malarial infection somehow plays a role in endemic Burkitt lymphoma as well, because patients with the highest antibody titers to *Plasmodium falciparum,* the causative organism of malaria, are most likely to develop the malignancy. Tumors with a similar histomorphology, commonly referred to as **sporadic** or **American Burkitt lymphoma,** have been observed in other countries, where the neoplasm is usually first detected as an abdominal mass. EBV is much less frequently identified in the sporadic tumors, however. Some HIV-related lymphomas may also have the microscopic features of Burkitt lymphoma, and these lesions have been designated **immunodeficiency-associated Burkitt lymphoma.** Similar tumors have been reported in other immunodeficiency settings, such as in patients who have received allografts or have a congenital immunodeficiency syndrome. Characteristic cytogenetic chromosomal translocations, which may also be responsible for neoplastic transformation, have been described in all three forms of Burkitt lymphoma.

Clinical and Radiographic Features

As many as 50%–70% of the cases of endemic Burkitt lymphoma present in the jaws. The malignancy usually affects children (peak prevalence, about 7 years of age) who live in Central Africa, and a male predilection is usually reported. The posterior segments of the jaws are more commonly affected, and the maxilla is involved more often than the mandible (a 2:1 ratio). Sometimes all four quadrants of the jaws show tumor involvement.

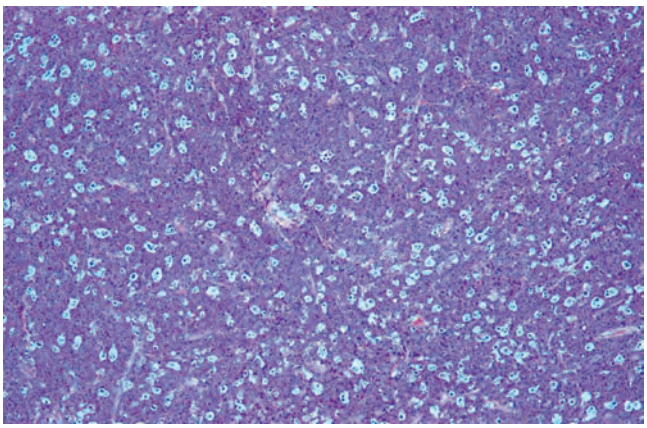


The tendency for jaw involvement seems to be age related; nearly 90% of 3-year-old patients have jaw lesions, in contrast to only 25% of patients older than age 15. Sporadic Burkitt lymphoma tends to affect patients over a greater age range than is noted for the African tumor. Although the abdominal region is typically affected, jaw lesions have been reported in sporadic Burkitt lymphoma (Fig. 13.37).

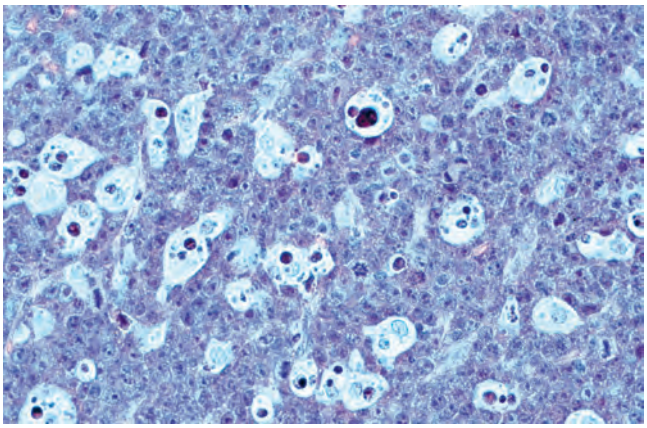
The growth of the tumor mass may produce facial swelling and proptosis. Pain, tenderness, and paresthesia are usually minimal, although marked tooth mobility may be present because of the aggressive destruction of the alveolar bone. Premature exfoliation of deciduous teeth and enlargement of the gingiva or alveolar process may also be seen.

The radiographic features are consistent with a malignant process and include a radiolucent destruction of the bone with ragged, ill-defined margins (Fig. 13.38). This process may begin as several smaller sites, which eventually enlarge and coalesce. Patchy loss of the lamina dura has been mentioned as an early sign of Burkitt lymphoma.

• **Fig. 13.37 Burkitt Lymphoma.** This patient had documented American Burkitt lymphoma involving the abdominal region. The retromolar swelling represents oral involvement with the malignancy.



• **Fig. 13.38 Burkitt Lymphoma.** This 4-year-old child had evidence of bone destruction with tooth mobility in all four quadrants of his jaws. Note the patchy, ill-defined loss of bone. (Courtesy of Dr. Gregory Anderson.)



dentlearn.ir

Histopathologic Features

Burkitt lymphoma histopathologically represents an undifferentiated, small, noncleaved B-cell lymphoma. The lesion invades as broad sheets of tumor cells that exhibit round nuclei with minimal cytoplasm. Each tumor nucleus often has several prominent nucleoli, and numerous mitoses are seen. Immunohistochemical studies using markers that identify proliferating cells (e.g., Ki-67) typically indicate that almost 100% of the tumor cells are in the process of replicating. On viewing the lesion on low-power magnification, a classic "starry-sky" pattern is often appreciated—a phenomenon that is caused by the presence of macrophages within the tumor tissue (Fig. 13.39). These macrophages have abundant cytoplasm, which microscopically appears less intensely stained in comparison with the surrounding process. Thus these cells tend to stand out as "stars" set against the "night sky" of deeply hyperchromatic neoplastic lymphoid cells (Fig. 13.40).

• **Fig. 13.39 Burkitt Lymphoma.** This low-power photomicrograph shows the classic "starry-sky" appearance, a pattern caused by interspersed histiocytic cells with abundant cytoplasm ("stars") set against a background of malignant, darkly staining lymphoma cells ("night sky").

• **Fig. 13.40 Burkitt Lymphoma.** This high-power photomicrograph demonstrates the undifferentiated, small, dark lesional cells with numerous histiocytes.

Because the histopathologic features of Burkitt lymphoma can appear similar to some cases of diffuse large B-cell lymphoma, standard of care now dictates that, in addition to immunohistochemical studies, molecular genetic analysis of the tumor tissue should be performed. This distinction is important because these two malignancies are treated differently. Burkitt lymphoma is characterized by one of several specific translocations, the most common being t(8;14)(q24;q32), that results in overexpression of the oncogene *c-myc,* an event that presumably drives the neoplastic proliferation.

Treatment and Prognosis

Burkitt lymphoma is an aggressive malignancy that usually results in the death of the patient within 4–6 months after diagnosis if it is not treated. In the past, even with treatment, the prognosis for Burkitt lymphoma was poor, with a median survival time of only 10.5 months.

More recently, intensive, multiagent chemotherapeutic protocols, which emphasize the use of high doses of cyclophosphamide, have shown an 85%–95% event-free (no evidence of recurrence) survival rate 3–5 years after treatment for younger patients, particularly those with relatively early, stage I or II, disease. Adults tend to be less tolerant of intensive multiagent chemotherapy; however, a large controlled study has shown that the addition of the monoclonal antibody, rituximab, to a less aggressive multiagent chemotherapeutic regimen can improve the 3-year, event-free survival rate in adults with Burkitt lymphoma to 75%, compared to 62% for those patients who received chemotherapy without rituximab. Relapsed Burkitt lymphoma has a very poor prognosis unfortunately.

◆ EXTRANODAL NK/T-CELL LYMPHOMA, NASAL-TYPE (ANGIOCENTRIC T-CELL LYMPHOMA; MIDLINE LETHAL GRANULOMA; IDIOPATHIC MIDLINE DESTRUCTIVE DISEASE; POLYMORPHIC RETICULOSIS; MIDLINE MALIGNANT RETICULOSIS; ANGIOCENTRIC IMMUNOPROLIFERATIVE LESION)

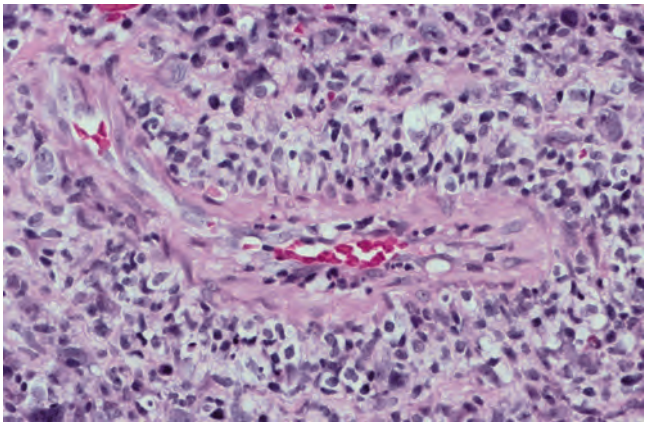
Extranodal NK/T-cell lymphoma, nasal-type is a rare malignancy that is characterized clinically by aggressive, nonrelenting destruction of the midline structures of the palate and nasal fossa. For many decades, the nature of this process was controversial, a fact that can readily be appreciated by the wide variety of terms by which it has been called. In actuality, many of the cases reported as "midline lethal granuloma" in the past represented a wide variety of immunologic (e.g., Wegener granulomatosis) and infectious (e.g., tertiary syphilis) diseases. The term **midline lethal granuloma** should be used only as a descriptive designation of a destructive midline condition, and thorough diagnostic evaluation, including biopsy and culture, is necessary to make a definitive

dentlearn.ir

diagnosis. Once the other causes of midline destruction have been eliminated, in most cases this disorder can be identified as a *natural killer (NK)/T-cell lymphoma,* based on modern cytogenetic, immunologic, and molecular studies. Epstein-Barr virus (EBV) is thought to play a significant role in the pathogenesis of this malignancy, and by the WHO criteria, *in situ* evidence of EBV in the lesional cells is necessary to make this diagnosis. The difficulty in distinguishing among these destructive disorders can be appreciated by the fact that **lymphomatoid granulomatosis,** which had been considered part of this T-cell lymphoma spectrum, is now known to be an EBV-driven proliferation of B lymphocytes.

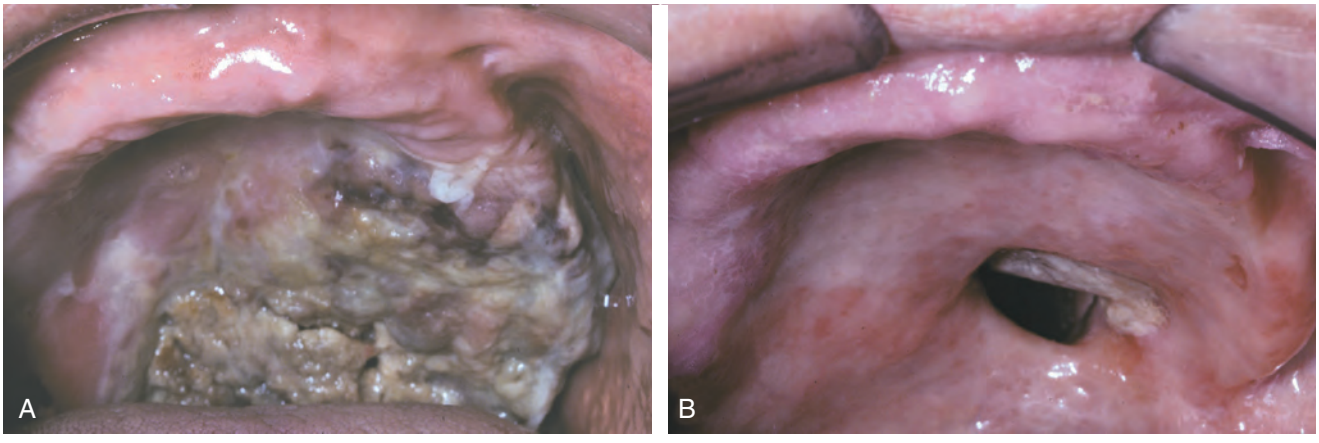
Even though extranodal NK/T-cell lymphoma often does not have the classic histopathologic features of lymphoma microscopically, it behaves in a malignant fashion and responds to the same treatments to which lymphomas respond. For reasons that are unclear, this condition is seen with greater frequency in Asian, Guatemalan, and Peruvian populations.

Clinical Features



Extranodal NK/T-cell lymphoma is typically observed in adults, and a male predilection is noted in most case series. The initial signs and symptoms are often localized to the nasal region and include nasal stuffiness or epistaxis. Pain may accompany the nasal symptoms. Swelling of the soft palate or posterior hard palate may precede the formation of a deep, necrotic ulceration, which usually occupies a midline position. This ulceration enlarges and destroys the palatal tissues, which typically creates an oronasal fistula (Fig. 13.41). Secondary infection may complicate the course of the disease, and life-threatening hemorrhage is a potential problem in some instances.

Histopathologic Features



Histopathologic examination of one of these lesions shows a mixed infiltrate of a variety of inflammatory cells, often arranged around blood vessels (angiocentric) (Fig. 13.42). The lesional process appears to invade and destroy the normal tissue in the area. Necrosis is often present in some areas of the lesion, presumably secondary to infiltration of the blood vessels by the tumor cells. Medium to large, angular, lymphocytic cells with an atypical appearance are usually identified as a component of the cellular infiltrate. Immunohistochemical evaluation of this infiltrate shows that the atypical cells mark with antibodies directed against either NK-cell antigens (such as CD56) or T-lymphocyte antigens (such as CD3). Probes for EBV-encoded RNA (EBER) should label nearly all of the tumor cells as well. Molecular genetic studies may show monoclonal gene rearrangements of the T-lymphocyte receptor, consistent with a lymphoreticular malignancy, in those tumors that have T-cell, rather than NK-cell, differentiation.

Treatment and Prognosis

Without treatment, extranodal NK/T-cell lymphoma is a relentlessly progressive, highly destructive process that ultimately leads to the patient's death by secondary infection,

• **Fig. 13.42 Extranodal NK/T-Cell Lymphoma, Nasal-Type.** This medium-power photomicrograph shows atypical lymphoid cells infiltrating the wall and filling the lumen of a blood vessel. Such a pattern is termed *angiocentric* (i.e., around blood vessels).

• **Fig. 13.41 Extranodal NK/T-Cell Lymphoma, Nasal-Type. A,** This 62-year-old man had a destructive palatal lesion that proved to be a T-cell lymphoma, and evaluation showed cervical lymph node involvement as well. **B,** Resolution of the lesion 1 month later, after multiagent chemotherapy.

dentlearn.ir

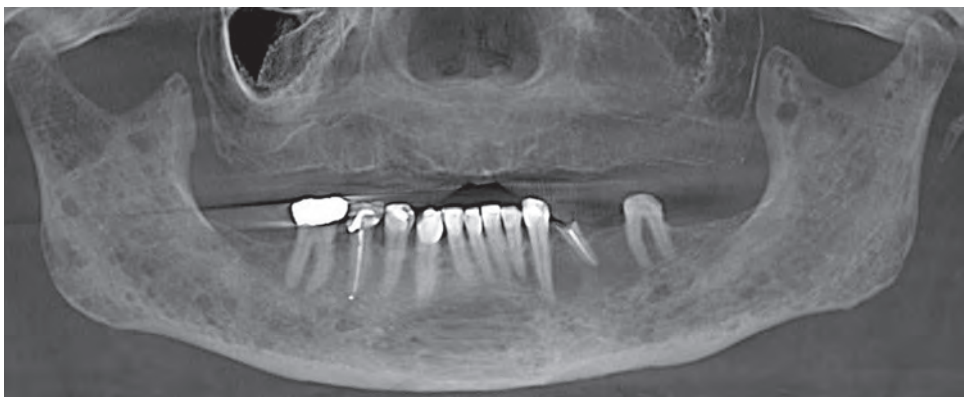
massive hemorrhage, or infiltration of vital structures in the area. Lesions that are localized usually respond to radiation therapy, a feature that is similar to that of T-cell lymphomas of other sites. Treatment with 40–50 Gy will appear to control the disease, although dissemination of the lesion develops in approximately 30% of these patients. Similarly, multiagent chemotherapy that includes anthracyclines results in relapse. Concurrent or sequential radiation therapy, in conjunction with a multidrug chemotherapeutic regimen that includes a platinum compound or pegylated asparaginase, is now recommended. Five-year survival rates are usually reported to be in the range of 65%–85%. For patients with more disseminated disease, combination chemotherapy is indicated, and a less favorable prognosis can be expected, with 30%–50% 5-year survival generally reported.

◆ MULTIPLE MYELOMA

Multiple myeloma is a relatively uncommon malignancy of plasma cell origin that often appears to have a multicentric origin within bone. The cause of the condition is unknown, although sometimes a plasmacytoma (see page 611) may evolve into multiple myeloma. This disease makes up about 1% of all malignancies and 10%–15% of hematologic malignancies. If metastatic disease is excluded, then multiple myeloma accounts for nearly 50% of all malignancies that involve the bone. Over 32,000 cases are diagnosed annually in the United States.

The abnormal plasma cells that compose this tumor are typically monoclonal. The abnormal cells probably arise from a single malignant precursor that has undergone uncontrolled mitotic division and has spread throughout the body. Because the neoplasm develops from a single cell, all of the daughter cells that comprise the lesional tissue have the same genetic makeup and produce the same proteins. These proteins are the immunoglobulin components that the plasma cell would normally produce, although in the case of this malignant tumor the immunoglobulins are not normal or functional. The signs and symptoms of this disease result from the uncontrolled proliferation of the tumor cells and the uncontrolled manufacture of their protein products.

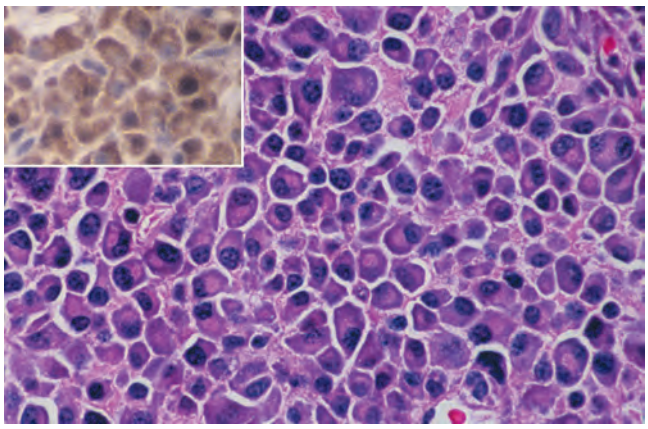
Clinical and Radiographic Features



Multiple myeloma is typically a disease of adults, with men being affected slightly more often than women. The median age at diagnosis is between 60 and 70 years, and it is rarely diagnosed before age 40. For reasons that are not understood, the disease occurs twice as frequently in blacks as whites, making this the most common hematologic malignancy among black persons in the United States.

Bone pain, particularly in the lumbar spine, is the most characteristic presenting symptom. Some patients experience pathologic fractures caused by tumor destruction of bone. They may also complain of fatigue as a consequence of myelophthisic anemia. Petechial hemorrhages of the skin and oral mucosa may be seen if platelet production has been affected. Fever may be present as a result of neutropenia with increased susceptibility to infection. Metastatic calcifications may involve the soft tissues and are thought to be caused by hypercalcemia secondary to tumor-related osteolysis.

Radiographically, multiple well-defined, punched-out radiolucencies or ragged radiolucent lesions may be seen in multiple myeloma (Fig. 13.43). These may be especially evident on a skull film. Although any bone may be affected, the jaws have been reported to be involved in as many as 30% of cases. The radiolucent areas of the bone contain the abnormal plasma cell proliferations that characterize multiple myeloma.



Renal failure may be a presenting sign in these patients because the kidneys become overburdened with the excess circulating light chain proteins of the tumor cells. These light chain products, which are found in the urine of 30%–50% of patients with multiple myeloma, are called **Bence Jones proteins,** after the British physician who first described them in detail.

Approximately 10%–15% of patients with multiple myeloma show deposition of amyloid (see page 824) in various soft tissues of the body, and this may be the initial manifestation of the disease. Amyloid deposits are due to the accumulation of the abnormal light chain proteins. A recent study found that approximately 3% of newly diagnosed multiple myeloma patients presented with oral mucosal amyloid deposition. The tongue is the oral site that is most common affected, typically showing diffuse enlargement and firmness. A nodular pattern may also involve tongue, and sometimes the nodules are ulcerated. Another area that is commonly

• **Fig. 13.43 Multiple Myeloma.** Multiple myeloma affecting the mandible. The disease produced multiple, small, "punch-out" radiolucencies. (Courtesy of Dr. Matthew D'Addario.)

dentlearn.ir

• **Fig. 13.44 Multiple Myeloma.** This high-power photomicrograph reveals sheets of malignant plasma cells with eccentric nuclei and stippled nuclear chromatin. Immunohistochemical studies *(inset)* show a uniform reaction of the lesional cells for antibodies directed against kappa light chains, indicating a monoclonal neoplastic proliferation.

affected is the periorbital skin, with the amyloid deposits appearing as waxy, firm, plaquelike lesions (see Fig. 17.7 on page 825).

Histopathologic Features

Histopathologic examination of the lesional tissue in multiple myeloma shows diffuse, monotonous sheets of neoplastic, variably differentiated, plasmacytoid cells that invade and replace the normal host tissue (Fig. 13.44). Mitotic activity may be seen with some frequency. The monoclonality of the plasma cell population can be demonstrated using antibodies directed against the lambda and kappa light chain components of the immunoglobulin molecule. In a neoplastic proliferation of plasma cells, virtually all of the lesional cells will mark with only one of these antibodies. In contrast, a reactive plasma cell infiltrate will show a mixture of lambda- and kappa-producing plasma cells. Occasionally, deposition of amyloid may be observed in association with the neoplastic cells. Like other types of amyloid, this material appears homogeneous, eosinophilic, and relatively acellular. It stains metachromatically with crystal violet and shows an affinity for Congo red, demonstrating apple-green birefringence on viewing with polarized light. A biopsy specimen of bone marrow from a patient with multiple myeloma should show at least 10% atypical plasma cells making up the marrow cell population.

Diagnosis

Although the histopathologic and radiographic findings may strongly suggest a diagnosis of multiple myeloma, screening of the serum or urine by protein electrophoresis should be performed. If an abnormality is detected, then this should be confirmed by protein immunoelectrophoresis, which is a more sensitive test, as an additional parameter to establish the diagnosis. The serum and urine protein immunoelectrophoresis should show the presence of myeloma protein (M-protein). This represents the massive over-production of one abnormal immunoglobulin by the neoplastic clone of plasma cells, thus this feature is termed **monoclonal gammopathy.** This monoclonal protein consists of two heavy chain polypeptides of the same immunoglobulin (Ig) class (IgA, IgG, IgM, IgD, or IgE) and one of two light chain polypeptides of the same class (kappa or lambda). Occasionally, the neoplastic cells produce only the light chain component.

Treatment and Prognosis

The goals of treatment related to multiple myeloma include not only controlling the malignancy but also making the patient comfortable and prolonging the patient's survival. Initial attempts to control multiple myeloma generally consist of chemotherapy. Several combinations of chemotherapeutic agents are available, and the choice of which regimen to use in a particular patient often depends on the cytogenetic profile of their myeloma cells. The cytogenetic profile identifies the presence or absence of any of several chromosomal translocations, deletions, or trisomies of patient's tumor, which predicts a low-, standard-, intermediate- or high-risk of progression of the malignancy. Detailed discussion of the treatment of multiple myeloma is beyond the scope of this text, however the drugs that are used to treat this disease typically include a corticosteroid (usually dexamethasone or prednisone) in addition to one or more other drugs, such as an alkylating agent (melphalan or cyclophosphamide), an immune-modulating agent (thalidomide, lenalidomide, or pomalidomide), a proteasome inhibitor (bortezomib, carfilzomib, or ixazomib), or a monoclonal antibody (elotuzumab, daratumumab, or isatuximab). Usually the malignancy responds to the multidrug therapy, however relapse is common, and autologous stem cell transplantation is then performed. More aggressive chemotherapeutic regimens, as well as allogeneic bone marrow transplantation, may be considered in otherwise healthy patients under the age of 55–65 years, but these individuals comprise a minority of multiple myeloma patients. Radiation therapy is useful only as palliative treatment for painful bone lesions. Any one of several bisphosphonate medications (clodronate, pamidronate, or zoledronic acid) can be prescribed to reduce the possibility of myeloma-related fracture with its attendant pain, but these medications do not increase survival. A small percentage of these patients may experience the complication of medication-related osteonecrosis of the jaws (see page 286), and many oncology centers insist that myeloma patients receive a complete oral examination in order to identify and resolve any potential conditions that could predispose to jaw infection.

While it is unlikely that multiple myeloma can be cured, the prognosis varies considerably among affected individuals. A variety of factors play a role in predicting prognosis, with younger patients tending to do better than older ones. Patients with other systemic diseases have a worse prognosis, as do patients who present with more widespread lesions, and patients who do not respond well to initial therapy. As mentioned earlier, the prognosis is also dependent on certain chromosomal and molecular genetic features, with hyperdiploid lesions being more aggressive, as well as those with certain chromosomal translocations.

dentlearn.ir

Patients who fall in the standard-risk category can expect to have a median survival rate of 6–7 years following diagnosis, whereas those who are high-risk can expect a median survival of 2–3 years. These figures, while not encouraging at first glance, are much improved compared to just two to three decades ago, when a 10% 5-year survival was typical.

◆ PLASMACYTOMA

The **plasmacytoma** is a unifocal, monoclonal, neoplastic proliferation of plasma cells that usually arises within bone. Infrequently, it is seen in soft tissue, in which case, the term **extramedullary plasmacytoma** is used. Some investigators believe that this lesion represents the least aggressive part of a spectrum of plasma cell neoplasms that extends to **multiple myeloma.** Therefore, the plasmacytoma is important because it may ultimately give rise to the more serious problem of multiple myeloma.

Clinical and Radiographic Features

The plasmacytoma usually is detected in an adult male, with an average age at diagnosis of 55 years. The male-to-female ratio is approximately 2:1. Most of the lesions present centrally within a single bone, and the spine is the most commonly involved site. About one-third of the cases are reported in that location. The initial symptoms often relate to swelling or bone pain; occasionally, however, this lesion is detected on routine radiographic examination. The extramedullary plasmacytoma appears as a relatively nondescript, well-circumscribed, nontender soft tissue mass. A slightly stronger male predilection is seen with this lesion, approaching a 3:1 male-to-female ratio. Approximately 25% of extramedullary plasmacytomas develop in the head and neck region, and such lesions have been reported in the tonsils, the nasopharynx, the paranasal sinuses, the nose, and the parotid gland.

Radiographically, the lesion may be seen as a well-defined, unilocular radiolucency with no evidence of sclerotic borders or as a ragged radiolucency similar to the appearance of multiple myeloma (Fig. 13.45). No other lesions should be identifiable by a skeletal survey using MRI, PET/CT, and careful physical examination, however.

Histopathologic Features

The histopathologic features of the plasmacytoma are identical to those of multiple myeloma. Sheets of plasma cells show varying degrees of differentiation. Immunohistochemical studies demonstrate that these plasma cells are monoclonal. As many as 25%–50% of these patients also show a monoclonal gammopathy on evaluation by serum protein immunoelectrophoresis, although the amount of abnormal protein is much less than that seen with multiple myeloma. Solitary plasmacytoma also differs from multiple myeloma in that no evidence of plasma cell infiltration should be seen by a random bone marrow biopsy, and the patient should not show signs of anemia, hypercalcemia, or renal failure.

• **Fig. 13.45 Plasmacytoma.** This computed tomography (CT) scan depicts a solitary plasmacytoma involving the left maxillary sinus and nasal cavity.

Immunohistochemically, extramedullary plasmacytoma appears to differ from its intrabony counterparts in that it shows a marked decrease or lack of immunoreactivity for antibodies directed against cyclin D1 and CD56.

Treatment and Prognosis

Plasmacytomas are usually treated with radiation therapy, and typically a dose of at least 40 Gy is delivered to the tumor site. A few lesions have been surgically excised with good results, although this is not the preferred treatment in most instances. PET/CT is typically used to determine the efficacy of therapy, based on the marked reduction in metabolic activity at the tumor site. Unfortunately, when patients with plasmacytoma of bone are observed on a long-term basis, most will eventually develop multiple myeloma. From 65%–85% show evidence of disseminated disease by 10 years after their initial diagnosis. However, virtually all of these patients will develop multiple myeloma by 15 years following their diagnosis. Extramedullary plasmacytoma seems to have a much better prognosis, with less than 30% of these patients showing progression to multiple myeloma and 70% having a 10-year disease-free period after treatment.

Bone Pathology

◆ OSTEOGENESIS IMPERFECTA ("BRITTLE BONE DISEASE")

Osteogenesis imperfecta comprises a heterogeneous group of heritable disorders characterized by osteopenia (low bone density) and bone fragility. This condition represents one of the most common heritable bone diseases and is estimated to affect 1 in 10,000 to 15,000 live births.

Approximately 90% of cases exhibit an autosomal dominant inheritance pattern with mutations in one of two type I collagen genes: *COL1A1* and *COL1A2.* In addition, there are numerous other variants (mainly autosomal recessive) caused by recently discovered mutations in genes related to type I collagen post-translational modification, processing, and cross-linking; bone mineralization; osteoblast differentiation; and other functions. Sporadic cases are possible as well.

Type I collagen is a major constituent of bone, dentin, sclerae, ligaments, and skin; osteogenesis imperfecta may affect any of these tissue types. Type I collagen is a triple helical molecule composed of peptide chains encoded by *COL1A1* and *COL1A2.* Defects in the complex process of synthesis, post-translational modification (including hydroxylation, crosslinking, and terminal propeptide cleavage), and chaperone-guided protein folding result in abnormal type I collagen with low tensile strength. Consequently, the bone is brittle; upon fracture, healing will occur but may be associated with exuberant callus formation.

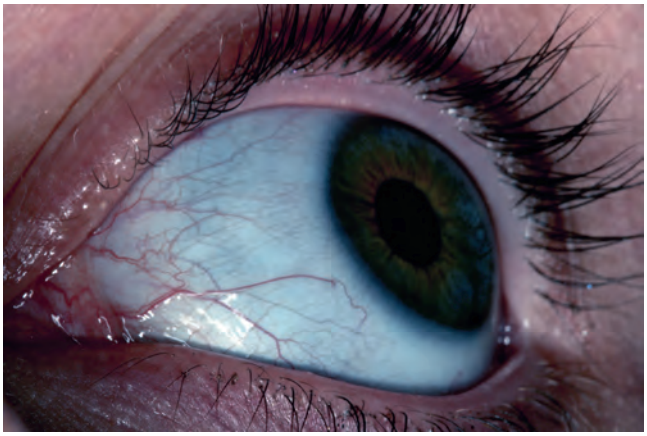
Classification of the various forms of osteogenesis imperfecta continues to evolve as molecular genetic discoveries are made. Based on clinical and genetic findings, at least 18 types are recognized by the Online Mendelian Inheritance in Man (OMIM) database. Other authorities prefer to delineate disease types based on a functional genetic approach. In clinical practice, classification based on phenotype alone is used most widely. Table 14.1 summarizes the International Skeletal Dysplasia Society (ISDS) Nosology Committee's clinical classification scheme (which represents an adaptation of the original Sillence classification) along with corresponding genetic mutations and OMIM disease types.

Clinical and Radiographic Features

Severity varies widely by disease type, and mutations in even a single gene locus may produce extensive phenotypic variation. Disease characterization as mild, moderate, or severe generally is based on the number of bone fractures, degree of long bone and spine deformity, degree of growth impairment, and age at which abnormalities initially become evident. For example, osteogenesis imperfecta type 1—the mildest and most common form—is characterized by a variable number of bone fractures, no significant bone deformity, and essentially normal growth. Typically, fractures first occur when the patient begins to walk and decrease in frequency after puberty. In contrast, osteogenesis imperfecta type 2 is the most severe form, characterized by extreme bone fragility and deformity. Most patients with this disease type die *in utero* or shortly after birth; death often results from respiratory distress due to multiple rib fractures and a small thorax.

Additional clinical findings may include blue sclerae (Fig. 14.1), hearing loss, and joint hyperextensibility or contractures. Infrequently, patients may develop muscle weakness and cardiopulmonary complications. The radiographic hallmarks include osteopenia, bowing deformity of the long bones, multiple fractures, and an increased number of Wormian bones in the skull. Wormian bones are small sutural bones arranged in a mosaic pattern; they also can be seen in other processes, such as cleidocranial dysplasia (see page 623).

Dental alterations that appear clinically and radiographically identical to dentinogenesis imperfecta (see page 104) may be evident as well. Both dentitions demonstrate blue, yellow, or brown translucence (Fig. 14.2, *A*); however, this finding may be less prominent in the permanent teeth. The underlying dentinal defects often lead to severe attrition, resulting in loss of vertical dimension and potential tooth loss. Radiographs typically reveal premature pulpal obliteration (Fig. 14.2, *B*), although shell teeth rarely may be seen. The teeth often exhibit bulbous crowns, cervical constriction, and narrow or corncob-shaped roots. Other possible dental findings include pulp stones, taurodontism, radicular dilaceration, hypodontia, and microdontia. Despite exhibiting similar tooth alterations, osteogenesis imperfecta and dentinogenesis imperfecta are distinct diseases resulting from different mutations. Therefore, the dental defects associated with the systemic disorder osteogenesis imperfecta should be designated **opalescent teeth,** whereas the term *dentinogenesis imperfecta* should be reserved for patients with alterations isolated to the teeth.



Craniofacial findings in osteogenesis imperfecta may include triangular facies, frontal bossing, relative macrocephaly, a flattened vertex and skull base, and a prominent

TABLE 14.1 Osteogenesis Imperfecta Classification Scheme

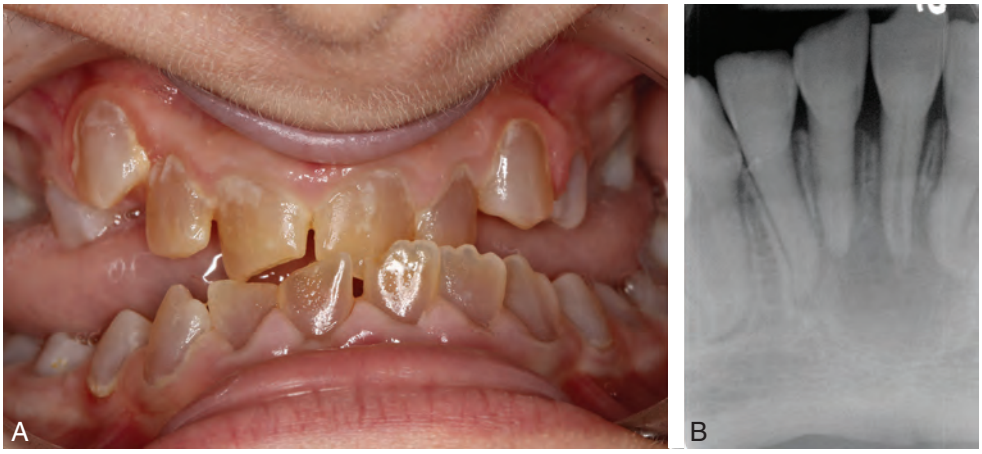
ISDS Classification	Phenotype	Inheritance Pattern(s)	Gene(s) Mutated	OMIM Disease Type(s)
OI type 1	Mild, nondeforming disease with persistently blue sclerae	AD	*COL1A1, COL1A2*	I
OI type 2	Severe, perinatal lethal disease	AD, AR	*COL1A1, COL1A2, CRTAP, LEPRE1, PPIB*	II, VII, VIII, IX
OI type 3	Moderate to severe, progressively deforming disease	AD, AR	*COL1A1, COL1A2, IFITM5, SERPINF1, CRTAP, LEPRE1, PPIB, SERPINH1, FKBP10, TMEM38B, BMP1, WNT1, CREB3L1, SPARC, TENT5A*	III, V, VI, VII, VIII, IX, X, XI, XIII, XIV, XVI, XVII, XVIII
OI type 4	Moderate disease, normal sclera in adults	AD, AR	*COL1A1, COL1A2, WNT1, IFITM5, CRTAP, PPIB, FKBP10, SP7*	IV, V, VII, IX, XI, XII, XV
OI type 5	Moderate disease with calcification of interosseous membranes and/or hypertrophic callus formation	AD	*IFITM5*	

AD, Autosomal dominant; *AR,* autosomal recessive; *BMP1,* bone morphogenetic protein 1 gene; *COL1A1,* collagen, type 1, alpha 1 gene; *COL1A2,* collagen, type 1, alpha 2 gene; *CREB3L1,* cAMP response element-binding protein 3-like 1 gene; *CRTAP*, cartilage-associated protein gene; *FKBP10,* FK506 binding protein 10 gene; *IFITM5,* interferon-induced transmembrane protein 5 gene; *ISDS,* International Skeletal Dysplasia Society; *LEPRE1,* leucine- and proline-enriched proteoglycan 1 gene; *OI*, osteogenesis imperfecta; *OMIM*, Online Mendelian Inheritance in Man; *PPIB,* peptidylprolyl isomerase B gene; *SERPINF1,* serpin peptidase inhibitor, clade F, member 1 gene; *SERPINH1,* serpin peptidase inhibitor gene; *SPARC,* secreted protein, acidic, cysteine-rich gene; *SP7,* transcription factor Sp7 gene; *TENT5A*, terminal nucleotidyltransferase 5A gene; *TMEM38,* transmembrane protein 38B gene; *WNT1,* wingless-type MMTV integration site family, member 1 gene.

• **Fig. 14.1 Osteogenesis Imperfecta.** Blue sclera in a patient with osteogenesis imperfecta.

occiput. Craniocervical junction anomalies may result in brainstem compression, central apnea, and decreased muscle tone. In addition, there is an increased prevalence of Class III malocclusion (caused by maxillary hypoplasia, with or without mandibular hyperplasia), crossbite, open bite, and deviated nasal septum (Fig. 14.2, *A*). Individuals with osteogenesis imperfecta type 5 may exhibit bimaxillary retrusive malocclusion with reduced lower face height. Furthermore, a few investigators have noted somewhat accelerated tooth development and eruption among pediatric patients with osteogenesis imperfecta and no history of bisphosphonate therapy.

There are a few reported probands with osteogenesis imperfecta occurring in association with other heritable conditions, such as Ehlers-Danlos syndrome (see page 760), Stickler syndrome, and *gnathodiaphyseal dysplasia*. The latter condition previously was thought to represent a variation of osteogenesis imperfecta but currently is considered a distinct condition, characterized by *ANO5* mutations, autosomal dominant inheritance, generalized bone fragility, bowing and cortical sclerosis of tubular bones, and fibro-osseous lesions of the jaws (similar to florid cemento-osseous dysplasia or familial gigantiform cementoma).



Diagnosis

Diagnosis requires correlation of the clinical features, radiographic and/or prenatal ultrasound findings, and family history. For diagnostic confirmation, genetic testing is more sensitive than electrophoresis for type I collagen secreted by cultured dermal fibroblasts. Bone biopsy may be helpful in select cases. Serum concentrations of vitamin D, calcium, phosphorus, and alkaline phosphatase usually are normal, although occasionally the latter may be slightly elevated.

Treatment and Prognosis

Management of bone fractures and deformity may be difficult. The mainstays of treatment are physiotherapy, rehabilitation, and orthopedic surgery. In addition, intravenous

dentlearn.ir

• **Fig. 14.2 Osteogenesis Imperfecta. A,** Opalescent teeth, class III malocclusion, and posterior open bite in a patient with osteogenesis imperfecta. **B,** Periapical radiograph of the same patient showing several teeth with pulpal obliteration. (Courtesy of Dr. Taylor Cox.)

bisphosphonates typically are administered to children with moderate to severe disease. Such therapy may decrease pain, induce reshaping of vertebrae after compression fractures, improve growth, and increase mobility. However, there is conflicting data regarding whether this treatment reduces fracture rates. The benefits of bisphosphonate therapy for adult or mild childhood disease and the long-term safety of bisphosphonate therapy require further study. Investigational treatments for osteogenesis imperfecta include denosumab (a monoclonal antibody targeting receptor activator of nuclear factor-kappa B ligand [RANKL]), growth hormone, recombinant human parathyroid hormone (teriparatide), transforming growth factor-beta (TGF-β) inhibitors, sclerostin inhibitors, and stem cell therapy.

Dental treatment is similar to that for dentinogenesis imperfecta (see page 104). Successful implant placement has been reported in a few cases, although the impact of the altered bone on osseointegration is not well studied. In patients with significant malocclusion, orthognathic surgery and orthodontic treatment may be performed. Alternatively, osteodistraction may be considered to reduce the risk of atypical fractures from conventional orthognathic procedures (e.g., Le Fort I osteotomy). Presurgical planning should take into account an increased risk for bleeding disorders, cardiac malformations, and hyperthermia. Intubation may be difficult because of a short neck, kyphoscoliosis, and fragility of the mandible and cervical vertebrae. Also, patients previously treated with bisphosphonates may exhibit delayed healing after osteotomy. Although there is concern regarding the potential for bisphosphonates to induce osteonecrosis of the jaws, this complication has not been reported thus far among children and young adults who have been administered these medications for the management of osteogenesis imperfecta. In addition, some studies suggest that patients receiving intravenous bisphosphonate therapy for osteogenesis imperfecta are at increased risk for tooth impaction, ectopic teeth, pulp stones, and pulpal obliteration.

The prognosis varies by disease type. Patients with mild disease exhibit a normal life span, whereas those with especially severe disease die *in utero* or in the perinatal period.

◆ OSTEOPETROSIS (ALBERS-SCHÖNBERG DISEASE; MARBLE BONE DISEASE)

Osteopetrosis is a group of rare hereditary skeletal disorders characterized by markedly increased bone density. The name of this disease is derived from the Greek words for "bone" (*osteo*) and "stone" (*petros*). The condition is characterized by a failure of osteoclast function or differentiation. Decreased osteoclastic bone resorption results in sclerotic yet fragile bone.

The underlying genetic abnormality is unknown in about 25% of patients. Mutations discovered thus far primarily cause defects in osteoclastic proteins necessary for formation and acidification of resorption lacunae. In particular, such defects may interfere with intracellular lysosomal/vesicular trafficking, fusion of acidified vesicles with the "ruffled border" (folded osteoclast cell membrane in areas of bone resorption), and regulation of ionic charge across the cell membrane. In addition, some patients have mutations that interfere with the RANK (receptor activator of nuclear factor-kappa B)/RANK ligand pathway, which is important for osteoclastogenesis.

Although several disease subtypes have been identified, there are three major clinical patterns:

1. **Autosomal recessive infantile ("malignant") type**
2. **Intermediate autosomal recessive type**
3. **Autosomal dominant adult ("benign") type**

The estimated frequency is 1 in 250,000 live births for the recessive types and 1 in 20,000 live births for the autosomal dominant type. A very rare X-linked recessive type has been described as well.

Table 14.2 summarizes a classification system based on phenotype and corresponding genetic defects. Disease

dentlearn.ir

TABLE 14.2 Classification Scheme for Major Forms of Osteopetrosis

Form	Mutated Gene(s)	Gene Product and/or Affected Osteoclast Function(s)	Clinical Phenotype
Autosomal recessive infantile	*TCIRG1*	Proton pump subunit, acid secretion, vesicular trafficking	Severe, osteopetrorickets
	CLCN7	Chloride channel, lysosomal trafficking, acidification	Severe, possible neurodegeneration
	OSTM1	Chloride channel function, lysosomal trafficking, acidification	Severe, neurodegeneration
	RANK (TNFRSF11A)	Cell surface receptor, osteoclast differentiation	Severe
	RANKL (TNFSF11)	Ligand that binds RANK receptor, osteoclast differentiation	Severe
	SNX10	Endolysosomal trafficking/fusion	Severe, osteopetrorickets
Intermediate autosomal recessive	*PLEKHMI*	Vesicle trafficking and acidification	Intermediate
	CAII	Acidification	Intermediate, renal tubular acidosis, cerebral calcifications
Autosomal dominant	*CLCN7*	Chloride channel, lysosomal trafficking, acidification	Mild to severe, rarely lethal
X-linked recessive	*IKBKG (NEMO)*	Osteoclast differentiation and activation	Severe, immunodeficiency, ectodermal dysplasia

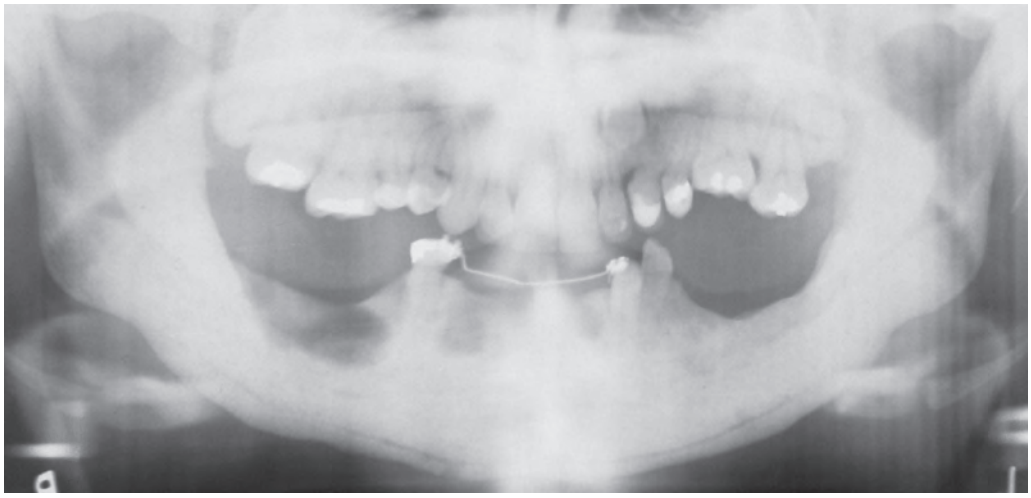
CAII, carbonic anhydrase II gene; *CLCN7,* chloride channel 7 gene; *IKBKG*, inhibitor of nuclear factor kappa B kinase subunit gamma gene; *NEMO*, nuclear factor-kappa B essential modulator gene; *OSTM1,* osteopetrosis-associated transmembrane protein 1 gene; *PLEKHM1,* pleckstrin homology domain gene; *RANK,* receptor activator of nuclear factor-kappa B gene; *RANKL,* receptor activator of nuclear factor-kappa B ligand gene; *SNX10,* sorting nexin 10 gene; *TCIRG1,* T-cell immune regulator 1 gene; *TNFRSF11A,* tumor necrosis factor receptor superfamily, member 11A gene (also known as *RANK*); *TNFSF11,* tumor necrosis factor ligand superfamily member 11 gene (also known as *RANKL*).

severity varies widely, potentially even among patients with the same disease subtype.

Clinical and Radiographic Features

Autosomal Recessive Infantile Osteopetrosis

This severe form usually is diagnosed at birth or in early infancy. Typical findings include a diffusely sclerotic skeleton, bone marrow failure, frequent fractures with defective healing, cranial nerve compression, and growth impairment.



The initial signs often are normocytic anemia with hepatosplenomegaly resulting from compensatory extramedullary hematopoiesis. Granulocytopenia causes increased susceptibility to infection. The bone is dense but prone to pathologic fracture. A paradoxical condition termed *osteopetrorickets* often develops; the altered bone is unable to mobilize its overly abundant mineral stores, which results in hypocalcemia, hypophosphatemia, and impaired mineralization of newly formed bone. Individuals with autosomal recessive infantile osteopetrosis typically exhibit a broad face, hypertelorism, snub nose, frontal bossing, and macrocephaly. Cognitive function is usually normal, although neurodegeneration may develop in some disease subtypes. Failure of resorption and remodeling of the skull produces hydrocephalus and narrow skull foramina; cranial nerve compression may result in blindness, deafness, and facial paralysis. Osteomyelitis of the jaws is a frequent complication of tooth extraction (Fig. 14.3).

• **Fig. 14.3 Osteopetrosis.** This 24-year-old white man has the infantile form of osteopetrosis. He has mandibular osteomyelitis, and multiple draining fistulae are present on his face. (Courtesy of Dr. Dan Sarasin.)

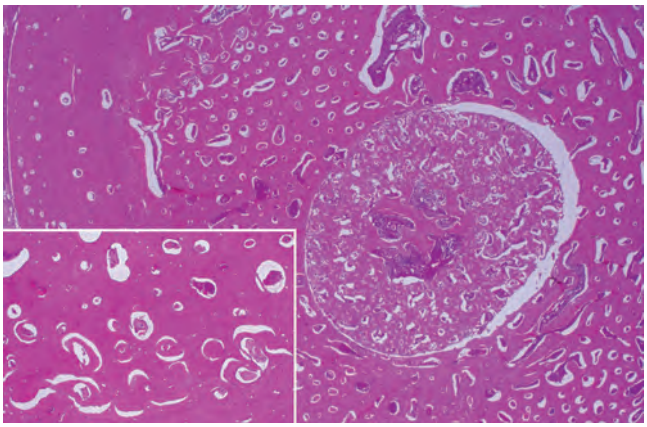
Radiographically, there is a widespread increase in skeletal density with defects in metaphyseal remodeling. The radiographic distinction between cortical and cancellous bone is

dentlearn.ir

• **Fig. 14.4 Osteopetrosis.** Extensive mandibular involvement is apparent in this radiograph of a 31-year-old woman. She received a diagnosis of osteopetrosis as a child. There is a history of multiple fractures and osteomyelitis of the jaws. (Courtesy of Dr. Dan Sarasin.)

lost (Fig. 14.4). There is often marked thickening of the calvarium and skull base, and there may be poor sinus development. Tooth roots often are difficult to visualize radiographically because of the density of the surrounding bone. In addition, failure of tooth eruption is common. Other possible dental findings include tooth agenesis, malformed crowns and roots, and enamel hypoplasia.

Intermediate Autosomal Recessive Osteopetrosis



Affected patients often are asymptomatic at birth but exhibit fractures by the end of the first decade. Mild to moderate anemia and extramedullary hematopoiesis are common, but bone marrow failure is rare. Short stature, mandibular prognathism, unerupted teeth, and osteomyelitis also have been reported. Individuals with intermediate disease caused by carbonic anhydrase II deficiency typically exhibit renal tubular acidosis and cerebral calcifications.

Autosomal Dominant Adult Osteopetrosis

This most common type usually is discovered in adolescence or adulthood and exhibits less severe manifestations. Sclerosis mainly affects the axial skeleton, with relative sparing of the long bones. Marrow failure is infrequent, and approximately 40% of affected patients are asymptomatic. Among symptomatic patients, findings may include bone pain, frequent fractures, and cranial nerve compression.

Occasionally, the diagnosis is discovered initially on review of dental radiographs that reveal diffusely increased radiopacity of the medullary bone. Mandibular involvement may be associated with an increased risk for fracture and osteomyelitis following tooth extraction.

Other rare conditions causing widespread osteosclerosis should be considered in the differential diagnosis. Such diseases include autosomal dominant endosteal hyperostosis (autosomal dominant osteosclerosis), sclerosteosis, and van Buchem disease.

• **Fig. 14.5 Osteopetrosis.** Low-power photomicrograph showing sclerotic bone that is replacing the normal cancellous bone. The *inset* shows a nodular pattern of the dense bone obliterating the marrow spaces.

Histopathologic Features

Several patterns of abnormal endosteal bone formation have been described. These include the following:

- Tortuous lamellar trabeculae replacing the cancellous portion of the bone
- Globular amorphous bone deposition in the marrow spaces (Fig. 14.5)
- Osteophytic bone formation

Osteoclasts may be increased, decreased, or normal in number; however, they do not appear to be functional because Howship lacunae are absent or minimal. In osteoclast-rich disease forms, the scant remaining hematopoetic marrow is fibrotic, and there may be a concurrent increase in the number of activated osteoblasts. In osteoclast-poor disease, the scant residual marrow does not exhibit fibrosis.

dentlearn.ir

Treatment and Prognosis

Treatment is guided by the disease subtype and underlying genetic defect. Because a variety of complications are possible, management may require a multidisciplinary team, including specialists in orthopedics, hematology, developmental pediatrics, endocrinology, infectious disease, neurology, neurosurgery, otolaryngology, and ophthalmology. In addition, dental evaluation is recommended for all patients regardless of disease severity. Preventive oral health care is essential for avoiding extractions or other surgical procedures that may increase the risk for developing osteomyelitis.

For autosomal dominant adult osteopetrosis, no specific treatment is available other than management of disease complications. Although the prognosis varies, most patients exhibit long-term survival.

In contrast, the prognosis for untreated autosomal recessive infantile osteopetrosis is poor, with most patients dying during the first decade of life. For patients with certain disease subtypes, allogeneic hematopoietic stem cell transplantation (HSCT) potentially may be curative. The rationale for this procedure is based on the hematopoietic origin of osteoclasts. HSCT should be performed as soon as possible (before the age of 10 months) in order improve the likelihood of a favorable outcome. However, finding an appropriate donor can be difficult, and the procedure is associated with considerable risk. Alternative treatments include interferon gamma-1b and corticosteroids.

Supportive measures include blood transfusions, analgesics for bone pain, and bone fracture stabilization. Osteomyelitis of the jaws requires rapid intervention to minimize osseous destruction; management typically includes drainage and surgical débridement, bacterial culture with sensitivity testing, and prolonged IV antibiotic therapy. Hyperbaric oxygen may be a useful adjunct in recalcitrant cases, and surgical reconstruction may be necessary.

◆ CLEIDOCRANIAL DYSPLASIA (CLEIDOCRANIAL DYSOSTOSIS; SCHEUTHAUER-MARIE-SAINTON SYNDROME; MARIE-SAINTON DISEASE)

Best known for its dental and clavicular abnormalities, **cleidocranial dysplasia** is a generalized bone disorder caused by mutations in the *RUNX2* (or *CBFA1*) gene on chromosome 6p21. This gene encodes a key transcription factor for osteoblastic differentiation and skeletal morphogenesis. This condition initially was thought to involve only membranous bones (e.g., clavicles, skull, and flat bones), but it is now known to affect endochondral ossification as well. Studies suggest that *RUNX2* additionally plays an important role in odontogenesis via participation in odontoblast differentiation, osteoclastogenesis (in association with the dental follicle and periodontal ligament), enamel organ formation, and dental lamina proliferation. Disruption of these functions might explain the distinct dental anomalies associated with this disorder. The estimated worldwide prevalence is 1:1,000,000. There is an autosomal dominant inheritance pattern, although as many as 40% of cases may represent spontaneous mutations. In addition, investigators have proposed that an autosomal recessive form and germline mosaicism are possible.

Clinical and Radiographic Features

The bone defects chiefly involve the clavicles and skull, although various other skeletal anomalies may be present (Table 14.3). The clavicles typically are hypoplastic or discontinuous, either unilaterally or bilaterally; in about 10% of cases, the clavicles are completely absent. The patient's neck appears long, and the shoulders are narrow with marked drooping. The clavicular abnormalities result in unusual

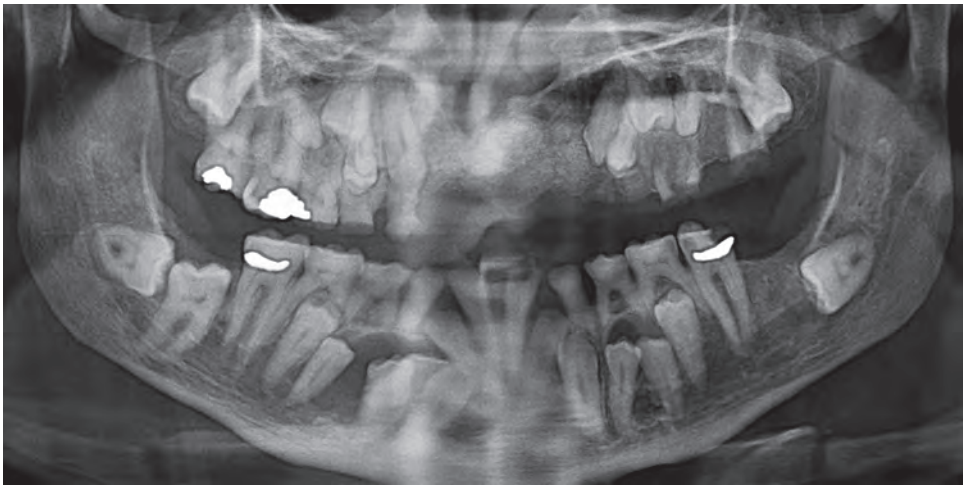
TABLE 14.3 Major Clinical and Radiographic Features of Cleidocranial Dysplasia

Anatomic Region	Features
Craniofacial/ oral region	• Large skull • Frontal and parietal bossing • Brachycephaly • Ocular hypertelorism • Nose with depressed bridge and broad base • Delayed closure of sutures and fontanels • Wormian bones • Small or absent paranasal sinuses • Narrow, high-arched palate; cleft palate • Numerous unerupted/variably misshapen permanent and supernumerary teeth • Retention of primary dentition; delayed eruption of permanent dentition • Mandible: Prognathism, coarse trabeculation, narrow and parallel-sided rami, slender and pointed coronoid processes with distal curvature, patent symphysis • Hypoplastic maxilla
Thorax	• Hypoplastic, discontinuous, or absent clavicles • Hypoplastic scapulae • Narrow upper thorax • Absent ribs
Pelvis	• Hypoplastic iliac wings • Widening of the pubic symphysis and sacroiliac joints • Delayed ossification of the pubic bone
Extremities	• Genus valgus (knock knees) • Pes planus (flat feet) • Brachydactyly • Tapered fingers and short, broad thumbs • Short terminal phalanges • Long second metacarpals • Short and deformed middle phalanges
Other	• Short stature • Scoliosis

dentlearn.ir

hypermobility, and many patients can approximate their shoulders anteriorly (Fig. 14.6).

Additional features include short stature, narrow chest, wide pubic symphysis, short arms, genu valgu (knock knee deformity), flat feet, and scoliosis. Craniofacial findings include enlarged skull, brachycephaly, and pronounced frontal and parietal bossing. Ocular hypertelorism and a broad-based nose with a depressed bridge often are noted as well. On skull radiographs, the sutures and fontanels show delayed closure or may remain open throughout life. Secondary centers of ossification appear in the suture lines, and many Wormian bones may be seen. Abnormal development of the temporal bone and eustachian tube may lead to conductive or sensorineural hearing loss and recurrent ear infections.



• **Fig. 14.6 Cleidocranial Dysplasia.** Patient can almost approximate her shoulders in front of her chest. (Courtesy of Dr. William Bruce.)

The gnathic and dental manifestations are distinctive and may lead to the initial diagnosis. Patients often have a narrow, high-arched palate, and there is an increased prevalence of cleft palate. Over-retained deciduous teeth and delay or complete failure of permanent tooth eruption are characteristic features. There may be abnormal spacing in the mandibular incisor area because of widening of the alveolar bone. On dental radiographs, the most dramatic finding is the presence of numerous unerupted permanent and supernumerary teeth, often exhibiting distorted crown and root shapes (Fig. 14.7). Dentigerous cysts occasionally may arise in association with these unerupted teeth. The number of supernumerary teeth can be impressive, with some patients demonstrating more than 60 such teeth. In addition, the mandible often demonstrates coarse trabeculation with areas of increased density; narrow rami with nearly parallel anterior and posterior borders; and slender, pointed coronoid processes with a distal curvature. In some cases, the mandibular symphysis remains patent. There may be a thin zygomatic arch with a downward bend and small or absent maxillary sinuses. Generalized hypoplasia of the paranasal sinuses may predispose the patient to recurrent sinus infections.

As the patient ages, a short lower face height, acute gonial angle, anterior inclination of the mandible, and mandibular prognathism develop. These changes may result from inadequate vertical growth of the maxilla and hypoplastic alveolar ridge development caused by delay or lack of permanent tooth eruption.

Histopathologic Features

The reason for failure of permanent tooth eruption in cleidocranial dysplasia is poorly understood. Some microscopic studies have reported a lack of secondary cementum in unerupted teeth, although other studies have disputed this finding. Additional proposed hypotheses include increased

• **Fig. 14.7 Cleidocranial Dysplasia.** Panoramic radiograph showing multiple unerupted and supernumerary teeth. (Courtesy of Dr. Samer Joudeh.)

dentlearn.ir

jawbone density, abnormally coarse trabecular pattern of the jaws, and insufficient alveolar bone resorption—possibly resulting from altered periodontal ligament cells with reduced capacity to induce osteoclastogenesis. The development of supernumerary teeth has been theorized to result from hyperactive or persistent dental lamina.

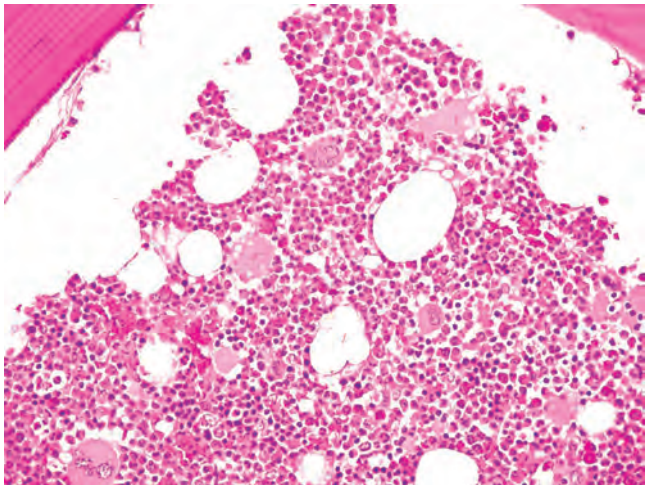
Treatment and Prognosis

Most patients function well. An affected individual may be unaware of the disease until a professional calls it to his or her attention.

The dental problems may be difficult to address, and early intervention is recommended. Treatment typically involves removal of primary and supernumerary teeth followed by exposure and orthodontic extrusion of permanent teeth. The extractions may be conducted in stages (according to the extent of root development of the unerupted permanent dentition) or in a single procedure. If completed before adulthood, then such treatment may prevent short lower face height and mandibular prognathism. Orthognathic surgery also may be considered after growth completion. Additional treatment options include full-mouth extractions or autotransplantation of selected impacted teeth followed by fabrication of an appropriate prosthesis. In several reported cases, dental implants have been placed successfully; however, further studies are needed to assess whether the altered bone might compromise osseointegration.

◆ FOCAL OSTEOPOROTIC MARROW DEFECT

The **focal osteoporotic marrow defect** is an area of hematopoietic marrow that is sufficient in size to produce a radiolucency. This entity does not represent a pathologic process, but its radiographic features may be confused with an intraosseous neoplasm or other pathosis. The pathogenesis is unknown, although the following theories have been proposed:



- Aberrant bone regeneration after tooth extraction or dental implant placement
- Persistence of fetal marrow
- Marrow hyperplasia in response to increased demand for erythrocytes

Clinical and Radiographic Features

Approximately 75% of cases occur in adult females, and about 70% involve the posterior mandible, most often in edentulous areas. The defect is typically asymptomatic and nonexpansile. Most cases are detected incidentally during radiographic examination, which shows a radiolucency ranging from several millimeters to several centimeters in diameter. The borders typically appear well-circumscribed on panoramic radiographs; however, more detailed periapical radiographs may exhibit ill-defined borders and fine central trabeculation (Fig. 14.8). There is usually an isolated defect, although multifocal involvement is possible.

• **Fig. 14.8 Focal Osteoporotic Marrow Defect.** Fairly well-circumscribed radiolucency with fine central trabeculation in the extraction site of a mandibular molar. (Courtesy of Dr. R. Sidney Jones.)

• **Fig. 14.9 Focal Osteoporotic Marrow Defect.** Photomicrograph showing normal hematopoietic bone marrow.

Histopathologic Features

Microscopically, the defect contains cellular hematopoietic and/or fatty marrow (Fig. 14.9). The associated bony trabeculae show no evidence of abnormal osteoblastic or osteoclastic activity.

Treatment and Prognosis

The radiographic findings are often suggestive of the diagnosis but are nonspecific. Incisional biopsy, therefore, often is necessary to establish the diagnosis. Once the diagnosis is made, no further treatment is needed. The prognosis is excellent, and there appears to be no significant association with anemia or other hematologic disorders.

dentlearn.ir

◆ IDIOPATHIC OSTEOSCLEROSIS

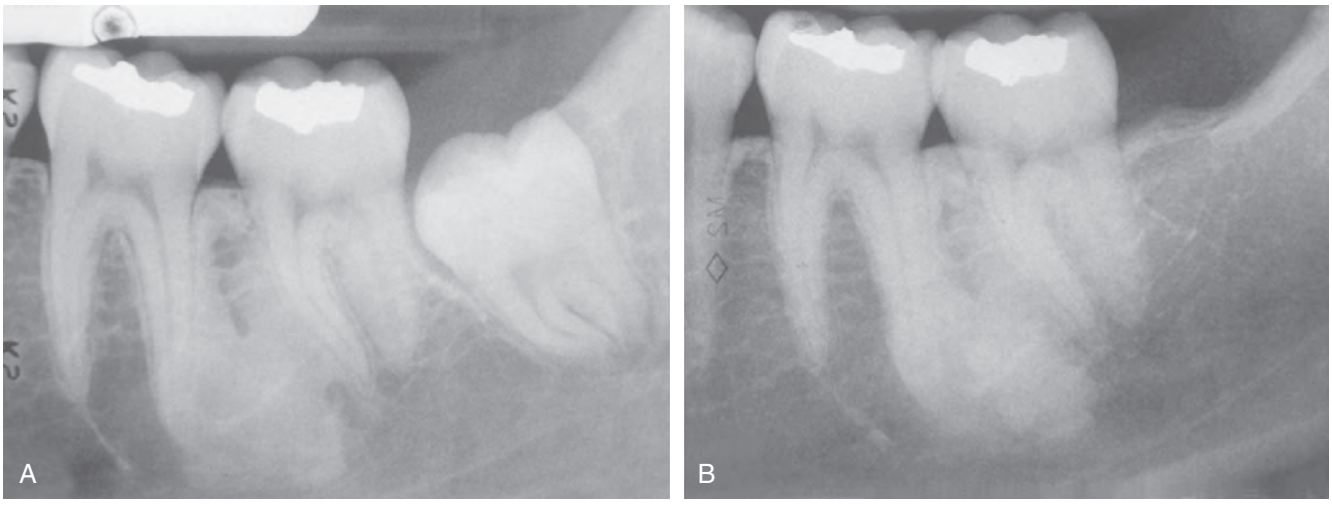
Idiopathic osteosclerosis represents focally increased bone density of unknown cause. It cannot be attributed to any inflammatory, dysplastic, neoplastic, or systemic disorder. Some authorities consider this condition to represent a developmental variation of normal bony architecture. Idiopathic osteosclerosis also has been termed *dense bone island, bone eburnation, bone whorl, bone scar, enostosis*, and *focal periapical osteopetrosis.* The following discussion focuses on jaw involvement, although similar sclerotic areas may occur in other bones.

In addition, similar radiopaque foci may develop in the periapical areas of teeth with nonvital or inflamed pulps; these lesions most likely represent a response to inflammation. Such reactive foci are termed **condensing osteitis** or **focal chronic sclerosing osteomyelitis** (see page 141) and should not be designated *idiopathic osteosclerosis.* Because past studies did not distinguish between idiopathic and inflammatory lesions, confusion in terminology has resulted.

Clinical and Radiographic Features

The estimated prevalence is 6%, with some investigators suggesting a slightly increased frequency in blacks and Asians. Most authors report either a female predilection or no significant sex predilection. According to several long-term studies, most examples of idiopathic osteosclerosis arise in the late first or early second decade. The sclerotic area may slowly increase in size, with peak diameter usually attained once the patient reaches full maturity. The peak prevalence is in the third decade, with peak bone mass in the fourth decade. Later in adulthood, the sclerosis typically remains stable, decreases in size, or undergoes complete regression.

Idiopathic osteosclerosis is invariably asymptomatic and nonexpansile. The condition typically is detected incidentally during routine radiographic examination. About 90% of cases occur in the mandible, most often in the molar and premolar regions. In most patients, only one sclerotic focus is present, although some patients have two to four foci. For patients with multifocal involvement, the possibility of multiple osteomas within the setting of Gardner syndrome (see page 656) should be excluded.



Radiographically, idiopathic osteosclerosis typically appears as a well-defined radiopacity, ranging from 0.2 to 2.0 cm in diameter. However, ill-defined borders, diameter as large as 7.0 cm, or a mixed radiolucent-radiopaque appearance have been described infrequently. The radiopacity may be round, oval, square, elongated, triangular, or irregular. There is no radiolucent rim, with the exception of unusual cases involving the mandibular canal. Most examples are uniformly radiopaque, although a nonhomogeneous core sometimes may be evident. The condition often is associated with tooth roots—the opacity may obscure a portion of the root, contact the lamina dura, or arise in close proximity to the root. Many examples are associated with a root apex or occur between the roots of teeth, but cases unrelated to teeth also are possible (Fig. 14.10). Rarely, the sclerotic bone may surround an impacted tooth. Root resorption and tooth movement have been noted infrequently.

Histopathologic Features

Microscopic examination shows dense lamellar bone with scant fibrofatty marrow. Inflammatory cells are inconspicuous or absent.

Diagnosis

Usually a diagnosis of idiopathic osteosclerosis may be made with confidence, based on history, clinical features, and radiographic findings. Biopsy is warranted if there are symptoms or significant cortical expansion. Although idiopathic osteosclerosis demonstrates radiographic and histopathologic

• **Fig. 14.10 Idiopathic Osteosclerosis. A,** An asymptomatic area of bone sclerosis is seen between and apical to the roots of the first and second mandibular molars. **B,** No appreciable change can be seen on this radiograph taken 10 years later. (Courtesy of Dr. Michael Quinn.)

dentlearn.ir

similarities with a compact osteoma (see page 655), lack of cortical expansion and failure of continued growth rule against a neoplastic process. Tooth vitality and the absence of a deep restoration or caries help to distinguish idiopathic osteosclerosis from condensing osteitis.

Treatment and Prognosis

If the lesion is discovered during adolescence, periodic radiographs appear prudent until the area stabilizes. After that point, no treatment is indicated, because there is little or no tendency for the lesions to progress in adulthood.

◆ MASSIVE OSTEOLYSIS (GORHAM DISEASE; GORHAM-STOUT SYNDROME; VANISHING BONE DISEASE; PHANTOM BONE DISEASE; IDIOPATHIC OSTEOLYSIS)

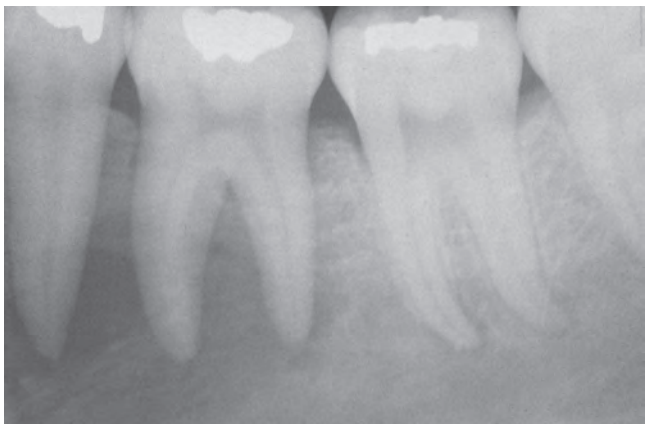
Massive osteolysis is a rare disease characterized by spontaneous and usually progressive destruction of one or more bones. The destroyed bone is replaced by a vascular proliferation and, ultimately, dense fibrous tissue without bone regeneration.

The etiopathogenesis is unknown. There is no evidence of underlying metabolic or endocrine imbalance. Proposed pathogenetic mechanisms include the following:

- Trauma-induced proliferation of vascular granulation tissue
- Trauma-induced activation of a previously silent hamartoma
- Slow blood flow through dilated lesional vessels, resulting in local hypoxia, reduced pH, and activation of hydrolytic enzymes
- Increased osteoclastic activity (mediated by interleukin-6) and increased sensitivity of osteoclast precursors to humoral factors (such as receptor activator of nuclear factor kappa B ligand [RANKL] and macrophage colony-stimulating factor [M-CSF])
- Lymphangiogenesis mediated by vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF)
- Agenesis or dysfunction of thyroid C cells

In addition, based on molecular genetic studies in a limited number of cases, some investigators have suggested a potential pathogenetic role for *TNFRSF11A*, *TREM2*, and *PTEN* mutations.

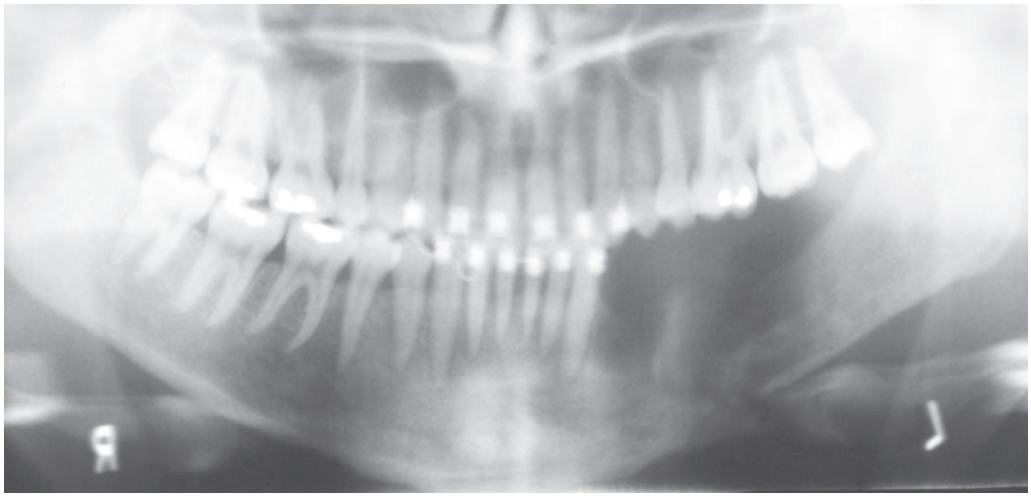
Clinical and Radiographic Features



The disease occurs over a broad age range (1 month to 76 years), with a predilection for children and young adults. Among patients with jaw involvement, the mean age is approximately 32 years, and the male-to-female ratio is 1.7:1. Although any bone can be affected, commonly reported sites include the pelvic bones, shoulder bones, craniomaxillofacial skeleton, ribs, sternum, and spine. Multicentric involvement and extension into soft tissue may be evident.

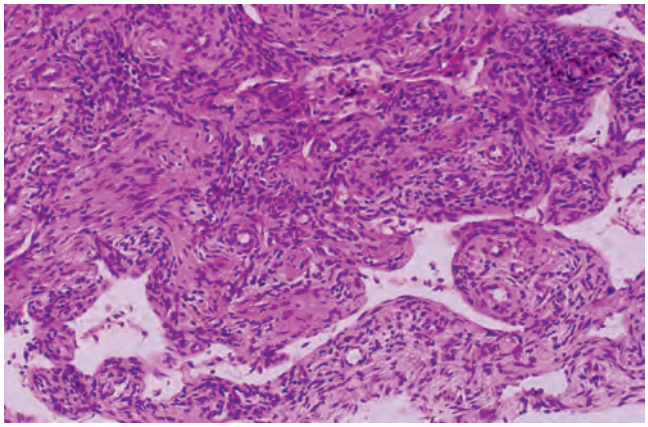
Gnathic lesions most often involve the mandible. Simultaneous involvement of both jaws and extension to adjacent extragnathic sites are possible. About half of patients are symptomatic. Signs and symptoms include mobile teeth, pain, malocclusion, deviation of the mandible, and clinically obvious deformity. Potential sequelae include pathologic fracture and obstructive sleep apnea; the latter may occur secondary to posterior mandibular displacement after extensive osteolysis. Temporomandibular joint (TMJ) involvement may be confused with other conditions that can cause TMJ dysfunction. Elevated serum alkaline phosphatase has been noted in about a fourth of reported gnathic cases.

Radiographically, the earliest changes consist of intramedullary radiolucent foci of varying size with indistinct margins (Fig. 14.11). Loss of the lamina dura and thinning of the cortical plates may precede development of obvious radiolucency. In some cases, the bone destruction may mimic periodontitis or periapical inflammatory disease. With progression, the radiolucent foci coalesce, enlarge, and extend to the cortical bone. Eventually, large portions of bone disappear (Fig. 14.12).



Histopathologic Features

Microscopically, early lesions exhibit a nonspecific vascular proliferation intermixed with fibrous connective tissue and chronic inflammatory cells (Fig. 14.13). Blood vessels and/or lymphatic vessels may be present, although current evidence suggests the latter predominate. Immunohistochemistry with the D2-40 antibody may be performed to highlight lymphatic endothelium. The vascular channels are thin-walled and may vary in size. Within the adjacent bone, the osteocyte lacunae may be enlarged without significant alteration in the number of osteoclasts present. In later stages, there is fibrosis without bone regeneration.



• **Fig. 14.11 Massive Osteolysis.** Periapical radiograph showing an ill-defined radiolucency associated with vital mandibular teeth. Note the loss of lamina dura. (Courtesy of Dr. John R. Cramer.)

dentlearn.ir

• **Fig. 14.12 Massive Osteolysis.** Panoramic radiograph of the same patient shown in Fig. 14.11, showing extensive bone loss and a pathologic fracture of the left mandible. This destruction occurred over an 8-month period. (Courtesy of Dr. John R. Cramer.)

• **Fig. 14.13 Massive Osteolysis.** Biopsy specimen from the same patient shown in Figs. 14.11 and 14.12. The loose, highly vascular connective tissue shows a diffuse chronic inflammatory cell infiltrate.

Treatment and Prognosis

The clinical course of massive osteolysis is variable and unpredictable. In most cases, bone destruction progresses over months to a few years and results in complete loss of the affected bone or bones. Some patients, however, experience spontaneous arrest of the process without complete loss of the affected bone. Uncommonly, death results from respiratory compromise due to severe thoracic involvement or from spinal cord compression due to vertebral destruction.

There is no standardized therapy, and treatment is not particularly satisfactory. Maxillofacial lesions most commonly are managed by observation or surgical resection. Surgical reconstruction may be complicated by bone graft resorption and inadequate bone for fixation; therefore, it is advisable to delay reconstruction until arrest of the osteolytic disease phase. Alternative treatment options includes radiation therapy or medications, which at times may be combined with surgery. However, particularly in young patients, there are concerns regarding the potential for post-irradiation sarcoma and radiation-induced developmental defects. Medical treatments include bisphosphonates, interferon alpha-2b, sirolimus, anti-VEGF antibodies, corticosteroids, calcitonin, vitamin D, and calcium-containing compounds. However, the effectiveness of any therapeutic intervention is difficult to evaluate because the disease is so rare and the condition may arrest spontaneously in some patients. Therefore, further studies are needed.

◆ PAGET DISEASE OF BONE (OSTEITIS DEFORMANS)

Paget disease of bone is characterized by abnormal, anarchic resorption and deposition of bone, resulting in skeletal distortion and weakening. It represents the second most common metabolic bone disorder after osteoporosis and primarily affects older adults of Anglo-Saxon ancestry. There is marked variation in reported prevalence by geographic region, with the highest rates in the United Kingdom. The disease also frequently occurs in Australia, New Zealand, Western and Southern Europe, and North America. In the United States, the disease affects approximately 1%–2% of the general population. For reasons unclear, significant declines in disease incidence and severity have been observed in recent decades in many high-prevalence regions.

The etiology is unknown, but both genetic and environmental factors have been proposed. Approximately one-third of patients have a first-degree relative with the disease, and an autosomal dominant inheritance pattern with incomplete penetrance has been observed. In about 40% of familial cases and 5% of sporadic cases, germline mutations in the sequestosome 1 gene *(SQSTM1)* (which encodes the p62 protein) have been identified. Patients with *SQSTM1* mutations tend to have more severe disease than those without such mutations. *SQSTM1* mutations result in activation of the nuclear factor-kappa B (NF-κB) signaling pathway and increased osteoclastic activity. In addition, rare mutations in other

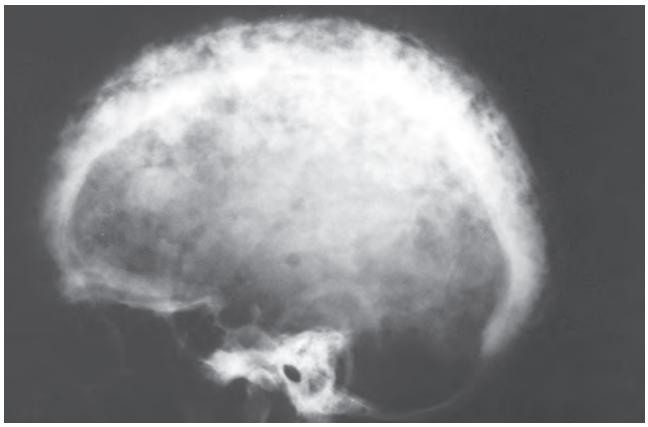
dentlearn.ir

genes affecting this pathway have been detected in some patients with familial Paget disease or Paget-like disorders. Furthermore, genome-wide association studies have identified polymorphisms in various genes that appear to confer increased susceptibility to Paget disease.

The possibility that Paget disease results from a slow virus infection has received considerable attention but remains controversial. Inclusion bodies resembling nucleocapsids from a paramyxovirus have been detected in osteoclasts from affected individuals; however, attempts to demonstrate mRNA and proteins from paramyxoviruses in patient tissue samples have yielded variable results. In animal models, interactions between measles virus infection and *SQSTM1* mutations can produce Paget-like bone lesions. Additional circumstantial evidence is provided by epidemiologic studies that have noted an association with rural living, thereby suggesting possible transmission of an infectious agent via contact with farm animals.

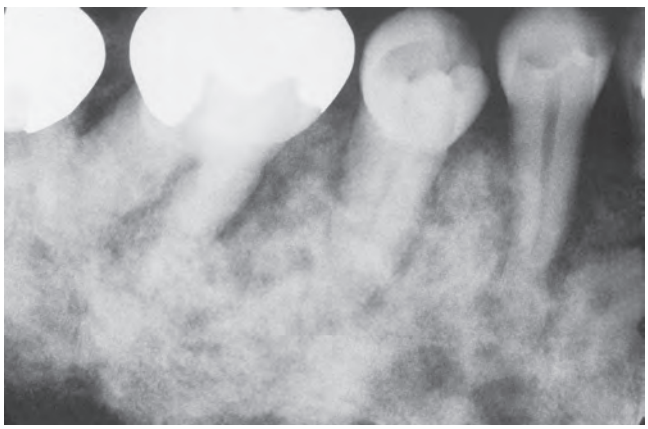
The primary underlying abnormality in Paget disease appears to be in the osteoclasts, which are increased in size, number, and activity. *In vitro* studies suggest that increased osteoclastogenesis may result from hyperresponsiveness of osteoclast precursors to receptor activator of nuclear factor kappa B ligand (RANKL), tumor necrosis factor-alpha (TNF-α), and 1, 25-dihydroxyvitamin D3. In response to increased bone resorption by osteoclasts, there is accelerated but haphazard bone formation by osteoblasts.

Clinical and Radiographic Features



Paget disease of bone primarily affects older patients. Disease frequency increases with age, and the mean age at diagnosis has been increasing in many populations. The condition is rare in patients younger than 50 years. Most studies report a male predilection.

At diagnosis many patients present with bone pain, although at least 25% are asymptomatic. Asymptomatic disease may be discovered incidentally when radiographic examination or serum alkaline phosphatase measurement is performed for unrelated reasons. Bone pain may result from either increased bone turnover or secondary complications (e.g., osteoarthritis, spinal stenosis, pathologic fracture, and pseudofracture). Pagetic bone pain typically is mild to moderate, with worsening at rest and improvement during movement. In contrast, secondary osteoarthritic pain tends to be severe and excerbated by movement.



The disease arises in one or more bones simultaneously, and involvement typically remains restricted to these original sites throughout the disease course. The pelvis, vertebrae, femur, tibia, and skull are involved most commonly. Affected bones become thickened, enlarged, and weakened, with an increased risk for fracture. Involvement of weight-bearing bones often leads to bowing deformity, resulting in a "simian (monkeylike) stance." Skull involvement generally causes a progressive increase in head circumference. Deafness and visual impairment may result from nerve compression or other mechanisms. Cardiovascular complications, including arterial calcifications and high-output congestive heart failure, also are possible.

Jaw involvement is present in about 17% of patients, with a predilection for the maxilla (approximate 2:1 maxilla-to-mandible ratio). Maxillary disease produces enlargement of the middle third of the face and may result in nasal obstruction, enlarged turbinates, obliterated sinuses, and deviated septum. In extreme cases, there is a lion-like facial deformity **(leontiasis ossea).** The alveolar ridges tend to remain symmetrical but become grossly enlarged. Alveolar enlargement may cause spacing between teeth, and edentulous patients may complain that their dentures feel too tight.

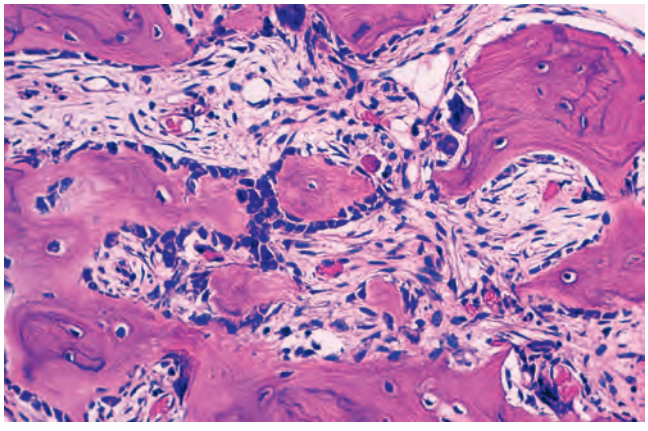
Radiographically, in early disease stages, the affected bone exhibits decreased radiodensity and a coarse trabecular pattern. Particularly in the skull, large circumscribed radiolucencies may be present **(osteoporosis circumscripta).** In later disease stages, patchy areas of bone sclerosis form and tend to become confluent. The patchy sclerotic areas characteristically exhibit a "cotton wool" appearance, and marked bony expansion is evident (Figs. 14.14 and 14.15). In addition, the teeth may demonstrate generalized hypercementosis.

• **Fig. 14.14 Paget Disease.** Lateral skull film shows marked enlargement of the cranium with new bone formation above the outer table of the skull and a patchy, dense, "cotton wool" appearance. (Courtesy of Dr. Reg Munden.)

• **Fig. 14.15 Paget Disease.** Periapical film showing the "cotton wool" appearance of the bone.

dentlearn.ir

Radiographic findings of Paget disease may resemble those of cemento-osseous dysplasia (see page 645). Patients with presumed cemento-osseous dysplasia who develop significant jaw expansion should be evaluated further to rule out Paget disease.



Histopathologic Features

Microscopic examination shows uncontrolled resorption and formation of bone. In the resorptive phase, numerous hyperactive osteoclasts surround the bone trabeculae; these osteoclasts tend to be enlarged with an increased number of nuclei. In addition, highly vascular fibrous connective tissue replaces the marrow. Behind the "leading edge" of osteoclastic activity, there is a gradual conversion from predominantly osteoclastic to osteoblastic activity. The osteoblasts form osteoid rims around the bone trabeculae, and the bone lacks an organized lamellar pattern. Basophilic reversal lines, which indicate the junction between alternating bone resorption and formation, result in a characteristic "jigsaw puzzle" or "mosaic" appearance (Fig. 14.16). In the sclerotic phase, there are large masses of dense bone with prominent reversal lines.

Diagnosis

Diagnosis typically requires correlation of the clinical and radiographic findings with laboratory test results. In addition, bone scintigraphy may help to determine the extent of involvement. Histopathologic examination can be confirmatory but often is unnecessary for diagnosis.

Laboratory testing typically shows elevated serum alkaline phosphatase levels with normal blood calcium and phosphorus levels. Although serum bone-specific alkaline phosphatase is considered the most sensitive marker of bone formation, total serum alkaline phosphatase is more widely available and, thus, typically used in routine clinical practice. When measuring total serum alkaline phosphatase, liver enzymes also should be assessed in order to exclude elevated alkaline phosphatase of hepatic origin.

• **Fig. 14.16 Paget Disease.** Prominent osteoblastic and osteoclastic activity surround the bone trabeculae. Note the resting and reversal lines.

In patients with limited disease extent, total serum alkaline phosphatase may be within normal range. In such cases, it may be helpful to assess specialized markers of bone formation (e.g., serum procollagen type 1 N-terminal propeptide) or resorption (e.g., urinary N-terminal telopeptide of type 1 collagen).

Treatment and Prognosis

Paget disease is chronic and slowly progressive but seldom fatal. Asymptomatic patients with limited disease do not require treatment. Patients with symptomatic or extensive disease typically receive bisphosphonate therapy (i.e., single infusion of zoledronic acid; oral risedronate or alendronate administered daily for several months). Studies have demonstrated that such treatment can reduce bone turnover, induce normalization of alkaline phosphatase levels, and decrease bone pain. In particular, single-infusion therapy with zoledronic acid is highly effective in achieving sustained disease remission. However, there is currently insufficient evidence regarding whether bisphosphonates may reduce the risk for long-term complications, such as osteoarthritis, bone deformity, and deafness. Analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs) may be useful for controlling pain caused by secondary osteoarthritis. Management of Paget disease also may include orthotics, canes or other mobility devices, and orthopedic surgery (e.g., hip or joint replacement). Prior to orthopedic surgery involving an active disease site, bisphosphonates may be administered in order to reduce the risk for excessive blood loss.

Potential dental complications include difficulties in extracting teeth with hypercementosis and/or ankylosis; extensive hemorrhage from oral surgical procedures performed during the vascular lytic phase; and poor wound healing with increased susceptibility to osteomyelitis during the avascular sclerotic phase. Edentulous patients may require new dentures periodically to compensate for progressive alveolar enlargement. Pagetic bone and a history of bisphosphonate therapy generally are considered unfavorable factors for osseointegration of dental implants, although successful implant placement has been reported in a few cases.

Malignant transformation of pagetic bone into osteosarcoma or other sarcomas is a rare disease complication, with an estimated lifetime risk of less than 1%. A sudden increase in bone pain or swelling should raise suspicion of possible underlying malignancy. Osteosarcoma in adults older than 40 years is quite uncommon in individuals who do not have Paget disease. Most Paget-related osteosarcomas develop in the pelvis and long bones of the extremities—the skull and jaws are affected only rarely. Osteosarcoma in Paget disease is very aggressive and associated with a poor prognosis.

Another rare complication of Paget disease is the development of benign and malignant giant cell tumors (see page 633), most often involving the craniofacial skeleton. Heritable mutations in the *ZNF687* gene recently have been identified in an unusual subset of patients with early-onset Paget disease, subsequent development of giant cell tumors, and often Italian descent.

dentlearn.ir

◆ CENTRAL GIANT CELL GRANULOMA (GIANT CELL LESION; GIANT CELL TUMOR)

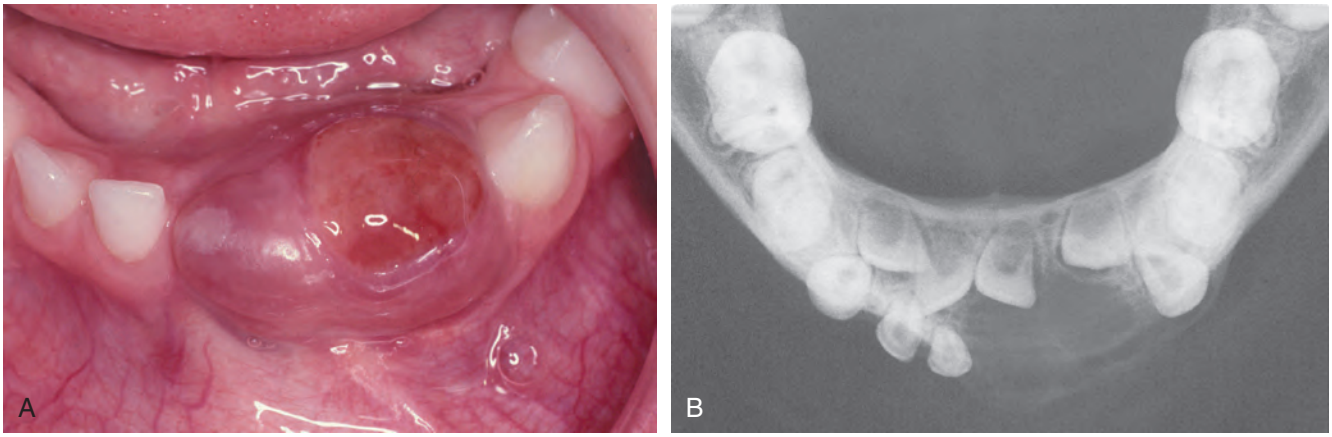
The **central giant cell granuloma** is an intraosseous lesion of unknown etiology. There has been much debate regarding whether this entity represents a reactive process or a benign neoplasm, with mounting evidence favoring the latter. In the past, it was hypothesized to represent a reparative response to trauma-induced hemorrhage—hence, its former designation *giant cell reparative granuloma.* However, there is little evidence to support a reparative response; therefore, most oral and maxillofacial pathologists today prefer the term *giant cell granuloma* or the more noncommittal term *giant cell lesion.* In fact, some examples demonstrate locally aggressive behavior similar to that of a benign neoplasm, and the recent identification of pathogenic mutations supports a monoclonal proliferation. In particular, genetic studies have demonstrated recurrent somatic mutations in *TRPV4*, *KRAS*, or *FGFR1* in approximately 70% of cases examined. These mutations activate the Ras-MAPK (mitogen-activated protein kinase) pathway and appear to be important drivers in disease development. Interestingly, similar mutations stimulating this pathway have been identified in a host of other conditions that produce giant cell proliferations in the oral cavity (Table 14.4). Furthermore, the nonossifying fibroma—a lesion often occurring in the metaphysis of long bones in young individuals—frequently harbors activating mutations in *KRAS, FGFR1,* and *NF1*. This observation has prompted some investigators to suggest that the nonossifying fibroma of long bones and the central giant cell granuloma of the jaws may represent variants of the same entity.

Clinical and Radiographic Features

Central giant cell granulomas of the jaws occur over a broad age range (0–86 years), although about 70% of cases occur before age 30. There is a female predilection, and approximately 70% of cases arise in the mandible. Lesions are more common in the anterior portions of the jaws, and mandibular lesions frequently cross the midline. Although central giant cell granulomas also have been reported in various extragnathic sites, it is uncertain whether such cases actually represent true **giant cell tumors** (see next topic).

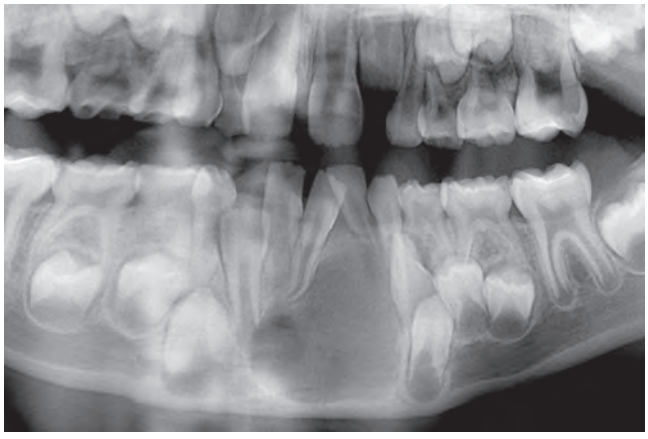
Based on the clinical and radiographic features, central giant cell granulomas of the jaws may be divided into two categories:

1. **Nonaggressive lesions** comprise most cases. They are relatively small, exhibit few or no symptoms, grow slowly, and do not cause cortical perforation or root resorption. Such lesions typically are discovered during routine radiographic examination or as a result of painless jaw expansion.
2. **Aggressive lesions** are characterized by pain, rapid growth, cortical perforation, root resorption, tooth displacement, and/or paresthesia. Extension into soft tissue and ulceration of the overlying mucosal surface also are possible (Fig. 14.17). Compared to nonaggressive lesions, aggressive lesions tend to be larger at diagnosis, develop in somewhat younger patients, and exhibit a greater recurrence potential.



Radiographically, the central giant cell granuloma appears as a unilocular or multilocular radiolucency, with well-delineated but generally noncorticated borders (Fig. 14.18). The lesion may vary from a 5 mm incidental radiographic

TABLE 14.4 Lesions or Conditions with Oral Giant Cell Proliferation and Mutations Activating the Ras-MAPK Pathway



Lesion or Condition	Comment
Central giant cell granuloma	Recent studies have demonstrated recurrent somatic activating mutations in *TRPV4*, *KRAS*, or *FGFR1* in approximately 70% of cases examined.
Peripheral giant cell granuloma (see page 527)	This gingival lesion may be considered the soft tissue counterpart of the central giant cell granuloma. In one study, activating mutations in *KRAS* and *FGFR1* were detected in about 70% and 10% of examined cases, respectively. Implant-associated peripheral giant cell granulomas also may exhibit *KRAS* mutations.
Brown tumor of hyperparathyroidism (see page 840)	In one study, about half of examined cases from the jaws exhibited activating *KRAS* mutations.
"RASopathies" (disorders of the Ras-MAPK pathway)	These disorders are caused by germline mutations in genes encoding Ras-MAPK signaling pathway components. Multifocal giant cell lesions of the jaws can occur in association with various heritable syndromes within this category, including Noonan syndrome, neurofibromatosis type 1 (see page 537), cardio-facio-cutaneous syndrome, and Noonan syndrome with multiple lentigines (LEOPARD syndrome).
Osteoglophonic dysplasia	This rare heritable disorder is caused by FGFR1 mutations. Giant cell lesions of the gingiva and nonossifying fibromas of long bones may develop. Other features include craniosynostosis, rhizomelic dwarfism, hypertelorism, depressed nasal bridge, midface hypoplasia, frontal bossing, macroglossia, prognathism, oligodontia or anodontia, and impacted teeth.

FGFR1, fibroblast growth factor receptor 1 gene; *KRAS,* Kirsten rat sarcoma viral oncogene; LEOPARD, multiple lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness; MAPK, mitogen-activated protein kinase; *TRPV4,* transient receptor potential cation channel subfamily V member 4 gene.

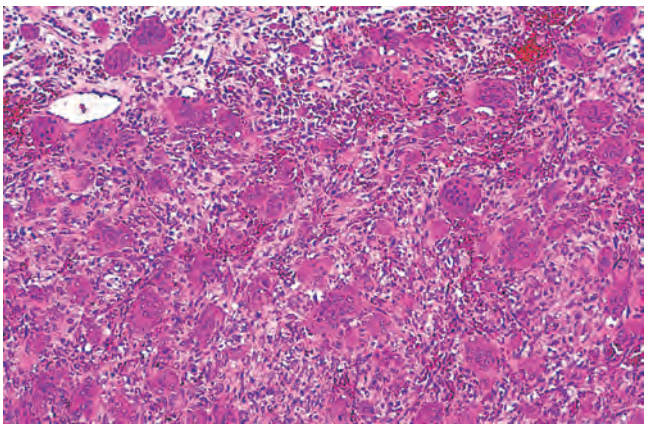
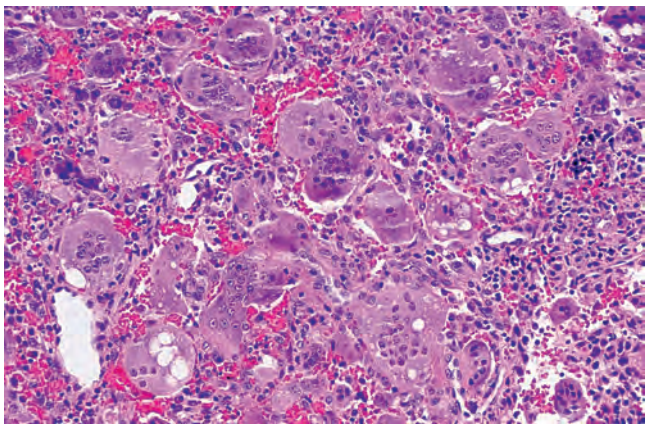
finding to a destructive lesion greater than 10 cm. Small unilocular lesions may be confused with periapical granulomas or cysts (Fig. 14.19), and multilocular lesions may appear similar to ameloblastomas. On CBCT examination, the bone at the periphery of the lesion may demonstrate a subtle, granular pattern, and multilocular examples may exhibit a mixture of wispy and coarse septa.

• **Fig. 14.19 Central Giant Cell Granuloma.** The periapical radiograph shows a radiolucent area involving the apex of an endodontically treated tooth. This was considered preoperatively to represent a periapical granuloma or periapical cyst.



Histopathologic Features

Microscopically, giant cell lesions of the jaws exhibit few to many multinucleated giant cells in a background of ovoid to spindle-shaped mononuclear stromal cells (Fig. 14.20). Investigators have proposed that the spindle cell component is the proliferating cell population and recruits monocyte-macrophage precursors, inducing them to differentiate into osteoclastic giant cells by activation of the RANK/RANKL signaling pathway. The giant cells may be aggregated focally in the lesional tissue or may be present diffusely throughout the lesion. These cells vary considerably in size and shape from case to case. Some are small and irregular in shape with only a few nuclei, whereas others are large and round with 20 or more nuclei.



The stroma may be loosely arranged and edematous or more cellular. Older lesions may show considerable stromal fibrosis. Erythrocyte extravasation and hemosiderin deposition are often prominent. Focal bone or osteoid formation may be present.

Correlation of the histopathologic features with clinical behavior remains debatable. There are conflicting reports regarding whether more aggressive giant cell lesions of the jaws may be associated with an increased number of giant cells, larger giant cells, a greater fractional surface area occupied by giant cells, and a higher mitotic index. A few studies

• **Fig. 14.21 Giant Cell Tumor.** This photomicrograph shows large giant cells that are distributed in a cellular mesenchymal tissue. This specimen was from an aggressive lesion that had destroyed most of the maxilla.

suggest that increased vascular density, increased expression of markers of angiogenesis, and increased expression of matrix metalloproteinases might correlate with aggressive clinical behavior.

The microscopic differential diagnosis includes numerous other entities. Because giant cell granulomas are histopathologically identical to brown tumors, hyperparathyroidism (see page 840) should be ruled out in all instances. In addition, areas microscopically identical to central giant cell granuloma have been noted in aneurysmal bone cysts (see page 638) and intermixed with central odontogenic fibromas (see page 731). Associations with benign fibro-osseous lesions and, more rarely, melorheostosis (an unusual bone disease characterized by cortical hyperostosis with a radiographic pattern likened to dripping candle wax and recently found to harbor somatic mutations in *MAP2K1* or other genes) have been noted as well. Furthermore, multifocal giant cell lesions of the jaws may occur infrequently as an isolated finding or in association with certain heritable conditions, including cherubism (see page 634), Ramon syndrome, Jaffe-Campanacci syndrome, and so-called "RASopathies" (see Table 14.4).

Treatment and Prognosis

Central giant cell granulomas of the jaws usually are treated by thorough curettage. Recurrent lesions may require further curettage (at times combined with peripheral ostectomy) or *en bloc* resection. Alternative treatments include intralesional corticosteroid injections, subcutaneous or nasal calcitonin, subcutaneous interferon alpha-2a, imatinib, denosumab, and bisphosphonates. Although further studies are needed, nonsurgical approaches may be desirable when surgical removal of a large tumor would result in significant deformity.

Among reported cases, the overall recurrence rate is approximately 18%. Lesions with aggressive clinicoradiographic features exhibit increased recurrence potential. In spite of the potential for recurrence, the long-term prognosis is good.

◆ GIANT CELL TUMOR ("TRUE GIANT CELL TUMOR")

The relationship between **giant cell tumors** of the extragnathic skeleton and giant cell lesions of the jaws is uncertain and controversial. Many authorities regard these two groups of lesions as distinct entities, based on differences in clinicopathologic features and biologic behavior. Extragnathic giant cell tumors have been found to exhibit somatic mutations in *H3F3A* (which encodes a histone protein) and, less often, *IDH1 or IDH2* (which encode isocitrate dehydrogenase 1 and 2, respectively), whereas giant cell lesions of the jaws have not been found to harbor such alterations. Instead, recent studies suggest that somatic *TRPV4*, *KRAS*, and *FGFR1* mutations are important drivers in the etiopathogenesis of the jaw lesions. Clinically, extragnathic giant cell tumors most often occur in the epiphyses of long bones. Compared to giant cell lesions of the jaws, extragnathic tumors are more likely to cause pain and tend to be diagnosed in patients who are 1 to 2 decades older on average. Some microscopic studies suggest that extragnathic giant cell tumors tend to exhibit more stromal cellularity and larger, more uniformly distributed giant cells, with a greater number of nuclei. Nonetheless, jaw lesions occasionally may exhibit microscopic features that are indistinguishable from typical extragnathic giant cell tumors (Fig. 14.21). In terms of biologic behavior, compared to jaw lesions, extragnathic lesions tend to be more aggressive, with higher recurrence rates after curettage. Pulmonary metastases ("benign pulmonary implants") and malignant transformation have been noted in approximately 2% of extragnathic giant cell tumors.

On the other hand, some researchers have found that giant cell granulomas of the jaws and giant cell tumors of the extragnathic skeleton are similar in many respects when substratification by clinical behavior is taken into account. These investigators hypothesize that giant cell lesions tend to be diagnosed earlier in the jaws compared to other sites simply because of frequent routine dental examinations and readily apparent changes in facial appearance.

dentlearn.ir

CHERUBISM

Cherubism is a rare developmental jaw condition that can be inherited as an autosomal dominant trait with variable expressivity. However, some cases appear to represent *de novo* mutations. A few investigators have reported a higher penetrance in males than in females, but others have questioned this finding.

Most cases are caused by gain-of-function mutations in the *SH3BP2* gene on chromosome 4p16. These mutations lead to enhanced stability of the 3BP2 adaptor protein and consequent upregulation of various signal transduction pathways. As a result, enhanced osteoclastogenesis and hyperactive osteoclasts produce lytic bone lesions. In addition, mouse model studies demonstrating increased production of tumor necrosis factor-alpha (TNF-α) by macrophages suggest a role for inflammation in this disorder. However, it is unclear why the lesions in cherubism primarily affect the jaws. Investigators hypothesize that rapid bone remodeling during childhood tooth eruption and oral commensal bacteria may play a role.

The name *cherubism* was applied to this condition because the facial appearance is similar to that of the plump-cheeked little angels (cherubs) depicted in Renaissance paintings. Although cherubism also has been called *familial fibrous dysplasia,* this term should be avoided because cherubism has no relationship to fibrous dysplasia of bone (see page 641).

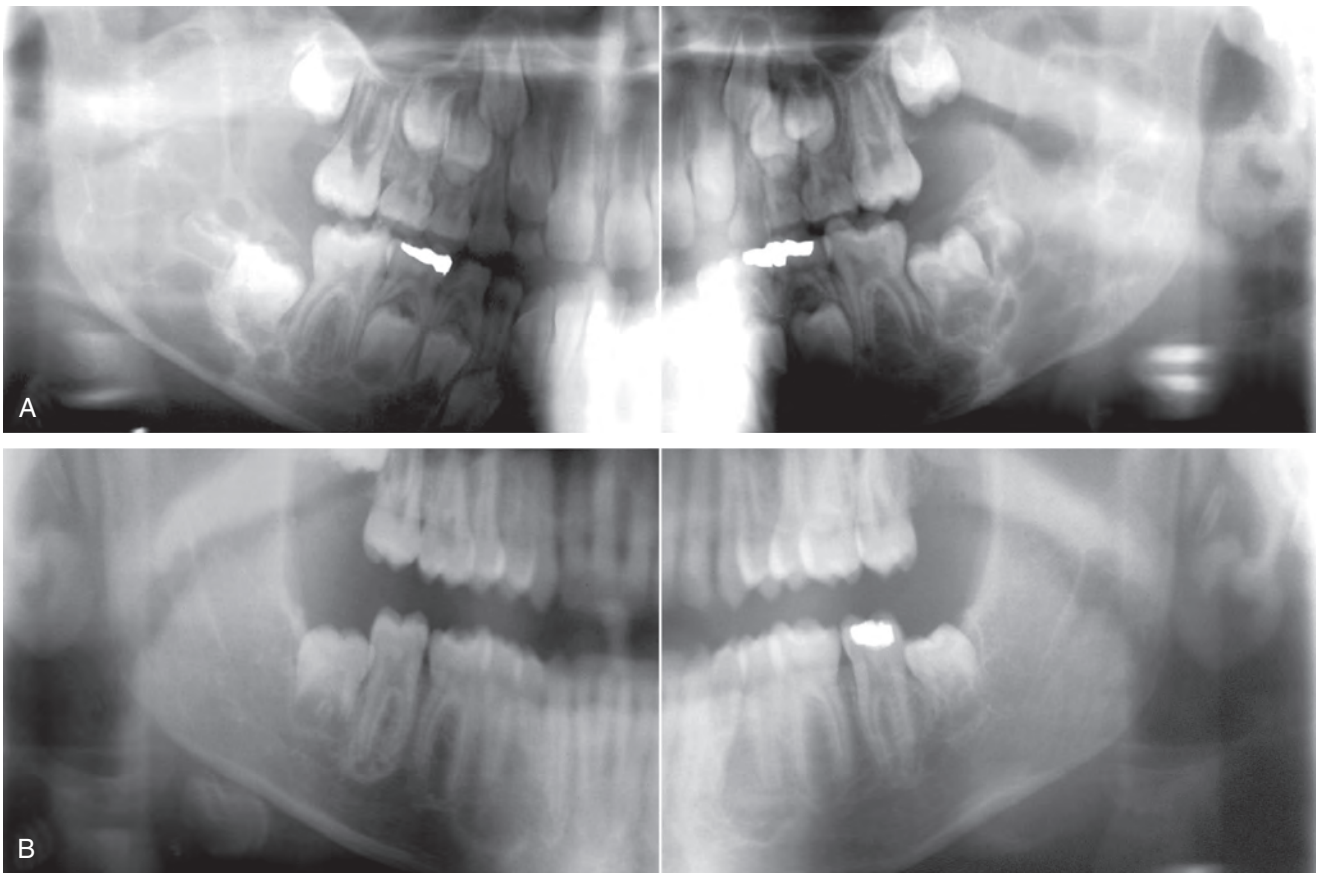
• **Fig. 14.22 Cherubism.** This young girl shows the typical cherubic facies resulting from bilateral expansile mandibular and maxillary lesions. (Courtesy of Dr. Román Carlos.)

Clinical and Radiographic Features

The condition usually first becomes evident at around 2–9 years of age, although in mild cases the diagnosis may not be made until 10–12 years. The clinical alterations typically progress until puberty and stabilize during adolescence. Some patients exhibit slow regression of lesions during adulthood, but others continue to experience marked bony changes and deformity.

The plump, cherub-like cheeks result from painless, bilaterally symmetric expansion of the posterior mandible (Fig. 14.22). In early disease, cervical lymphadenopathy also may contribute to the apparent fullness. In severe cases, involvement of the inferior and/or lateral orbital walls may tilt the eyeballs upward and retract the lower eyelid, thereby exposing the sclera below the iris to produce an "eyes upturned to heaven" appearance. Rare reports of unilateral cherubism are difficult to accept as true examples of this disease unless there is a strong family history or genetic confirmation.

In the mandible, lesions frequently develop in the angles, ascending rami, and coronoid processes, but the condyles usually are spared. In severe cases, most of the mandible is affected. Involvement of the maxillary tuberosities or entire maxilla also is possible, and there may be a V-shaped palatal arch. Extensive jaw involvement causes marked widening and distortion of the alveolar ridges. In addition to aesthetic compromise, the condition may cause tooth displacement, tooth mobility, premature loss of deciduous teeth, impacted or missing permanent teeth (especially molars), impaired mastication, speech difficulties, upper airway obstruction, and vision or hearing loss.



Radiographic examination typically shows bilateral, multilocular, expansile radiolucencies (Fig. 14.23, *A*). This radiographic presentation is virtually diagnostic. Less commonly, the lesions may appear unilocular. Additional findings may include resorption of adjacent tooth roots and thinning or perforation of the cortical bone. Although cherubism primarily is limited to the craniofacial region, rib involvement also has been reported in a few cases.

Biochemical findings (including serum calcium and phosphorus) typically are normal in patients with cherubism, although serum alkaline phosophatase and other markers of bone remodeling may be elevated in patients with active disease. If laboratory results do not suggest hyperparathyroidism, then most children with bilaterally symmetric giant cell lesions of the jaws represent examples of cherubism. However, multiple giant cell lesions may be seen in association with other conditions, including Ramon syndrome, Jaffe-Campanacci syndrome, and so-called "RASopathies" (e.g., Noonan syndrome, neurofibromatosis type 1) (see Table 14.4).

Histopathologic Features

Because the microscopic findings of cherubism are similar to those of isolated giant cell granulomas, correlation with the clinical and radiographic findings is essential for diagnosis. Microscopic examination shows vascular fibrous tissue with

dentlearn.ir

• **Fig. 14.23 Cherubism. A,** Panoramic radiograph of a 7-year-old white boy. Bilateral multilocular radiolucencies can be seen in the posterior mandible. **B,** Same patient 6 years later. variable numbers of multinucleated giant cells and scattered hemorrhage. The giant cells tend to be small and aggregated focally (Fig. 14.24). Like the giant cells in central giant cell granulomas, the giant cells in cherubism express markers suggestive of osteoclastic origin. The stroma in cherubism tends to be more loosely arranged than that in giant cell granulomas. In some cases, cherubism reveals eosinophilic, cuff-like deposits surrounding small blood vessels. This eosinophilic cuffing appears to be specific for cherubism but has been described in only about 28% of reported cases. In older, resolving lesions of cherubism, the tissue becomes more fibrous, the number of giant cells decreases, and new bone formation is seen.

Treatment and Prognosis

In most instances, lesion progression spontaneously ceases after puberty. According to a recent systematic review of the literature, lesion growth after 21 years of age has been noted in only about 5% of reported and genetically confirmed cases. Over time some patients exhibit lesion regression, with facial features approaching normalcy (Fig. 14.23). Nevertheless, the prognosis in any given case is difficult to predict, and persistent facial deformity or continued disease progression is possible.

A conservative treatment approach generally is preferred. Mild cases may require only observation. However, treatment typically is indicated for patients with aggressive lesions, severe functional impairment, or marked facial deformity. Surgical intervention may consist of curettage, recontouring, partial resection, or complete resection. The surgical defects may be filled with autogenous cancellous bone and bone marrow grafts. Outcomes of surgery performed during the active disease phase are variable, with some investigators reporting excellent results and others reporting aggressive regrowth. Generally, it is preferable to delay surgery until the disease has become quiescent, although severe aesthetic and functional compromise may demand earlier intervention. Alternative treatment with calcitonin, interferon, imatinib, denosumab, or tacrolimus has been reported anecdotally but requires further study. Attempts to treat cherubism with adalimumab (a TNF-α antagonist)—alone or in combination with bisphosphonates—have yielded disappointing results thus far. Radiation therapy is contraindicated because of the risk for post-irradiation sarcoma.

Dental management may include extraction or orthodontic extrusion of impacted teeth; orthodontics for malocclusion; and prostheses for missing teeth. Placement of dental implants and autotransplantation of teeth also have been reported in a few cases.

◆ SIMPLE BONE CYST (TRAUMATIC BONE CYST; HEMORRHAGIC BONE CYST; SOLITARY BONE CYST; IDIOPATHIC BONE CAVITY; UNICAMERAL BONE CYST)

The **simple bone cyst** is an empty or fluid-containing bone cavity. Because this lesion lacks an epithelial lining, it represents a pseudocyst rather than a true cyst.

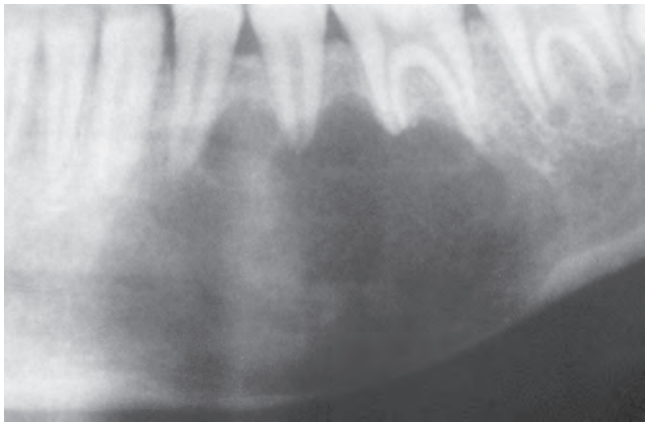
The etiopathogenesis is uncertain, and several theories have been proposed. In particular, the **trauma-hemorrhage theory** has many advocates, as evidenced by the widely used designation **traumatic bone cyst.** According to this theory, trauma that is insufficient to cause a bone fracture results in an intraosseous hematoma. If the hematoma does not undergo organization and repair, it may liquefy and result in a pseudocystic defect. However, a history of trauma to the affected area and the presence of blood within the cavity have been inconsistent findings. Other proposed theories include venous obstruction, interstitial fluid blockage, local disturbance in bone growth, altered calcium metabolism, ischemic marrow necrosis, aberrant synovial development, low-grade infection, and degeneration of a bone tumor or cyst. In addition, investigators recently have identified *FUS*::*NFATC2* or *EWSR1*::*NFATC2* fusions in a subset of extragnathic cases.

Clinical and Radiographic Features

Simple bone cysts have been reported in almost every bone of the body. Most cases involve the metaphyses of long bones, with a predilection for the proximal humerus and proximal femur. In addition, solitary bone cysts may arise in the jaws, with a marked mandibular predominance. Although any area of the mandible may be involved, the premolar, molar, and symphyseal regions are affected most commonly. Maxillary lesions tend to occur in the anterior region. Most solitary bone cysts are diagnosed in young patients, with a peak in the second decade. Jaw lesions exhibit no significant gender bias, whereas extragnathic lesions exhibit a male predilection. Unlike extragnathic lesions, jaw lesions tend to lack clinical signs or symptoms; thus, the true frequency of jaw lesions is undoubtedly greater than the literature would suggest. About 20% of patients, however, have a painless jaw swelling. Pain and paresthesia are noted infrequently.

Simple bone cysts of the jaws often are discovered incidentally during radiographic examination for some other reason. The lesion typically appears as a well-delineated, unilocular radiolucency. However, ill-defined and multilocular lesions also are possible. The defect may range from 1 to 10 cm in diameter. Occasionally, the radiolucent defect shows domelike projections that scallop upward between the roots of adjacent teeth. This feature is highly suggestive but not diagnostic of a simple bone cyst (Figs. 14.25 and 14.26). In many cases, a cone-shaped outline (pointed at one or both ends in the anterior-posterior direction) may be noted, particularly when the lesion is large. Oval, irregular, or rounded borders are possible as well. The adjacent teeth are generally vital and not displaced. Root resorption, loss of lamina dura, cortical expansion, cortical thinning or perforation, and displacement of the mandibular canal are evident in a minority of cases. Most lesions are solitary, but multifocal involvement has been reported occasionally. Extensive lesions involving a substantial portion of the mandibular body and ascending ramus also are possible.

Simple bone cysts at times may arise in association with cemento-osseous dysplasia (see page 645) (Fig. 14.27) and other fibro-osseous proliferations. Such cases tend to occur in older females.



Histopathologic Features

There is never an epithelial lining. Instead, the walls of the defect are lined by a thin band of vascular fibrous connective tissue (Fig. 14.28) or a thickened myxofibromatous proliferation with reactive bone. In addition, there may be fibrin, scattered erythrocytes, occasional giant cells, and lacelike dystrophic calcifications (Fig. 14.29). Some authors also have noted amorphous, cementum-like material, which may represent osteoid. The bony surface next to the cavity may show resorptive areas (Howship lacunae) indicative of past osteoclastic activity.

• **Fig. 14.29 Simple Bone Cyst.** Loose vascular connective tissue exhibiting areas of basophilic lacelike calcification in the wall of a simple bone cyst.

Diagnosis

The radiographic features of the simple bone cyst are not entirely specific and may be confused with a wide variety of odontogenic and non-odontogenic radiolucent jaw lesions. Surgical exploration is necessary to establish the diagnosis.

Typically, little to no tissue is obtained at the time of surgery; therefore, the diagnosis is based primarily on the clinical, radiographic, and intraoperative findings. In about one-third of cases, there is an empty cavity with smooth, shiny bony walls. In about two-thirds of cases, the cavity contains small amounts of serosanguineous fluid. The mandibular neurovascular bundle may be seen lying free in the cavity.

Treatment and Prognosis

Simple bone cysts of the long bones often are treated aggressively, with various combinations of curettage, cryosurgery, decompression, intralesional steroid injections, bone substitute or autologous bone marrow injection, and bone grafting. Reported recurrence rates are relatively high (mean 29%, range 12%–48%).

In contrast, simple bone cysts of the jaws typically are managed by surgical exploration and curettage. Intraoperatively, the bony walls of the cavity usually appear smooth and shiny, although it is wise to curette them and submit the small amount of tissue obtained for microscopic examination to rule out more serious diseases. Surgical exploration with or without curettage usually induces bone regeneration; normal radiographic findings typically are evident 12–17 months after surgery. Periodic radiographic examination should be performed until complete resolution has been confirmed. There are also anecdotal reports of favorable results with bone grafting, plasma-rich protein, or packing materials. Most studies report very low recurrence rates (approximately 1%–2%), although some report recurrence rates as high as 26%. There is an increased potential for recurrence when there are multiple lesions or with lesions arising in association with cemento-osseous dysplasia. In addition, one study reported an increased recurrence potential among jaw lesions exhibiting scalloped margins, resorption of the lamina dura, nodular bone expansion, and multiple cavities. Overall, the prognosis is excellent.

◆ ANEURYSMAL BONE CYST

The **aneurysmal bone cyst** is an intraosseous accumulation of variable-sized, blood-filled spaces surrounded by cellular fibrous connective tissue and reactive bone. Because the lesion lacks an epithelial lining, it represents a pseudocyst rather than a true cyst. Aneurysmal bone cysts may be classified as *primary* (i.e., arising *de novo*) or *secondary* (i.e., arising in association with another bone lesion). In extremely rare cases, the lesion may arise in soft tissue as well.

The etiopathogenesis is poorly understood. Traditionally, the aneurysmal bone cyst has been thought to result from a reactive process and/or altered hemodynamics. Many authors have theorized that a traumatic event, vascular malformation, neoplasm, or other pathologic condition may disrupt normal osseous hemodynamics, resulting in an enlarging area of hemorrhage and osteolysis. Consistent with this hypothesis is the observation that approximately 30% of aneurysmal bone cysts overall and 15% of gnathic examples form in association with other lesions. In contrast, cytogenetic evidence suggests that primary aneurysmal bone cysts may be neoplastic in nature. The majority of primary lesions analyzed exhibit recurrent translocations and consequent transcriptional upregulation of the ubiquitin-specific protease 6 *(USP6)* (also known as *Tre-2* or *TRE17*) oncogene on chromosome 17p13. The most commonly observed translocation is t(16;17)(q22;p13), which results in fusion of *USP6* with the cadherin 11 gene (*CDH11*). Other possible *USP6* fusion partners include the zinc-finger 9 gene (*ZNF9*), collagen 1A1 gene (*COL1A1*), thyroid receptor-associated protein gene (*TRAP150*), and osteomodulin gene (*OMD*). However, *USP6* translocations have been detected in very few craniofacial lesions thus far. The underlying mechanisms by which *USP6* upregulation leads to tumor

dentlearn.ir

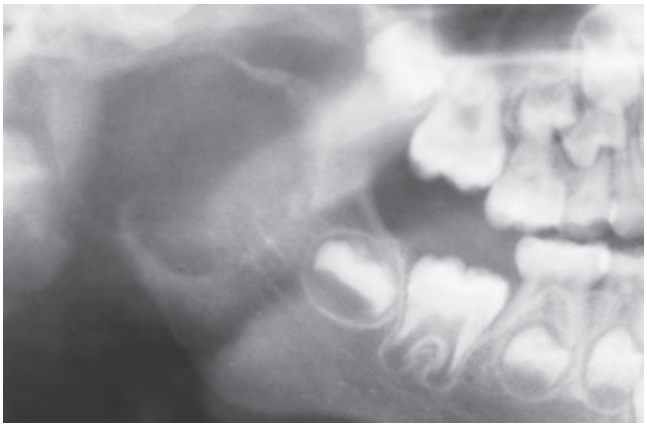
formation remain poorly understood. Some studies suggest there may be downstream dysregulation of bone morphogenetic protein resulting in disrupted osteoblastic maturation, and others have noted nuclear factor-kappa B (NF-κB)-mediated induction of matrix metalloproteinases that play an important role in angiogenesis and inflammatory processes.

Clinical and Radiographic Features

Aneurysmal bone cysts arise primarily in the long bones or vertebrae of patients younger than 30 years. Only about 2% of cases involve the jaws. Gnathic lesions mainly affect young patients (peak in the second decade) but may occur over a broad age range. Most authors report either no significant sex predilection or a slight female predilection. The lesions arise more often in the mandible than the maxilla, and the vast majority arises in the posterior segments of the jaws. Within the mandible, involvement of the ascending ramus and posterior body is common, whereas involvement of the condylar and coronoid processes is infrequent.

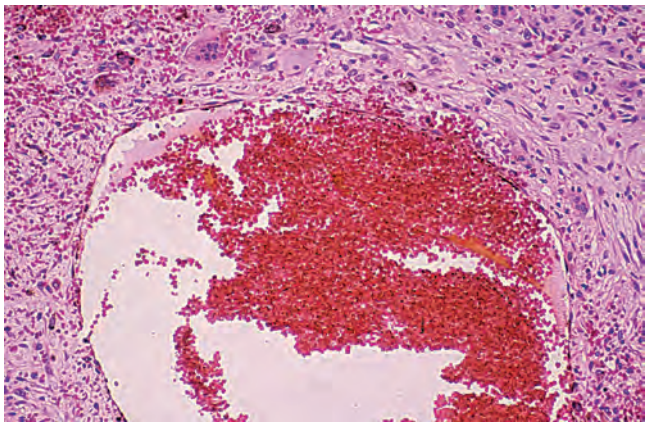
The most common clinical manifestation is a rapidly enlarging swelling. Pain is a variable finding; paresthesia and crepitus have been noted rarely. Malocclusion, mobility, migration, or resorption of involved teeth may be present. Maxillary lesions often bulge into the adjacent sinus and occasionally cause nasal obstruction, nasal bleeding, proptosis, and diplopia.

Radiographic examination shows a unilocular or multilocular radiolucency, often with marked cortical expansion and thinning (Fig. 14.30). The radiographic borders may be well defined or poorly defined. There is frequently a ballooning or "blow-out" distention of the affected bone. Uncommonly, small radiopaque foci, thought to be small trabeculae of reactive bone, are noted within the radiolucency.



Intraoperatively, intact periosteum and a thin shell of bone typically are evident overlying the lesion, although cortical perforation is possible. When the periosteum and bony shell are removed, the lesion exhibits dark venous-like bleeding with a "blood-soaked sponge" appearance.

Histopathologic Features



Microscopically, the aneurysmal bone cyst is characterized by blood-filled spaces of varying size. These blood-filled spaces lack an endothelial or epithelial lining (Fig. 14.31). The surrounding septa exhibit a proliferation of fibroblastic or myofibroblastic spindle cells with associated multinucleated giant cells, osteoid, and woven bone. The spindle cells harbor *USP6* and *CDH11* rearrangement and, thus, appear to represent the neoplastic component in primary lesions. Similar to the multinucleated giant cells in giant cell granulomas, the multinucleated giant cells in aneurysmal bone cysts exhibit an osteoclastic phenotype, as evidenced by immunohistochemical and *in situ* hybridization studies. Osteoid deposits may appear linear, nodular, or lacelike. Mitotic figures may be evident but should not be atypical. As noted earlier, aneurysmal bone cysts may be associated with other pathoses, such as cemento-ossifying fibromas, fibrous dysplasia, or central giant cell granulomas.

Treatment and Prognosis

Aneurysmal bone cysts of the jaws usually are treated by curettage or enucleation, sometimes supplemented with cryosurgery. *En bloc* resection is reserved for extensive or recurrent lesions. Preoperative embolization may be considered to control bleeding but often is unnecessary, because most gnathic lesions exhibit low-flow vascularity. Typically, the surgical defect heals within 6 months to 1 year and does not necessitate bone grafting. Alternative treatments reported anecdotally in the literature include denosumab and intralesional injection of various agents (e.g., aqueous calcium sulfate, calcitonin with methyprednisolone, Ethibloc). Irradiation generally is contraindicated.

• **Fig. 14.31 Aneurysmal Bone Cyst.** Photomicrograph showing a blood-filled space surrounded by fibroblastic connective tissue. Scattered multinucleated giant cells are seen adjacent to the vascular space.

dentlearn.ir

Recent reviews of the literature have noted recurrence rates of 3%–23% among reported jaw lesions. The risk for recurrence may be greater among secondary lesions compared to primary lesions. In addition, some reported recurrences actually may represent persistence after incomplete removal. Occasionally, recurrence also may be related to incomplete removal of a coexisting lesion, such as an ossifying fibroma or osteoblastoma. Overall, despite recurrences, the long-term prognosis is favorable.

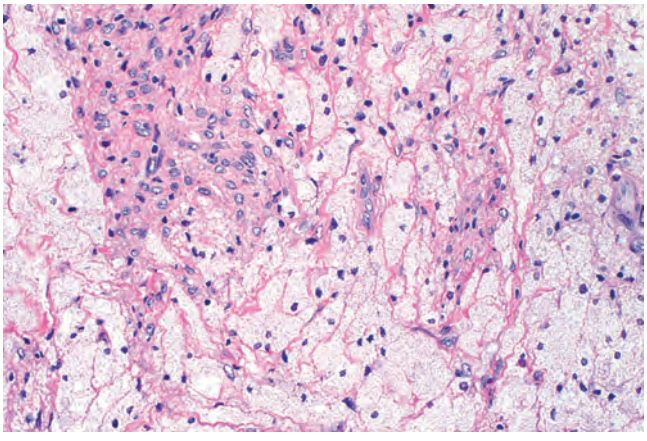
◆ CENTRAL XANTHOMA OF THE JAWS (PRIMARY XANTHOMA OF BONE; PRIMARY INTRAOSSEOUS XANTHOMA; FIBROUS XANTHOMA OF BONE; FIBROXANTHOMA OF BONE)

The central xanthoma of the jaws is a rare lesion characterized by the presence of lipid-laden macrophages (termed *xanthoma cells* or *foam cells*). Its etiopathogenesis is unclear, although it is believed to represent either a reactive process or a benign neoplasm. Some investigators have proposed that this lesion results from phagocytosis of lipids leaked from blood vessels after local trauma or hemorrhage. Unlike xanthomas involving soft tissue or extragnathic bones, central xanthomas of the jaws are not closely associated with metabolic or endocrine disorders, such as hyperlipidemia or diabetes mellitus.

Some authors consider xanthomas of the jaws to belong to a spectrum of conditions that also includes the nonossifying fibroma (fibrous cortical defect) and benign fibrous histiocytoma. The nonossifying fibroma is a lesion commonly arising in the metaphysis of the long bones in children and adolescents; it frequently undergoes spontaneous resolution, unlike the more slowly progressive central xanthoma of the mandible. The benign fibrous histiocytoma only rarely develops intraosseously, with a predilection for the pelvis and long bones; it typically exhibits more progressive growth compared to xanthomas of the jaws. Based on differences in clinicopathologic presentation and behavior, it seems more appropriate to regard the central xanthoma of the jaws as a distinct entity.

Clinical and Radiographic Features

The central xanthoma of the jaws has been reported over a broad age range, with a peak in the second and third decades of life and no significant gender predilection. The mandible is affected much more often than the maxilla. Mandibular lesions tend to occur in the posterior region. Most patients are asymptomatic, although swelling and pain are possible. Some cases have been discovered incidentally during radiographic examination performed for other reasons. Infrequent findings include tooth mobility and lower lip numbness.



Radiographic examination typically shows a solitary, unilocular radiolucency, although some examples appear as a multilocular radiolucency (Fig. 14.32), a mixed radiolucency-radiopacity, or a "ground-glass" radiopacity. Reported lesion size varies from 1 to 11 cm (median 2 cm). The borders may be either well- or ill-defined and may appear punched out or sclerotic. Larger tumors may exhibit cortical expansion. Infrequent findings include a scalloped border, resorption or splaying of adjacent tooth roots, cortical resorption or perforation, displacement of the inferior alveolar canal, and elevation of the maxillary sinus floor.

Histopathologic Features

Grossly, the tumor typically presents as a soft, yellow mass or yellow granules. Microscopic examination shows a sheet-like proliferation of ovoid cells with abundant, foamy or granular cytoplasm and small, round nuclei (Fig. 14.33). Unlike the nonossifying fibroma and benign fibrous histiocytoma, the

• **Fig. 14.33 Central Xanthoma of the Jaws.** Proliferation of ovoid cells with abundant foamy cytoplasm and small, round nuclei. There is only a minor fibrous connective tissue component.

dentlearn.ir

central xanthoma of the jaws include a variable fibrous connective tissue component, lacks a storiform growth pattern, and rarely exhibits multinucleated giant cells. Lymphocytes and plasma cells occasionally may be present within the background; however, the lack of a prominent mixed inflammatory background aids in avoiding confusion with periapical inflammatory disease. Small bony trabeculae and metaplastic ossification around bone spicules may be noted as well.

The foam cells exhibit strong immunoreactivity for CD68. Negative expression of S-100 protein, CD1a, and CD207 aids in distinction from Langerhans cell histiocytosis (see page 596). The microscopic differential diagnosis also includes Erdheim-Chester disease and lipid reticuloendotheliosis (see page 821), although these entities can be ruled out readily by clinical correlation.

Treatment and Prognosis

Most cases are treated by curettage, enucleation, or partial excision. Recurrence after complete removal has been reported rarely.

FIBRO-OSSEOUS LESIONS OF THE JAWS

Fibro-osseous lesions are a diverse group of processes that are characterized by replacement of normal bone by fibrous tissue containing a newly formed mineralized product. The term *fibro-osseous lesion* is descriptive and does not constitute a specific diagnosis. Lesions belonging to this category may be developmental (hamartomatous), reactive, dysplastic, or neoplastic.

The major types of fibro-osseous lesions of the jaws are listed in Box 14.1. Although these conditions differ in etiology, they may exhibit very similar histopathologic features. Therefore, correlation of the histopathologic findings with the clinical and radiographic features typically is essential for establishing a specific diagnosis. (However, in some cases of cemento-osseous dysplasia, a presumptive diagnosis may be made based on the clinical and radiographic findings.) A specific diagnosis is critical because the treatment, biologic behavior, and prognosis of these pathoses vary greatly. Some fibro-osseous lesions only require monitoring, whereas others necessitate surgical recontouring or complete removal.

• BOX 14.1 Major Types of Fibro-Osseous Lesions of the Jaws

Fibrous dysplasia

- Monostotic fibrous dysplasia
- Polyostotic fibrous dysplasia
  - Isolated
  - Syndrome-related (i.e., McCune-Albright syndrome, Mazabraud syndrome)
- Cemento-osseous dysplasia
  - Focal cemento-osseous dysplasia
  - Periapical cemento-osseous dysplasia
  - Florid cemento-osseous dysplasia
- Ossifying fibroma
  - Cemento-ossifying fibroma
  - Juvenile ossifying fibroma
    - Trabecular variant
    - Psammomatoid variant

◆ FIBROUS DYSPLASIA

Fibrous dysplasia is a developmental tumorlike condition, characterized by replacement of normal bone by a proliferation of cellular fibrous connective tissue with irregular bony trabeculae. This sporadic condition results from postzygotic, activating mutations in the *GNAS* gene, which encodes the alpha subunit of a stimulatory G protein. Such mutations have not been detected in ossifying fibroma or cemento-osseous dysplasia.

Clinically, fibrous dysplasia may involve one bone or multiple bones; in some cases, involvement of multiple bones may occur in conjunction with cutaneous and endocrine abnormalities. The extent of disease depends on when the *GNAS* mutation occurs. During early embryonic development, mutation of a pluripotent stem cell can cause abnormalities in multiple cell types, including osteoblasts, melanocytes, and endocrine cells. In contrast, if the mutation occurs in a skeletal progenitor cell in a later stage of embryonic development, then only osteoblasts will be affected. Alternatively, if the mutation occurs during postnatal life, then osteoblasts in only a single bone will be affected. Furthermore, the parental origin of the mutated *GNAS* allele may affect the phenotype, because in certain cell types (such as pituitary somatotrophs) genomic imprinting results in expression of only the maternal allele.

Constitutive activation of G-protein signaling impairs differentiation of skeletal progenitor cells into mature osteoblasts and osteocytes, induces an abnormal fibroblastic phenotype among bone marrow stromal cells, stimulates melanin production in melanocytes, and causes hyperplasia and hyperfunction of various endocrine cell types. In addition, mutated osteoblasts, osteocytes, and stromal cells overexpress interleukin (IL)-6 and receptor activator of nuclear factor-kappa B ligand (RANKL), which stimulate osteoclastogenesis and may contribute to bone lesion expansion.

Clinical and Radiographic Features

Monostotic Fibrous Dysplasia

About 80% of patients with fibrous dysplasia have disease limited to a single bone **(monostotic fibrous dysplasia).** Commonly involved sites include the craniofacial bones, ribs, femur, and tibia. Males and females are affected with about equal frequency. The condition is diagnosed most often during the second and third decades of life. The mean

dentlearn.ir

age at diagnosis for cases involving the jaws is approximately 24–37 years; some studies suggest that gnathic lesions may be diagnosed in a somewhat older age group compared to extragnathic lesions.

Among jaw cases, the maxilla is affected more often than the mandible. There is a predilection for the posterior region. Although mandibular lesions are truly monostotic, maxillary lesions often extend to involve adjacent bones (e.g., zygoma, sphenoid, ethmoid, frontal bone, temporal bone, occiput)—in which case the term **craniofacial fibrous dysplasia** is appropriate. Painless, unilateral swelling is the most common clinical finding (Fig. 14.34). Growth is generally slow, and many cases are discovered incidentally during radiographic examination. Occasionally, however, the growth may be fairly rapid. Adjacent teeth may be displaced by the bony mass but usually remain firm.

The classic radiographic finding is a fine "ground-glass" opacification with poorly defined margins (Figs. 14.35 through 14.37). However, some examples may appear radiolucent or mixed radiolucent-radiopaque. Sometimes there is "ground-glass" opacification surrounding a central radiolucency. As the patient ages, there may be increased lesion heterogeneity or sclerosis. Mottled, diffusely sclerotic, "rind" sign (thick sclerotic margin), cotton wool, chalky, soap bubble, and fingerprint patterns (Fig. 14.38) are possible. There is often buccolingual expansion with cortical thinning, which may be appreciated best by CT; the outer cortical contour typically remains smooth, although endosteal scalloping may be noted. Mandibular lesions may cause displacement of the inferior alveolar canal and bulging of the inferior border. Periapical radiographs may demonstrate narrowing of the periodontal ligament space and an ill-defined lamina dura that blends with the abnormal bone. Infrequent findings include tooth impaction and root resorption. Maxillary lesions often cause superior displacement of the sinus floor and obliteration of the antrum. In addition, extensive skull involvement may be evident (Fig. 14.39). CT is superior to conventional radiographs for visualizing the characteristic bony changes and determining the extent of disease. In addition, skeletal scintigraphy may aid in detecting metabolically active lesions and ruling out polyostotic disease.

Fibrous dysplasia of the jaws, *Oral Surg Oral Med Oral Pathol* 35:190–201, 1973.)

• **Fig. 14.38 Fibrous Dysplasia.** Radiograph showing a "fingerprint" pattern.

Polyostotic Fibrous Dysplasia; McCune-Albright Syndrome

A minority of patients with fibrous dysplasia exhibits involvement of two or more bones **(polyostotic fibrous dysplasia).** Most patients with polyostotic disease are diagnosed before 10 years of age, and there is a female predilection. The number of involved bones varies from a few to 75% of the entire skeleton. Commonly involved sites include the craniofacial region, pelvic bones, and femur.

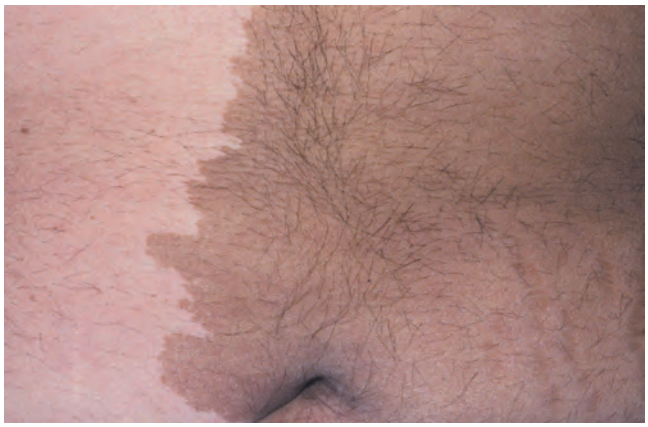
Presenting signs and symptoms related to long bone involvement may include pain, pathologic fracture, limping, leg length discrepancy, and bowing deformity. Radiographic examination may reveal malformation of the proximal femur (known as *coxa vara, shepherd's crook deformity,* or *hockey stick deformity*). Craniofacial involvement is present in as many as 87% of patients with polyostotic disease and may result in facial asymmetry (Fig. 14.40), malocclusion, vision changes,

• **Fig. 14.39 Fibrous Dysplasia.** Computed tomography (CT) image showing extensive involvement of the maxilla and skull.

hearing impairment, sinonasal congestion, and airway obstruction. Hypophosphatemia caused by renal phosphate wasting is a fairly common finding, which appears to be related to the release of fibroblast growth factor 23 *(FGF23)* by the affected bones.

A small subset of patients may exhibit polyostotic fibrous dysplasia in association with the following syndromes:

- **McCune-Albright syndrome**, characterized by two or more of the following features: polyostotic fibrous dysplasia, *café au lait* (coffee with milk) pigmentation, and hyperfunctioning endocrinopathies (In the past, some authors used the term *Jaffe-Lichtenstein syndrome* for cases of polysostotic fibrous dysplasia with café au lait pigmentation but no endocrinopathy; however, according to current convention, such cases are regarded as a variation of McCune-Albright syndrome.)
- **Mazabraud syndrome**, characterized by fibrous dysplasia and intramuscular myxomas



The *café au lait* pigmentation typically is seen on the skin at or shortly after birth. It consists of well-defined, tan macules with very irregular, jagged margins, resembling a map of the coastline of Maine (Fig. 14.41). In contrast, the *café au lait* spots of neurofibromatosis (see page 537) usually exhibit smooth borders (like the coast of California). The cutaneous lesions in McCune-Albright syndrome tend to be unilateral and more or less respect the midline. In addition, similar pigmentation of the lips and intraoral mucosa may be noted; however, unlike the skin lesions, the oral lesions tend to develop in adulthood and may progress with age.

In McCune-Albright syndrome, the most common endocrine abnormality is sexual precocity, particularly in females. Menstrual bleeding, breast development, and pubic hair may be apparent within the first few months or years of life. Other possible endocrinopathies include hyperthyroidism, hyperparathyroidism, neonatal hypercortisolism, and excess growth hormone. In addition, in one study of craniofacial fibrous dysplasia mainly occurring in McCune-Albright syndrome, investigators reported various dental anomalies, including tooth displacement, oligodontia, enamel hypoplasia, enamel hypomineralization, taurodontism, and retained deciduous teeth.

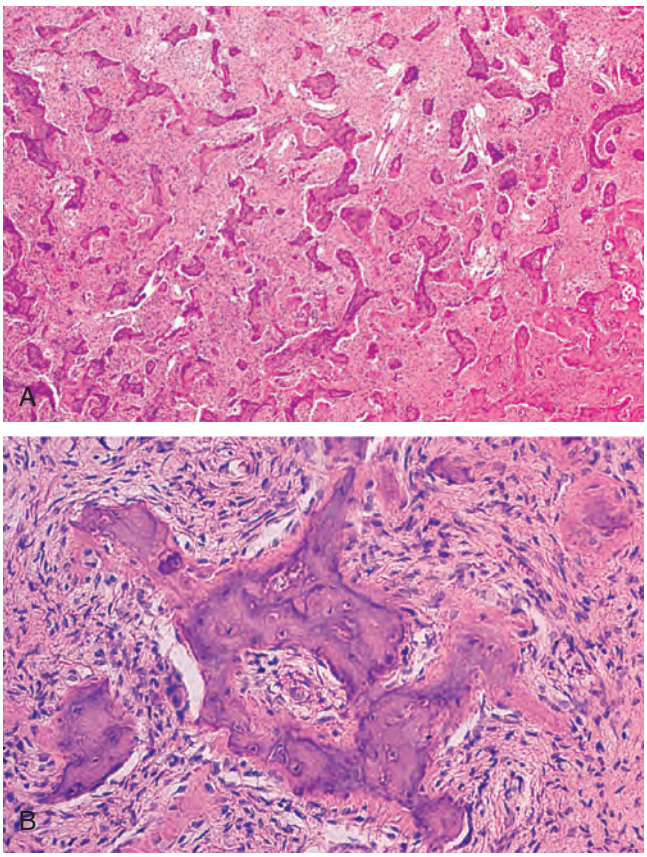
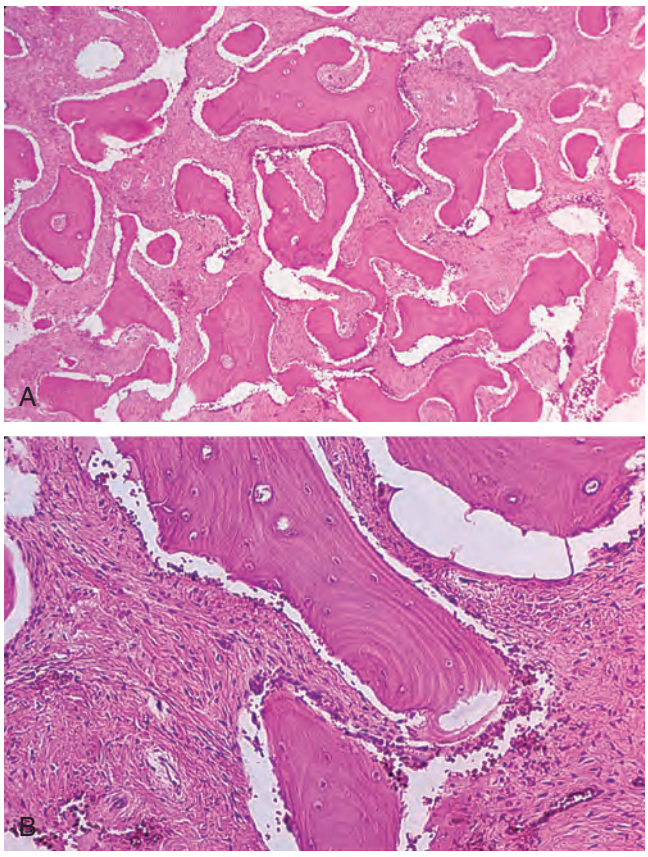
• **Fig. 14.41 Polyostotic Fibrous Dysplasia.** McCune-Albright syndrome. *Café au lait* pigmentation of the abdomen. This is the same patient as shown in Fig. 14.40.



Histopathologic Features

Microscopic examination typically shows irregularly shaped trabeculae of immature (woven) bone in a cellular fibrous stroma (Fig. 14.42). At the periphery, the lesional bone fuses with normal bone, without a capsule or line of demarcation. The abnormal bony trabeculae tend to be thin and disconnected, with elongated, curvilinear shapes likened to Chinese characters or alphabet soup (often forming the letters "C," "Y," and "U"). Osteoblastic rimming is usually absent or minimal, and peritrabecular clefting (artifactual retraction of the stroma from the bony trabeculae) is common. In addition, tiny calcified spherules rarely may be seen but are never numerous. In later stages, the woven bone is replaced by lamellar bone with roughly parallel trabeculae (Fig. 14.43). The rather monotonous pattern of calcification in fibrous dysplasia differs from the more haphazard mixture of woven bone, lamellar bone, and spheroid particles characteristic of ossifying fibroma and cemento-osseous dysplasia.



Fibrous dysplasia may appear more sclerotic in the jaw and skull than other sites. Microscopic variations include a pagetoid pattern (characterized by thick, interconnected bone trabeculae) and a hypercellular pattern (characterized by parallel bone trabeculae with numerous osteocytes and polarized osteoblastic rimming). Secondary aneurysmal bone cyst formation has been reported as well.

Genetic testing for *GNAS* mutations can be performed on lesional tissue or, possibly, peripheral blood samples. Such testing may be helpful when there is diagnostic uncertainty, but it exhibits low sensitivity and is not performed routinely.

• **Fig. 14.43 Mature Fibrous Dysplasia. A,** This long-standing lesion shows separate, broad trabeculae of bone within fibrous connective tissue. **B,** Note the lamellar maturation of the bone.

Treatment and Prognosis

Fibrous dysplasia tends to stabilize upon skeletal maturation, and spontaneous regression even has been reported in a few cases. Therefore, conservative management is preferred. Some lesions, nevertheless, exhibit continued growth into adulthood. The risk for severe deformity and complications is particularly elevated among patients with widespread polyostotic fibrous dysplasia—especially in the setting of McCune-Albright syndrome with uncontrolled growth hormone excess.

Patients with minimal cosmetic and functional disturbances may not require surgical treatment. For young patients with significant problems due to large or extensive lesions, surgical contouring, shaving, or other debulking procedures may be performed. However, subsequent regrowth may require additional surgery. Approximately 20%–50% of patients show some regrowth after surgical debulking, and the risk for regrowth is greater among younger than older patients. Therefore, if possible, many authorities prefer to delay surgery until the disease is quiescent.

Alternatively, complete surgical removal may be considered in some cases, such as small monostotic lesions, very aggressive lesions, or lesions refractory to repeated debulking. Combined orthodontic treatment and orthognathic surgery may be performed to correct malocclusion. Successful placement of dental implants has been reported in a few cases, but additional studies are needed. Investigational treatments include bisphosphonates and denosumab; these agents may help to relieve bone pain in fibrous dysplasia. Radiation therapy is contraindicated because of the risk for post-irradiation bone sarcoma.

Transformation into malignancy, usually an osteosarcoma, is estimated to occur in less than 1% of patients with fibrous dysplasia. The risk for sarcomatous transformation is greatest among those with a history of radiation therapy, McCune-Albright syndrome, or Mazabraud syndrome. Rapid lesion growth, sudden onset of pain, neurosensory changes, or marked changes in radiographic appearance should alert the clinician to rule out malignant transformation.

◆ CEMENTO-OSSEOUS DYSPLASIAS (OSSEOUS DYSPLASIA)

Cemento-osseous dysplasia occurs in the tooth-bearing areas of the jaws and is probably the most common fibro-osseous lesion encountered in clinical practice. Because the histopathologic features share many similarities with fibrous dysplasia and ossifying fibroma, correct diagnosis can be problematic but is critical for appropriate management.

dentlearn.ir

Some investigators have suggested that cemento-osseous dysplasia originates from the periodontal ligament, because of microscopic similarity and lesion proximity to this structure. Others believe this condition represents a defect in extraligamentary bone remodeling that may be triggered by local injury or, possibly, an underlying hormonal imbalance.

Occasionally, simple bone cysts (see page 636) may arise in association with cemento-osseous dysplasia (Fig. 14.27) or other fibro-osseous proliferations. Investigators have suggested that these simple bone cysts may result from interstitial fluid obstruction by the fibro-osseous proliferation.

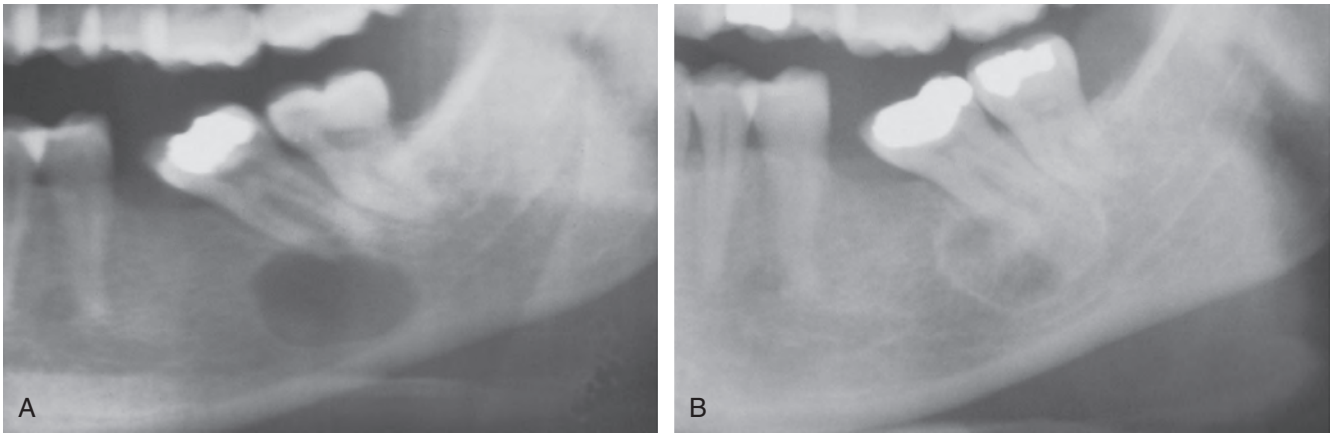
Clinical and Radiographic Features

Based on clinical and radiographic features, cemento-osseous dysplasia includes the following variants: (1) **focal,** (2) **periapical,** and (3) **florid.**

Focal Cemento-Osseous Dysplasia

Focal cemento-osseous dysplasia involves a single site. Before the concept of focal cemento-osseous dysplasia was clarified in the mid-1990s, most cases were misdiagnosed as a variant of ossifying fibroma.

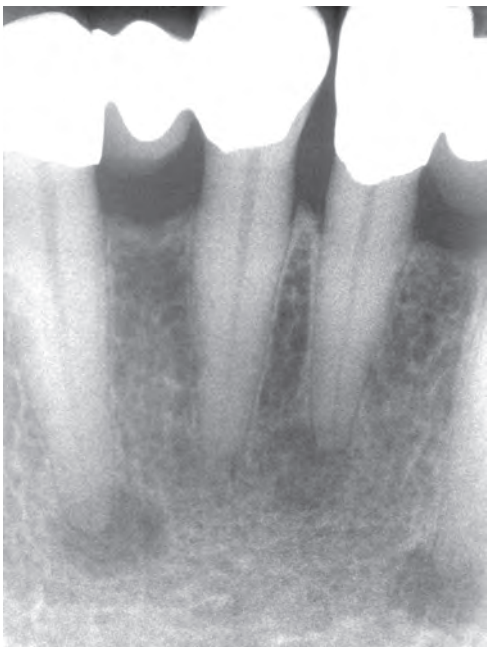
About 90% of cases of focal cemento-osseous dysplasia occur in females, with an approximate mean age of 41 years and a predilection for the third to sixth decades. The lesion has been reported across ethnic groups—most often blacks followed by East Asians and whites. In contrast to the periapical and florid variants, the focal variant seems to affect a greater proportion of whites, although this finding may be due to study population bias.



Focal cemento-osseous dysplasia most commonly involves the posterior mandible. The disease typically is asymptomatic and is detected incidentally by radiographic examination. Most lesions are smaller than 1.5 cm in diameter.

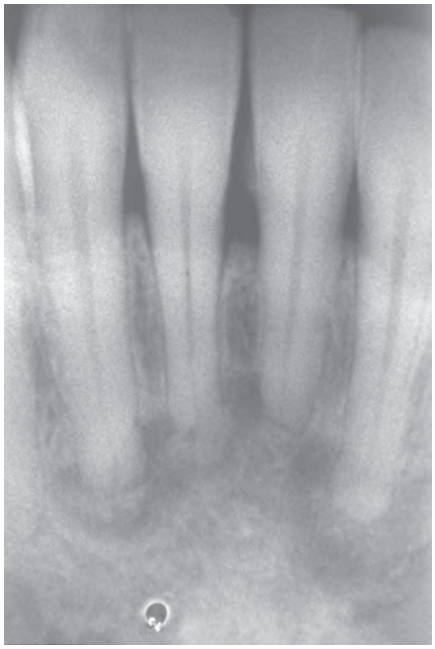
Radiographically, the lesion varies from completely radiolucent to densely radiopaque with a thin peripheral radiolucent rim. Most commonly, however, there is a mixed radiolucent and radiopaque pattern (Fig. 14.44). The borders tend to be well defined but slightly irregular, and a sclerotic margin occasionally may be noted. The condition typically occurs around tooth apices or in extraction sites. Thinning or perforation of the cortex and resorption of adjacent tooth roots may be evident in some cases on CBCT examination. Most examples are not expansile, although mild expansion is possible. A focal lesion occasionally may represent an early stage in the transition to multifocal involvement, especially in black females.

Periapical Cemento-Osseous Dysplasia (Osseous Dysplasia; Periapical Cemental Dysplasia; Periapical Cementoma; Anterior Mandibular Osseous Dysplasia)



Periapical cemento-osseous dysplasia predominantly involves the periapical region of the anterior mandible. Solitary lesions may occur, but multiple foci typically are present. There is a marked female predilection (female-to-male ratio ranging from about 10:1 to 14:1), and approximately 70% of cases arise in blacks. East Asians often are affected as well. Most patients are diagnosed initially between 30 and 50 years of age, with the diagnosis almost never made in individuals younger than 20 years. The associated teeth are usually vital and seldom have restorations.

Periapical cemento-osseous dysplasia is an asymptomatic condition that often is discovered when radiographs are taken for other purposes. Early lesions appear as circumscribed periapical radiolucencies, similar to periapical granulomas or periapical cysts (Fig. 14.45). However, unlike periapical inflammatory disease, periapical cemento-osseous dysplasia may produce lesions that are not exactly centered on the anatomic root apices, as evidenced by CBCT examination. In some cases, adjacent lesions fuse to form a linear radiolucency that envelops the apices of several teeth (Fig. 14.46). Over time, the lesions tend to "mature" and become mixed radiolucent-radiopaque (Fig. 14.47). The radiopaque component may appear round, ovoid, or irregular. In the end stage, the lesions appear as circumscribed, dense radiopacities with narrow radiolucent rims. The radiolucent rims may be



• **Fig. 14.44 Focal Cemento-Osseous Dysplasia. A,** A radiolucent area involves the edentulous first molar area and the apical area of the second molar. **B,** Radiograph of the same patient taken 9 years later showing a mixed radiolucent and radiopaque pattern.

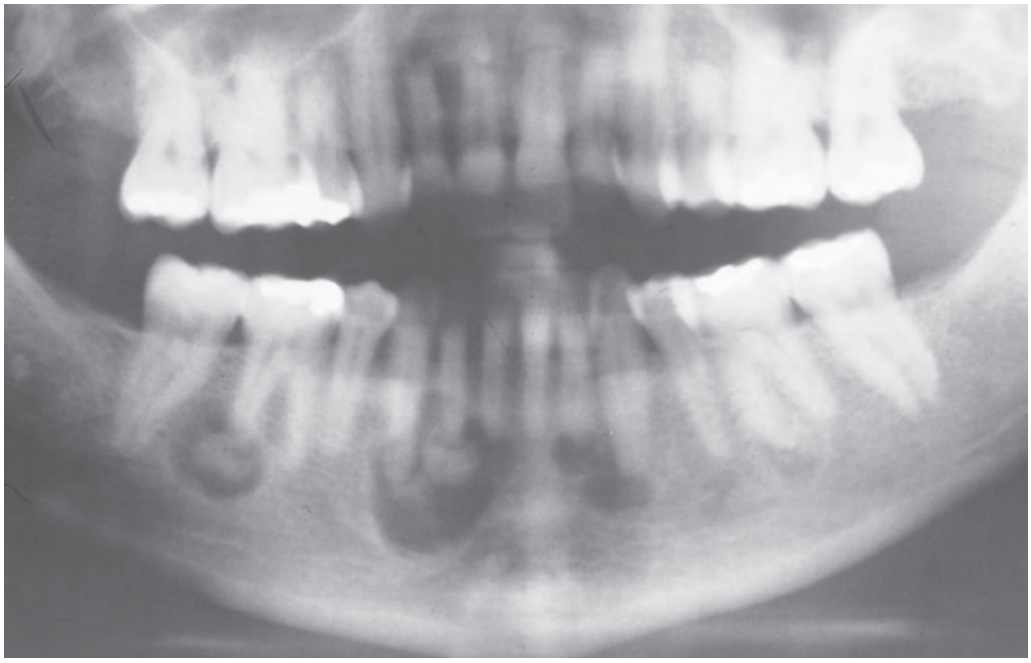
• **Fig. 14.46 Periapical Cemento-Osseous Dysplasia.** Later-stage lesions exhibiting significant mineralization.

surrounded by sclerotic margins. The periodontal ligament space usually appears intact, and fusion to the tooth is rare. Most lesions exhibit self-limiting growth, with individual lesions seldom exceeding 1.0 cm in diameter. The lesions are typically nonexpansile; however, mild expansion and thinning or perforation of the cortical plates at times may be appreciated with CBCT. In some cases, resorption of adjacent tooth roots also may be demonstrated by 3-dimensional imaging.

• **Fig. 14.47 Periapical Cemento-Osseous Dysplasia.** Later-stage lesions exhibiting significant mineralization.



Florid Cemento-Osseous Dysplasia

Florid cemento-osseous dysplasia exhibits multifocal involvement not limited to the anterior mandible. Although many cases affect only the posterior portions of the jaws, synchronous involvement of the anterior mandible may be observed as well (Fig. 14.48). Like the periapical pattern, this form predominantly affects black females (in some series, more than 90% of patients), with a marked predilection for middle-aged to older adults. An intermediate frequency among East Asian populations also has been described.

The lesions show a tendency for bilateral and fairly symmetrical involvement of the mandible (Fig. 14.49), and occasionally there may be extensive involvement in all four quadrants. At times the disease may be asymptomatic and discovered only when radiographs are taken for unrelated reasons. In other cases, patients may have dull pain, alveolar sinus tracts, and exposure of yellowish, avascular bone to the oral cavity (Fig. 14.50). Although rarely prominent, some jaw expansion may be evident.

Radiographically, the lesions demonstrate a maturation pattern similar to that noted in the other forms of cemento-osseous dysplasia. Initially, the lesions are predominantly radiolucent but with time become mixed, then predominantly radiopaque with only a thin radiolucent rim (see Fig. 14.49). On occasion, a lesion can become almost totally radiopaque and blend with the adjacent normal-appearing bone. Both dentulous and edentulous areas may be affected. Typically, the radiopacities remain separated from adjacent teeth with an intervening, intact periodontal ligament space. However, in some end-stage lesions, the cemento-osseous material may fuse with the tooth root surface to produce thickened root apices surrounded by radiolucency (or a "hypercementosis-like"

dentlearn.ir

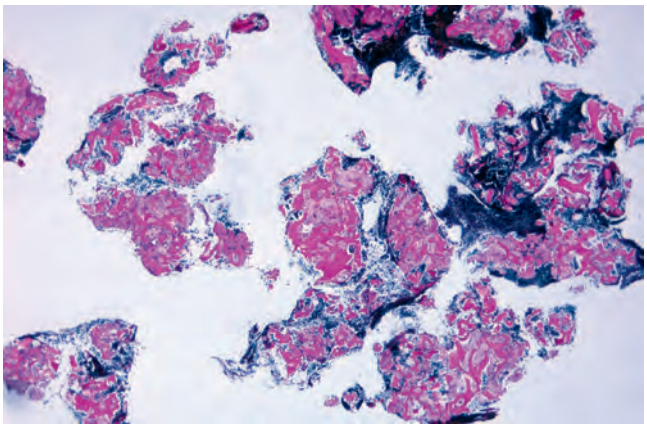
• **Fig. 14.48 Florid Cemento-Osseous Dysplasia.** Multiple mixed radiolucent and radiopaque lesions involving the anterior and posterior regions of the mandible.

• **Fig. 14.49 Florid Cemento-Osseous Dysplasia.** Multiple mixed radiolucent and radiopaque lesions throughout the mandible. (Courtesy of Dr. Haitham Hadeed.)

appearance). Cortical thinning or perforation, mild expansion, and adjacent tooth root resorption occasionally may be noted with CBCT examination.

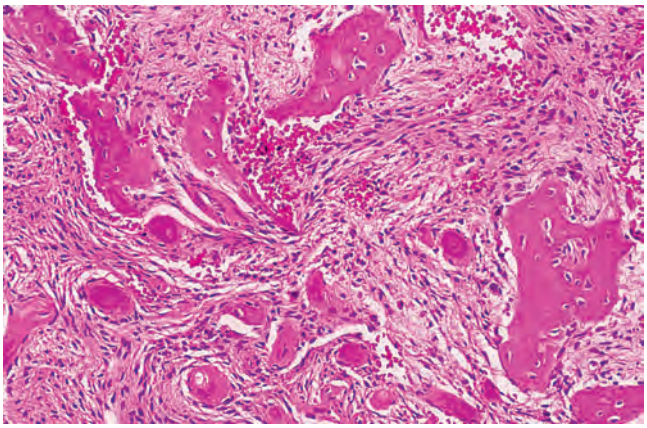
Histopathologic Features

All three patterns of cemento-osseous dysplasia demonstrate similar histopathologic features. There are typically fragments of cellular fibrovascular connective tissue with scattered hemorrhage and a variable mixture of woven bone, lamellar bone, and cementum-like particles (Figs. 14.51 and 14.52). As the lesions mature, the ratio of fibrous connective tissue to mineralized material decreases. Over time, the bony trabeculae become thick and curvilinear, with shapes likened to ginger roots. In the final radiopaque stage, the individual trabeculae fuse to form sheetlike or globular masses of sclerotic, disorganized cemento-osseous material (Fig. 14.53).



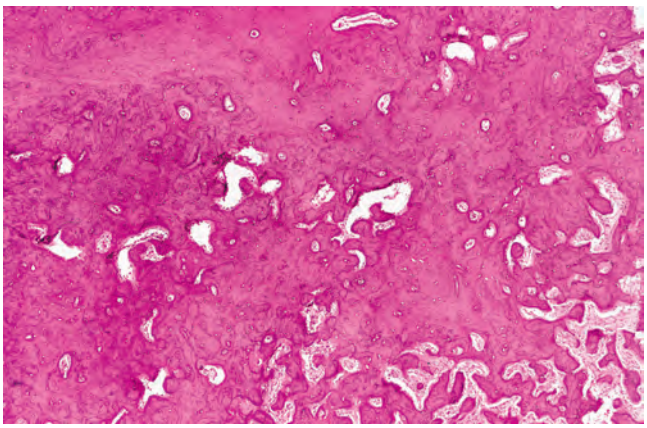
Diagnosis

In most instances of florid or periapical cemento-osseous dysplasia, the distinctive clinical and radiographic findings (e.g., a black female patient with multiquadrant involvement or multiple lesions involving vital lower incisor teeth) allow a strong presumptive diagnosis. In contrast, the features of focal cemento-osseous dysplasia tend to be less specific, and biopsy often is needed for diagnosis.

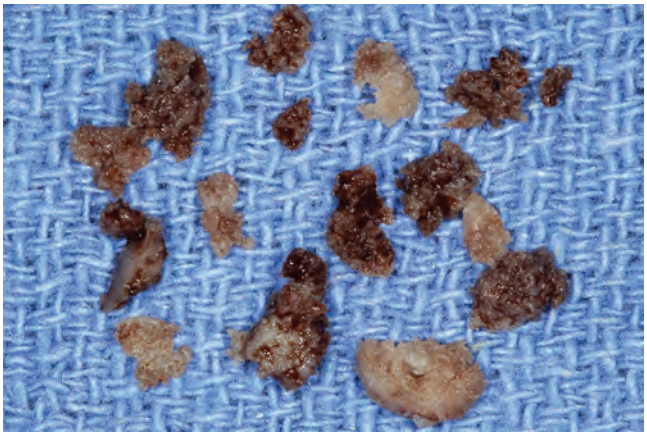


dentlearn.ir

• **Fig. 14.50 Florid Cemento-Osseous Dysplasia.** Yellowish, avascular cementum-like material is beginning to exfoliate through the oral mucosa.



• **Fig. 14.51 Cemento-Osseous Dysplasia.** Low-power photomicrograph showing fragments of cellular fibrous connective tissue containing scattered trabeculae of bone.



• **Fig. 14.52 Cemento-Osseous Dysplasia.** High-power photomicrograph showing spicules of bone and cementum-like hard tissue within moderately cellular fibrous connective tissue. Note the hemorrhage around the bony trabeculae.

In particular, distinguishing focal cemento-osseous dysplasia from ossifying fibroma can be difficult. However, the findings at surgery may be helpful in discriminating between these two lesions. Before the final sclerotic stage, cemento-osseous dysplasia consists of gritty tissue that the surgeon typically curettes into small fragments during biopsy (Fig. 14.54). In contrast, ossifying fibromas tend to separate cleanly and are removed in one or several large masses. Microscopically, both lesion types demonstrate a mixture of bone and cementum-like particles, although subtle histopathologic differences may be appreciated. The bony trabeculae in ossifying fibroma tend to be more delicate and show more prominent osteoblastic rimming compared to those in cemento-osseous dysplasia. Also, the cementum-like particles in cemento-osseous dysplasia are irregularly shaped and often exhibit retraction from the adjacent stroma, whereas those in ossifying fibroma are more ovoid and often demonstrate brush borders in intimate association with the adjacent stroma. Although ossifying fibroma can exhibit peripheral hemorrhage, cemento-osseous dysplasia typically reveals hemorrhage throughout the lesion and sinusoidal vascularity in close association with the bony trabeculae.

• **Fig. 14.53 Cemento-Osseous Dysplasia.** Late-stage lesion showing a sclerotic mass of cemento-osseous material.

• **Fig. 14.54 Cemento-Osseous Dysplasia.** Gross specimen comprised of small, gritty tissue fragments.

Treatment and Prognosis

Cemento-osseous dysplasia does not appear to be neoplastic and, therefore, generally does not require removal. During the predominantly radiolucent phase, the lesions cause few problems. However, in the sclerotic phase, the lesions tend

dentlearn.ir

to be hypovascular and prone to necrosis and secondary infection with minimal provocation. For the asymptomatic patient, the best management consists of regular recall examinations with prophylaxis and oral hygiene reinforcement to control periodontal disease and prevent tooth loss.

Because the onset of symptoms usually is associated with exposure of the sclerotic masses to the oral cavity, surgical procedures (e.g., biopsy, elective tooth extraction) should be avoided. In some instances, symptoms begin after lesion exposure resulting from progressive alveolar atrophy under a denture. Therefore, affected patients should be encouraged to retain their teeth. Dental implant placement in an area of cemento-osseous generally is not recommended, although there are anecdotal reports of successful implant placement. Management of the symptomatic patient who has developed secondary osteomyelitis is more difficult. Antibiotics may be indicated but often are not effective. Sequestration of the sclerotic cementum-like masses occurs slowly and is followed by healing. Saucerization of dead bone may speed healing. When simple bone cysts arise within foci of cemento-osseous dysplasia, surgical exploration is necessary to establish the diagnosis. These simple bone cysts often do not heal as rapidly as those noted in younger patients without cemento-osseous dysplasia. In some cases the cysts persist or enlarge after surgical intervention; when they fill in, the bone retains an abnormal radiographic appearance. Thorough curettage of the cyst and the surrounding fibro-osseous proliferation may assist healing.

Some investigators have noted a rare subset of cases (termed *expansive osseous dysplasia*) that exhibit progressive growth but otherwise typical clinicopathologic features of cemento-osseous dysplasia (Fig. 14.55). Such lesions have been reported most often in the anterior mandible of African black females, with a somewhat younger age at onset compared to conventional cemento-osseous dysplasia. Tooth displacement, cortical perforation, and limited extension into soft tissue are possible. Such lesions typically require surgical removal.

Overall, the prognosis is good. Development of a sarcoma within an area of cemento-osseous dysplasia has been reported but is extremely rare.

◆ FAMILIAL GIGANTIFORM CEMENTOMA (FAMILIAL EXPANSIVE OSSEOUS DYSPLASIA)

Although the term *gigantiform cementoma* has been used in the past as a synonym for florid cemento-osseous dysplasia, most authorities now restrict use of this term to a rare hereditary disorder known as **familial gigantiform cementoma.** This extremely rare disorder exhibits an autosomal dominant pattern of transmission with high penetrance and variable expressivity. It is characterized by a cemento-osseous proliferation involving multiple quadrants of the jaws with early onset and often massive expansion.

Based on microscopic similarities, some authors consider familial gigantiform cementoma to be a variant of cemento-osseous dysplasia (*familial expansive osseous dysplasia, familial florid cemento-osseous dysplasia*). Comparable to cemento-osseous dysplasia, familial gigantiform cementoma progresses through an early radiolucent stage, an intermediate mixed radiolucent-radiopaque stage, and a mature radiopaque stage with lesion stabilization. However, a tendency for early onset, gross bony expansion, and an extended growth phase prior to maturation distinguish this condition from cemento-osseous dysplasia. Alternatively, based on a tendency for marked lesion growth, other authors prefer to regard familial gigantiform cementoma as a distinct neoplasm or a subtype of ossifying fibroma.

Sporadic cases with clinical and radiographic features similar to those of familial gigantiform cementoma also have been reported using various terms, including *(nonfamilial) gigantiform cementoma, (nonfamilial) expansive osseous dysplasia, multiple (cemento-) ossifying fibromas,* and *bilateral ossifying fibromas.* Such sporadic examples appear to be more common than familial ones. Whether these sporadic cases represent an expansive form of cemento-osseous dysplasia, spontaneous mutations, or a variant of ossifying fibroma remains uncertain. Molecular genetic studies are needed to improve the understanding and appropriate classification of this problematic disease spectrum.

• **Fig. 14.55 Expansive Osseous Dysplasia. A,** Black female with bilateral mandibular cemento-osseous dysplasia, including an expansile lesion on the patient's right side. **B**, The computed tomography (CT) scan demonstrates both buccal and lingual expansion. (Courtesy of Dr. Peter Franco.)

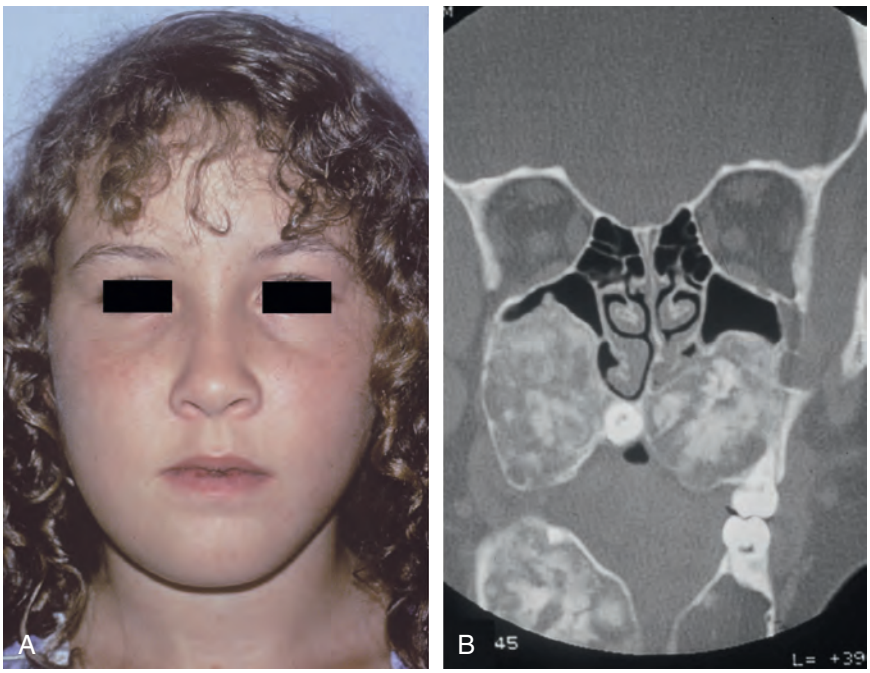
dentlearn.ir

Clinical and Radiographic Findings

Unlike florid cemento-osseous dysplasia, familial gigantiform cementoma exhibits neither a predilection for blacks nor a significant gender predilection. Although blacks may be affected, most reported families are Asian or white. Radiographic alterations may begin to develop during the first decade of life. By adolescence, most patients exhibit clinically obvious expansion of the jaws (Fig. 14.56). The lesions affect multiple quadrants, often with simultaneous involvement of the maxilla and mandible. Lesion growth may be rapid or slow. In a few reported cases, especially rapid growth has been noted during pregnancy. Although the course is variable, many patients develop significant facial deformity, as well as impaction, malposition, and malocclusion of the involved dentition. If not treated, then the osseous enlargement typically ceases by the fifth decade.

Radiographically, the lesions initially may appear as multiple periapical radiolucencies, resembling cemento-osseous dysplasia. With progression, the affected sites expand to replace much of the normal bone within the involved quadrant and develop a mixed radiolucent and radiopaque pattern. With further maturation, the lesions become predominantly radiopaque but often maintain a thin radiolucent rim. As noted in cemento-osseous dysplasia, the affected bone during the final radiopaque stage is very sensitive to inflammatory stimuli and becomes necrotic with minimal provocation.

Some investigators have reported elevated serum alkaline phosphatase that subsequently declines after surgical removal of the osseous proliferations. Anemia also has been reported in a number of affected females in different kindreds. In one family, two affected females demonstrated multifocal polypoid adenomas of the uterus that were associated with chronic hemorrhage and apparently caused anemia.



Furthermore, in a few kindreds diagnosed with familial gigantiform cementoma, bone fragility and a tendency for long bone fractures have been noted. However, such cases actually may represent examples of another entity known as *gnathodiaphyseal dysplasia* (a heritable autosomal dominant condition characterized by *GDD1* [or anoctamin 5 gene (*ANO5*)] mutations, diffuse fibro-osseous lesions of the jaws often with a prominent psammomatoid body component, bone fragility, and bowing/cortical sclerosis of tubular bones).

Histopathologic Features

Histopathologically, familial gigantiform cementoma shows features similar to cemento-ossifying fibroma and florid cemento-osseous dysplasia.

Treatment and Prognosis

Before the final sclerotic stage, shave-down surgical procedures typically are unsuccessful because the dysplastic tissue rapidly regrows. Once the lesions are predominantly radiopaque, partial removal may lead to sequestration of the remaining affected bone. Therefore, if feasible, complete resection and reconstruction are recommended. Because familial gigantiform cementoma might be associated with polypoid adenomas of the uterus, gynecologic evaluation is prudent for female patients—especially those with anemia.

◆ CEMENTO-OSSIFYING FIBROMA (CONVENTIONAL OSSIFYING FIBROMA; OSSIFYING FIBROMA; CEMENTIFYING FIBROMA)

Although it can resemble focal cemento-osseous dysplasia radiographically and histopathologically, **cemento-ossifying fibroma** is a true neoplasm with significant growth potential. This neoplasm is relatively rare, and many examples reported in the older literature actually represent cases of focal cemento-osseous dysplasia.

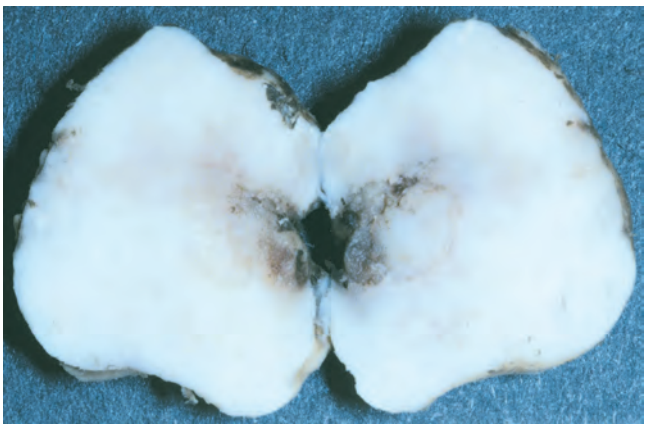
The origin of cemento-ossifying fibroma is somewhat controversial. Based upon its predilection for tooth-bearing areas of the jaws and ability to produce a variable mixture of bony trabeculae and cementum-like spherules, investigators have suggested that the origin is odontogenic or from periodontal ligament progenitor cells. However, microscopically identical neoplasms with cementum-like differentiation also have been reported in the orbital, frontal, ethmoid, sphenoid, and temporal bones or non-tooth-bearing areas of the jaws, and many authorities regard the cementum-like material in cemento-ossifying fibromas as a variation of bone. Indeed, some contend that bone and cementum are essentially the same mineralized product and only can be distinguished based on anatomic location (i.e., presence of cementum along root surfaces). Therefore, a non-odontogenic origin also has been proposed.

In this section, we use the term *cemento-ossifying fibroma*. However, various alternative terms (including *ossifying fibroma, conventional ossifying fibroma—odontogenic and non-odontogenic types,* and *cementifying fibroma*) have been applied to this tumor as well. Furthermore, some authors prefer the term *conventional ossifying fibroma* in order to distinguish this lesion from juvenile ossifying fibroma (see page 653).

Mutations in the tumor suppressor gene *HRPT2* (or *CDC73*) (which encodes the parafibromin protein) have been identified in patients with *hyperparathyroidism-jaw tumor syndrome.* This rare autosomal dominant disorder is characterized by parathyroid adenoma or carcinoma, cemento-ossifying fibromas of the jaws, renal cysts, Wilms tumors, and uterine tumors. In addition, investigators have found *HRPT2* mutations in a few sporadic cases of cemento-ossifying fibroma of the jaws. However, the potential pathogenetic role of such mutations in cemento-ossifying fibroma remains poorly understood. Also of interest, a recent study detected frequent copy number alterations—especially involving chromosomes 7 and 12—in cemento-ossifying fibromas but not fibrous dysplasia of the jaws.

Clinical and Radiographic Features

Cemento-ossifying fibromas occur over a broad age range, with a peak in the third and fourth decades of life. There is a female predilection, with the mandible involved far more often than the maxilla. The mandibular premolar and molar area is the most common site. Maxillary lesions tend to involve the antrum and canine fossa.



Small lesions are often asymptomatic and may be detected only by radiographic examination. Larger tumors may produce painless jaw swelling (Fig. 14.57) and obvious facial asymmetry. Some lesions may become massive and cause considerable deformity. Pain and tooth mobility are infrequent, and paresthesia is rare. Most examples are solitary; however, multiple synchronous lesions have been reported very rarely—either as an isolated finding or as a component of hyperparathyroidism-jaw tumor syndrome.

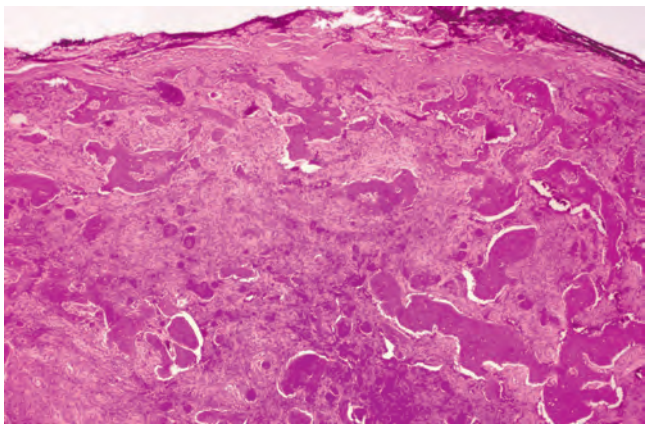
Depending on the amount of calcification, radiographic examination shows a well-defined lesion that is radiolucent, mixed radiolucent and radiopaque, or mostly radiopaque. Some examples exhibit a sclerotic border. Most radiolucent lesions are unilocular. Multilocular lesions at times may represent concurrent aneurysmal bone cyst (see page 638) formation. True ossifying fibromas that appear largely radiopaque with only a thin radiolucent periphery are

• **Fig. 14.57 Cemento-ossifying Fibroma.** Clinical image **(A)** and computed tomography (CT) scan **(B)** showing a large, expansile lesion of the posterior maxilla. (Courtesy of Dr. Greg Cobetto.)

dentlearn.ir

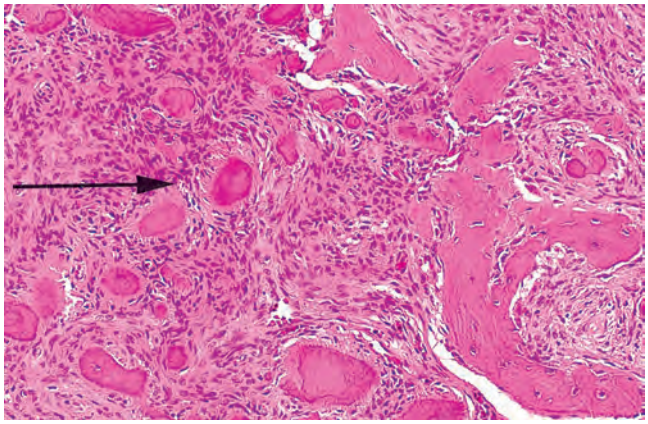
• **Fig. 14.58 Cemento-ossifying Fibroma.** Gross specimen showing a well-circumscribed tumor that shelled out in one piece and subsequently was hemisected.

infrequent; many reported examples with this radiographic pattern likely represent end-stage focal cemento-osseous dysplasia. Buccolingual bony expansion is common; in addition, large mandibular lesions often demonstrate a characteristic downward bowing of the inferior cortex, and inferior displacement of the mandibular canal is possible. The adjacent teeth may exhibit root divergence or root resorption. Maxillary lesions may displace the sinus floor.



Histopathologic Features

At surgery, the lesion tends to separate easily from the surrounding bone; thus, the tumor usually is submitted as one mass or a few large pieces (Fig. 14.58). Grossly and microscopically, most lesions are well demarcated but unencapsulated. However, a fibrous capsule may be present in some cases.



Microscopic examination shows cellular fibrous tissue with mineralized product (Fig. 14.59). The mineralized component may include a variable admixture of osteoid, bone, and basophilic acellular (or "cementum-like") spherules. The bony trabeculae vary in size and frequently demonstrate both woven and lamellar patterns. Peripheral osteoid and osteoblastic rimming are usually present. The cementum-like spherules often demonstrate brush borders that blend into the adjacent connective tissue (Fig. 14.60). These spherules may be surrounded by radiating collagen fibers reminiscent of Sharpey fibers within the periodontal ligament. Under polarized light, this cementum-like material may exhibit a quilted pattern. Significant intralesional hemorrhage is unusual. The heterogeneous mineralized product characteristic of cemento-ossifying fibroma differs from the more uniform osseous pattern of fibrous dysplasia. Rarely, a lesion may exhibit combined features of cemento-ossifying fibroma and central giant cell granuloma.

Treatment and Prognosis

The circumscribed nature of the cemento-ossifying fibroma generally permits enucleation or curettage of the tumor with relative ease. Large lesions that have caused considerable bone destruction may necessitate surgical resection and bone grafting. Recurrence after complete removal is uncommon, with an average recurrence rate of approximately 10% among various reported case series. Overall, the prognosis is very good, and there is no apparent potential for malignant transformation.

• **Fig. 14.59 Cemento-ossifying Fibroma.** This low-magnification photomicrograph shows a well-circumscribed solid tumor mass. Trabeculae of bone and droplets of cementum-like material can be seen forming within a background of cellular fibrous connective tissue.

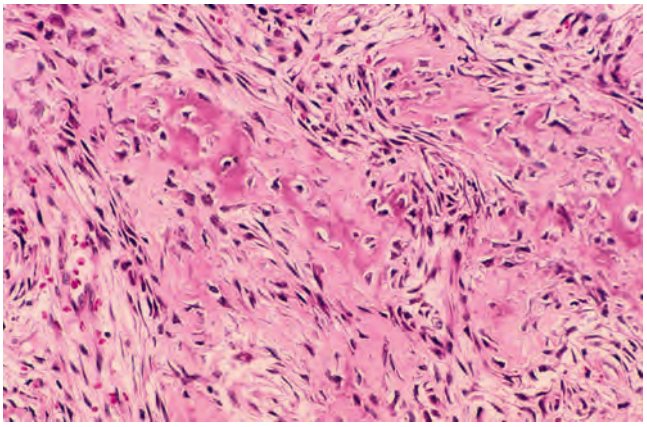
◆ JUVENILE OSSIFYING FIBROMA (JUVENILE ACTIVE OSSIFYING FIBROMA; JUVENILE AGGRESSIVE OSSIFYING FIBROMA; AGGRESSIVE OSSIFYING FIBROMA)

The **juvenile ossifying fibroma** is a controversial lesion that has been distinguished from cemento-ossifying fibroma on the basis of patient age, site predilection, and clinical behavior. The term includes two distinct clinicopathologic variants: (1) **trabecular** and (2) **psammomatoid.** Among lesions involving the craniofacial skeleton, the psammomatoid variant has been reported more frequently than the trabecular variant.

dentlearn.ir

The etiopathogenesis is poorly understood. In a small number of orbital psammomatoid ossifying fibromas, investigators have demonstrated nonrandom chromosomal breakpoints at Xq26 and 2q33 resulting in (X;2) translocation. Researchers also have identified *MDM2* (E3 ubiquitin-protein ligase gene) and *RASAL1* (RAS protein activator like 1 gene) amplification in juvenile ossifying fibromas; these changes may be associated with locally aggressive behavior and have been detected at a significantly higher frequency in this tumor type compared to cemento-ossifying fibroma and craniofacial fibrous dysplasia. Among studies conducted thus far, failure to detect *GNAS* or *HRPT2* mutations in juvenile ossifying fibromas suggests that these lesions are distinct from fibrous dysplasia and cemento-ossifying fibromas.

Clinical and Radiographic Features

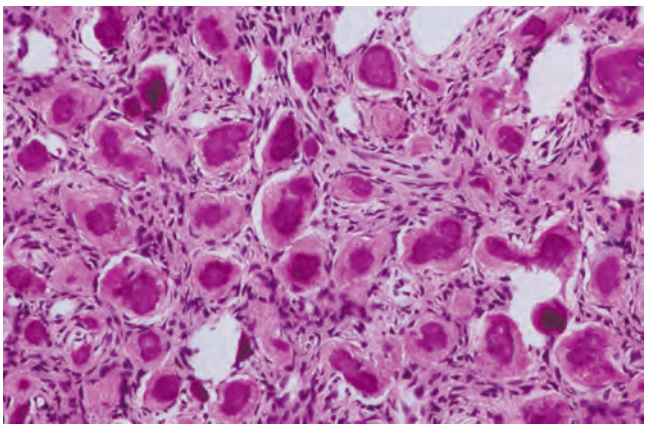


Juvenile ossifying fibromas most often arise in children, adolescents, and young adults; however, a broader age range has been reported for the psammomatoid variant (3 months to 72 years) than the trabecular variant (1–33 years). The average age at diagnosis is somewhat younger for the trabecular variant than the psammomatoid variant (approximately 12 years versus 19 years, respectively). Most authors report either a slight male predilection or no significant gender predilection. The trabecular variant arises primarily in the jaws, whereas the psammomatoid variant often involves the paranasal sinuses and orbital region. In both variants, gnathic involvement slightly favors the maxilla.

Although some cases exhibit slow, progressive enlargement, others exhibit rapid, aggressive growth. Small lesions may be discovered incidentally during routine radiographic examination, whereas larger lesions tend to cause painless swelling and obvious facial enlargement. Pain and paresthesia are infrequent findings. Tumors arising in the paranasal sinuses may penetrate the orbital, nasal, and cranial cavities. Nasal obstruction, epistaxis, sinusitis, headaches, proptosis, diplopia, and blindness may result. Rarely, intracranial extension may cause encephalitis and meningitis.

Radiographic examination typically shows a well-circumscribed radiolucency or mixed radiolucency and radiopacity (Fig. 14.61). A sclerotic border may be evident in some cases. Homogeneous "ground-glass" opacification, "ground-glass" opacification with central radiolucency, discrete calcifications, or a multilocular "honeycomb" pattern also may be observed. Aggressive lesions often cause expansion and cortical thinning or perforation. Similar to cemento-ossifying fibromas, juvenile ossifying fibromas may produce downward bowing of the inferior cortex of the mandible and inferior displacement of the mandibular canal. Jaw lesions also can cause tooth displacement, root resorption, and failure of tooth development. Sinus involvement may appear radiographically as cloudy opacification mimicking sinusitis.

• **Fig. 14.61 Juvenile Ossifying Fibroma.** Computed tomography (CT) scan showing a large tumor involving the left maxilla and maxillary sinus of a 12-year-old girl. Clinically, the tumor was growing rapidly.



• **Fig. 14.62 Juvenile Ossifying Fibroma, Trabecular Variant.** Trabeculae of cellular woven bone are present in a cellular fibrous stroma.

Histopathologic Features

Both patterns are typically well demarcated but unencapsulated. However, the mineralized component differs between the two variants. The trabecular variant shows irregular strands of highly cellular osteoid encasing plump and irregular osteocytes (Fig. 14.62). These strands often are lined by plump osteoblasts and multinucleated osteoclasts. In contrast, the psammomatoid variant exhibits concentric lamellated ossicles that vary in size and may be round, ovoid, or crescentic in shape. The ossicles typically appear basophilic with peripheral eosinophilic osteoid rims and brush borders that blend into the surrounding stroma (Fig. 14.63).

dentlearn.ir

• **Fig. 14.63 Juvenile Ossifying Fibroma, Psammomatoid Variant.** Cellular fibrous connective tissue containing spherical ossicles with basophilic centers and peripheral eosinophilic rims.

In both variants, the mineralized product is set within the background of a fibrous stroma. The stroma is often hypercellular, although cellularity may vary. Mitotic figures may be noted but are neither numerous nor atypical. Scattered aggregates of osteoclastic giant cells are often evident in the trabecular variant, whereas giant cells are an infrequent finding in the psammomatoid variant. In the trabecular variant, the newly formed osteoid often blends imperceptibly with the surrounding fibrous stroma. Zones of hemorrhage, giant cells, edema, and pseudocystic degeneration may correlate with grossly evident brown, curvilinear strands on the tumor's cut surface. In both variants, hemorrhagic cystic degeneration may resemble aneurysmal bone cyst formation.

Treatment and Prognosis

For small lesions, complete local excision or thorough curettage appears adequate. Combining enucleation with curettage or peripheral ostectomy may decrease the risk for recurrence. For large or aggressive lesions, wider resection may be required.

In contrast to the negligible recurrence rate for cementoossifying fibromas, an overall recurrence rate of 21% has been reported for juvenile ossifying fibromas. Many reported recurrences actually may represent tumor persistence after incomplete surgical removal. Malignant transformation has not been documented. Tumor-related deaths are extremely rare and primarily result from complications caused by direct intracranial extension.

◆ OSTEOMA

Osteomas are benign tumors composed of mature compact or cancellous bone. Osteomas primarily involve the craniofacial skeleton and rarely, if ever, are diagnosed in other bones. They may arise on the bone surface **(periosteal, peripheral,** or **exophytic osteomas)** or within medullary bone **(endosteal** or **central osteomas). Extraskeletal osteomas,** typically located within muscle or the dermis of the skin **(osteoma cutis),** also are possible.

There is some question whether osteomas represent true neoplasms, and not all lesions designated as osteomas may represent a single entity. Some likely result from injury, an inflammatory process, or a hamartomatous process. Because some osteomas arise in areas where muscle attaches to bone, investigators have hypothesized that muscle traction may be a contributory factor. Common palatal tori, mandibular tori, and buccal exostoses (see page 19) are not considered to be osteomas, although they are histopathologically identical. Because many osteomas are small and asymptomatic, there is little reliable information regarding their frequency and demographic distribution.

Clinical and Radiographic Features

Osteomas of the jaws most often are detected in adults, with a predilection for the mandibular body and condyle. Lesions involving the mandibular body frequently are found on the lingual surface adjacent to the premolars or molars. Less common mandibular locations include the angle (particularly at the inferior border), ramus, and coronoid process.

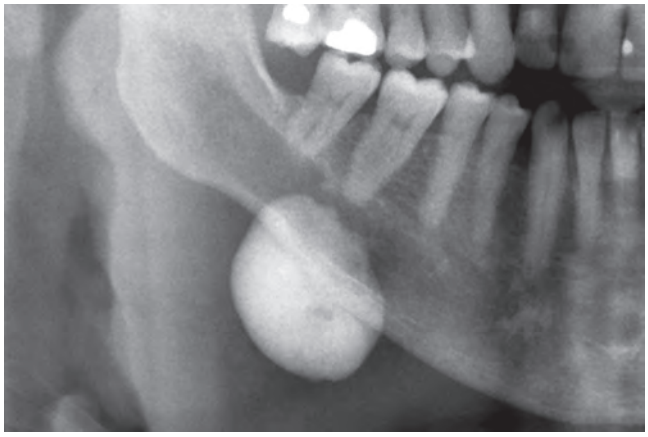
Most examples are solitary and asymptomatic with very slow growth. Pain, tooth displacement, and tooth impaction have been reported in a minority of cases. Rarely, a lesion may become especially large and produce marked facial deformity. Periosteal osteomas appear as polypoid or sessile masses on the bone surface, whereas endosteal osteomas may not be evident clinically unless they are large enough to cause expansion. Multifocal lesions may arise in association with Gardner syndrome (see page 656). In addition, unilateral osteomas of the jaws have been reported in association with encephalocraniocutaneous lipomatosis (Haberland syndrome).

Osteomas involving the mandibular condyle may limit mouth opening or cause malocclusion, with deviation of the dental midline and chin toward the unaffected side. Pain and swelling also are possible. Some authorities consider condylar osteomas to be true neoplasms, whereas others designate them as *hyperostoses.* Distinguishing this process from condylar hyperplasia can be difficult; however, a condylar osteoma typically is lobulated, whereas a hyperplastic condyle usually retains its original shape.

Osteomas of the sinonasal and orbital region (*sino-orbital osteomas*) are even more common than gnathic lesions. Among the paranasal sinuses, the frontal sinus is most often involved, followed by the ethmoid and maxillary sinuses. Sinus lesions are usually asymptomatic, although pain, swelling, sinusitis, and nasal discharge are possible. Orbital osteomas may cause proptosis, diplopia, and decreased visual acuity. Infrequently, intracranial extension may result in meningitis, cerebral abscesses, and intracranial mucoceles.

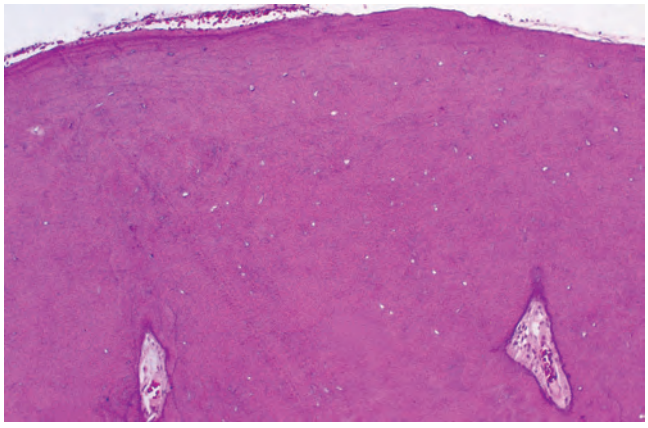
Radiographically, osteomas typically appear as circumscribed sclerotic masses, although early lesions may appear radiolucent or mixed radiolucent-radiopaque. Periosteal osteomas may show a uniformly sclerotic pattern or may demonstrate a sclerotic periphery with central trabeculation (Fig. 14.64). Smaller endosteal osteomas are difficult, if not

dentlearn.ir



impossible, to differentiate radiographically from condensing osteitis, focal chronic sclerosing osteomyelitis, or idiopathic osteosclerosis. The true nature of these osteomas can be confirmed only by documentation of continued growth.

Histopathologic Features

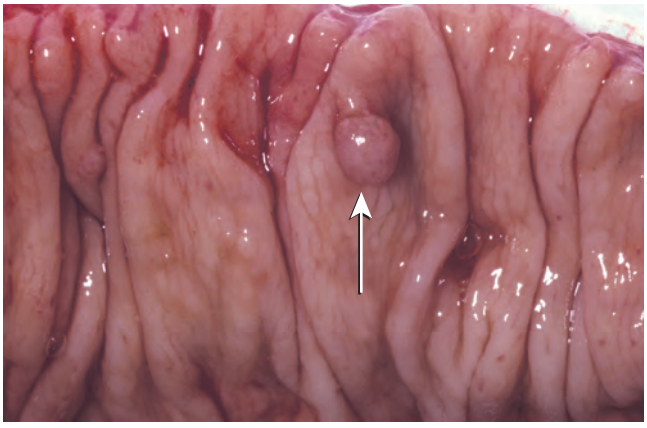


Compact (or **"ivory"**) osteomas are composed of normal-appearing, dense bone with minimal marrow (Fig. 14.65). **Cancellous** osteomas are composed of bony trabeculae and fibrofatty marrow. Osteoblastic activity may be fairly prominent. Some sino-orbital osteomas exhibit so-called "osteoblastoma-like features," characterized by enlarged osteoblasts, woven bone, and loosely arranged fibrovascular stroma.

Treatment and Prognosis

Small, asymptomatic osteomas may not require treatment but should be observed periodically. Conservative excision is appropriate for large or symptomatic osteomas of the mandibular body. Because they are frequently symptomatic, condylar osteomas usually are removed by local resection or condylectomy. Symptomatic paranasal sinus osteomas may be removed endoscopically or via an open surgical approach. Recurrence after excision is extremely rare, and there are no reports of malignant transformation.

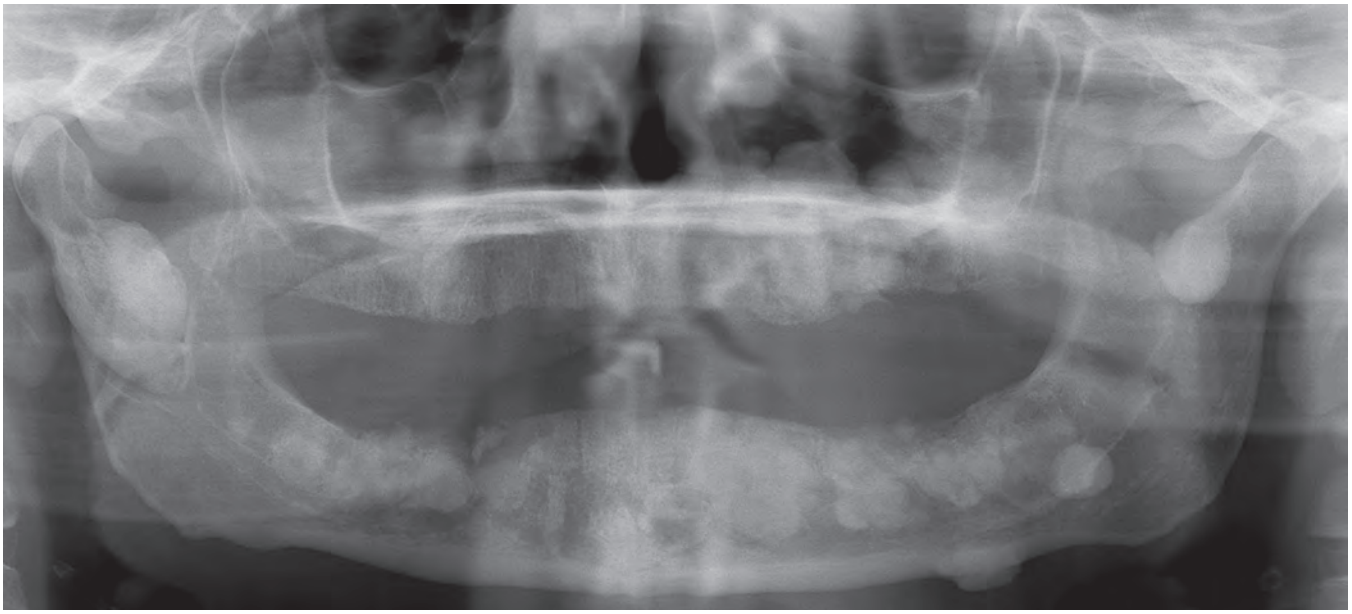
• **Fig. 14.64 Osteoma.** Panoramic radiograph showing a uniformly sclerotic mass arising from the surface of the posterior mandible. (Courtesy of Dr. James Lemon.)



• **Fig. 14.65 Osteoma.** This compact osteoma is composed of dense bone, with only minimal marrow elements.

◆ GARDNER SYNDROME

Gardner syndrome is a rare disorder, characterized by intestinal polyps as well as various abnormalities of bone, teeth, skin, soft tissue, and other sites. This syndrome represents a variant of *familial adenomatous polyposis*—an autosomal dominant disorder characterized by mutations in the adenomatous polyposis coli *(APC)* tumor suppressor gene on chromosome 5q21 and a markedly increased risk for colorectal cancer. The specific position of mutations within the *APC* gene determines the severity of gastrointestinal disease and the nature of the extraintestinal findings. In both classical familial adenomatous polyposis and the Gardner syndrome variant, patients develop hundreds to thousands of colorectal adenomatous polyps, with nearly 100% progression to colorectal cancer if left untreated. The term *Gardner syndrome* generally refers to cases in which the extraintestinal manifestations are especially prominent. Another disease variant, *attenuated familial adenomatous polyposis*, is characterized by similar extraintestinal findings but a smaller number (a few to a hundred) of colorectal polyps. The estimated frequency of familial adenomatous polyposis coli ranges from about 1 in 7,000 to 1 in 31,000 live births, although it is difficult to determinate the exact proportion of cases represented by Gardner syndrome or other disease variants.



Clinical and Radiographic Features

In patients with Gardner syndrome, colorectal polyps typically develop by the second decade of life (Fig. 14.66). The lesions often are asymptomatic but may cause diarrhea, constipation, rectal bleeding, anemia, and abdominal pain. The colorectal polyps are adenomatous (i.e., precancerous with varying degrees of dysplasia) and, if untreated, ultimately transform into adenocarcinoma. In addition, polyps

• **Fig. 14.66 Gardner Syndrome.** A segment of resected large bowel showing polyp formation *(arrow)*.

dentlearn.ir

• **Fig. 14.67 Gardner Syndrome.** Panoramic radiograph showing multiple osteomas of the jaws. (Courtesy of Dr. Terry Day.)

often arise in the duodenum or gastric fundus, although only a small percentage of polyps in these sites undergo carcinomatous transformation.

Up to 90% of patients with Gardner syndrome demonstrate skeletal abnormalities, the most common of which are osteomas. The osteomas usually are noted around puberty and often become evident before the intestinal polyps; indeed, the presence of multiple osteomas may lead to an early diagnosis of Gardner syndrome. Although the osteomas may affect any part of the skeleton, they most commonly involve the skull, paranasal sinuses, and mandible. Mandibular lesions often occur at the angle and may cause marked facial deformity. Occasionally, osteomas of the condyle may limit mouth opening. Most patients demonstrate between three and six osseous lesions. The osteomas appear as radiopacities that vary from a few millimeters to several centimeters in diameter (Fig. 14.67).

Dental abnormalities occur in about 22%–30% of patients and include odontomas, supernumerary teeth, and impacted teeth. The frequency of supernumerary teeth in Gardner syndrome is not nearly as high as that noted in cleidocranial dysplasia. Hypercementosis, fused or unusually long tooth roots, and congenitally missing teeth also have been reported in some individuals with Gardner syndrome.

Most patients show one or several epidermoid cysts of the skin (Fig. 14.68). Other cutaneous findings may include lipomas, fibromas, neurofibromas, and leiomyomas. Desmoid tumors (locally aggressive fibrous neoplasms of soft tissue) arise in approximately 10% of patients. These lesions are more frequent in females than males and often develop in the abdominal scar that forms after colectomy. Other possible extraintestinal neoplasms include thyroid carcinoma, adrenal adenoma or adenocarcinoma, hepatoblastoma, pancreatic adenocarcinoma, nasopharyngeal angiofibroma, and brain tumors. Furthermore, pigmented lesions of the ocular fundus (also known as *congenital hypertrophy of the retinal pigment epithelium*) are evident in about 75% of patients with familial adenomatous polyposis. This ocular abnormality correlates with specific mutated loci within the *APC* gene.

• **Fig. 14.68 Gardner Syndrome.** This patient has multiple, large epidermoid cysts. (Courtesy of Dr. William Welton.)

dentlearn.ir

Histopathologic Features

Histopathologically, the osteomas are generally of the compact type. An individual lesion cannot be differentiated microscopically from a solitary osteoma.

Treatment and Prognosis

The major problem for patients with Gardner syndrome is the high risk for transformation of colorectal polyps into adenocarcinoma. Without treatment, approximately 50% of patients will develop colorectal cancer by 30 years of age, and the frequency of malignant change approaches 100% by the fifth decade. Therefore, prophylactic colectomy usually is recommended. Clinical trials have shown some regression of polyps with cyclooxygenase-2 (COX-2) inhibitors, such as sulindac, but further studies are needed.

Patients also should be monitored for development of extracolonic malignancies or desmoid tumors. Genetic counseling is indicated as well. Osteomas and epidermoid cysts may be removed if they cause functional or cosmetic problems. Dental management typically involves surgical extraction of impacted teeth, removal of odontomas, and prosthodontic treatment. Orthodontic tooth movement may be difficult due to increased bone density from the osteomas.

◆ OSTEOBLASTOMA (GIANT OSTEOID OSTEOMA) AND OSTEOID OSTEOMA

Osteoblastoma and **osteoid osteoma** are closely related benign bone tumors that arise from osteoblasts. They exhibit very similar histopathologic features but differ somewhat in clinical presentation. The osteoid osteoma exhibits more limited growth potential than osteoblastoma; traditionally, the lesions are distinguished based on lesion size, with osteoid osteomas measuring less than 1.5 or 2 cm in diameter and osteoblastomas measuring at or above this threshold. In addition, although both lesion types often cause pain, the osteoid osteoma is associated more specifically with nocturnal pain relieved by nonsteroidal anti-inflammatory drugs (NSAIDs). This characteristic feature may be explained by the presence of a tumor nidus with a high concentration of peripheral nerves and prostaglandins.

Most investigators consider these lesions to be true neoplasms, although some have proposed that the limited growth of osteoid osteoma suggests an inflammatory or unusual healing process. In support of a neoplastic nature, recurrent *FOS* and *FOSB* rearrangements recently have been identified in both osteoblastoma and osteoid osteoma. These shared genetic alterations suggest that these entities may represent variants of the same lesion.

Clinical and Radiographic Features

Osteoblastoma

Osteoblastomas are rare and represent approximately 1% of all primary bone tumors. The most frequently affected sites are the vertebral column, long bones, pelvis, talus, facial bones, and small bones of the hands and feet. Among gnathic lesions, there is a mandibular predilection, with most examples involving the posterior regions. Approximately 85% of gnathic osteoblastomas occur before 30 years of age, and there is a slight female predominance.

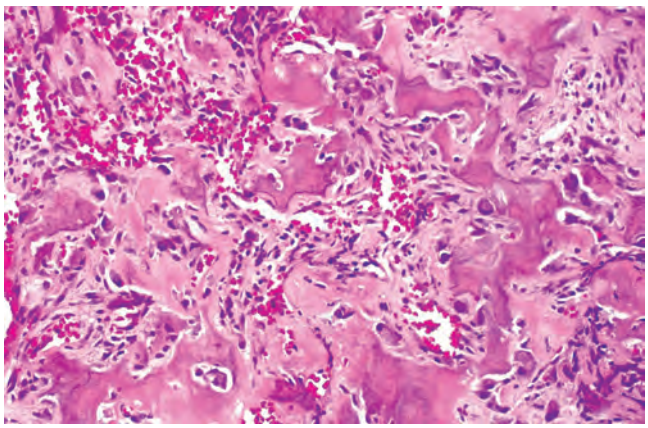
Most osteoblastomas are between 2 and 4 cm, but they may be as large as 10 cm. Dull pain, tenderness, and swelling are common presenting features. Unlike the pain associated with osteoid osteoma, the pain associated with osteoblastoma usually is not relieved by NSAIDs. Painful jaw lesions may be misinterpreted as odontogenic infections. Gnathic tumors also may cause tooth mobility, root resorption, or tooth displacement.

Radiographically, the osteoblastoma typically appears as a well- or ill-defined, round to oval radiolucency with patchy areas of mineralization (Fig. 14.69). Some examples demonstrate considerable mineralization. Surrounding reactive sclerosis is less prominent in osteoblastoma than osteoid osteoma. Most osteoblastomas arise within medullary bone, although a periosteal or intracortical origin also is possible.

A small subset of osteoblastomas **(aggressive osteoblastomas)** is characterized by atypical histopathologic features and locally aggressive behavior. These tumors usually occur in patients older than 30 years. A variety of bones, including the mandible, may be involved. Pain is common and may be severe. Aggressive osteoblastomas exhibit radiographic findings similar to those of conventional osteoblastoma but tend to be larger (typically greater than 4 cm in diameter).

Osteoid Osteoma

Osteoid osteoma comprises about 3% of all primary bone tumors. The lesion occurs most often in the femur and tibia but is very rare in the jaws. Gnathic tumors tend to occur in the posterior regions, with a slight mandibular predominance and a peak in the second and third decades of life. Although



• **Fig. 14.69 Osteoblastoma.** Computed tomography (CT) image showing an expansile, mixed radiolucent and radiopaque lesion of the maxilla. (Courtesy of Dr. Michael Zetz.)

dentlearn.ir

• **Fig. 14.70 Osteoid Osteoma.** A circumscribed, mixed radiolucent and radiopaque lesion near the apex of mesial root of mandibular first molar. The patient had dull, nocturnal pain that was relieved by aspirin. (Courtesy of Dr. Ellen Eisenberg.)

• **Fig. 14.71 Osteoblastoma.** High-power photomicrograph showing irregular bony trabeculae with prominent osteoblastic rimming and osteoclasts.

extragnathic lesions demonstrate a male predilection, jaw lesions exhibit no significant gender predilection. The most prominent clinical symptom is pain that is most severe at night and alleviated by NSAIDs. However, nocturnal pain relieved by NSAIDs has been documented more often among extragnathic lesions than jaw lesions.

Radiographically, the osteoid osteoma typically appears as a well-circumscribed, round to ovoid radiolucency (or "nidus") with a variable degree of surrounding reactive sclerosis. The radiolucent nidus may contain a small, central radiopacity, resulting in a target-like appearance (Fig. 14.70). The nidus typically measures less than 1.5 cm in diameter and most commonly arises within cortical bone, although a medullary or periosteal origin also is possible. A periosteal reaction occasionally may be seen.

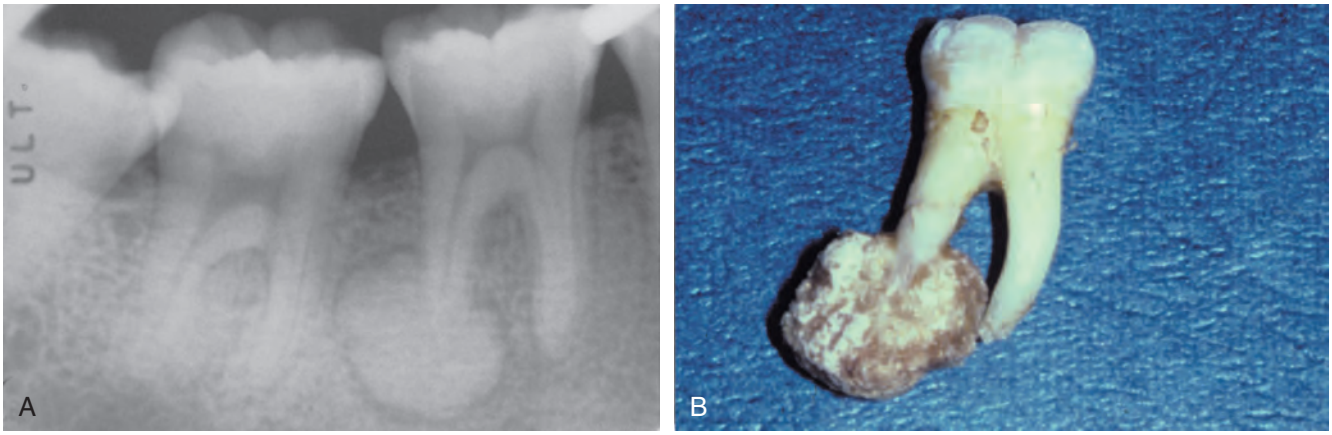
Histopathologic Features

Microscopically, both osteoid osteoma and osteoblastoma centrally exhibit irregular trabeculae of osteoid or woven bone, which are surrounded by numerous osteoblasts and scattered osteoclasts. The osteoblasts have ample cytoplasm and hyperchromatic nuclei (Fig. 14.71). The loose fibrous stroma includes dilated vessels and occasional hemorrhage. The vascularity tends to be more prominent in osteoblastoma than osteoid osteoma. At the periphery, there is typically a more prominent zone of dense, sclerotic bone in osteoid osteoma than osteoblastoma.

Aggressive osteoblastomas typically demonstrate sheets or single layers of large (epithelioid) osteoblasts with occasional mitotic activity, lacelike osteoid ("blue bone matrix"), and irregular bony trabeculae. However, epithelioid morphology does not always correlate with aggressive clinical behavior. Differentiation between aggressive osteoblastoma and low-grade osteosarcoma may be very difficult, although infiltrative growth, marked cytologic atypia, and atypical mitotic figures favor the latter. Another rare osteoblastoma variant is the *epithelioid multinodular osteoblastoma*, characterized by a multinodular proliferation of epithelioid osteoblasts with or without bone matrix.

Fluorescence *in situ* hybridization (FISH) may be performed to detect *FOS* or *FOSB* rearrangements in osteoblastomas and osteoid osteomas. In addition, FOS overexpression may be demonstrated by immunohistochemistry, although specimen decalcification may decrease immunoreactivity.

Treatment and Prognosis



Most osteoid osteomas and osteoblastomas of the jaws are treated by local excision or curettage. Some osteoid osteomas may regress spontaneously; however, most clinicians prefer surgical removal over long-term observation and pain management with NSAIDs. For extragnathic lesions, minimally invasive techniques (e.g., computed tomography [CT]-guided excision and radiofrequency ablation) have gained popularity recently.

Recurrence after complete removal is uncommon; many reported recurrences may be attributed to incomplete excision. Osteoid osteoma exhibits no potential for malignant transformation, and osteoblastoma only rarely transforms into osteosarcoma. Whether aggressive osteoblastoma exhibits a greater recurrence potential than conventional osteoblastoma is controversial, although metastasis or death from aggressive osteoblastoma has not been reported.

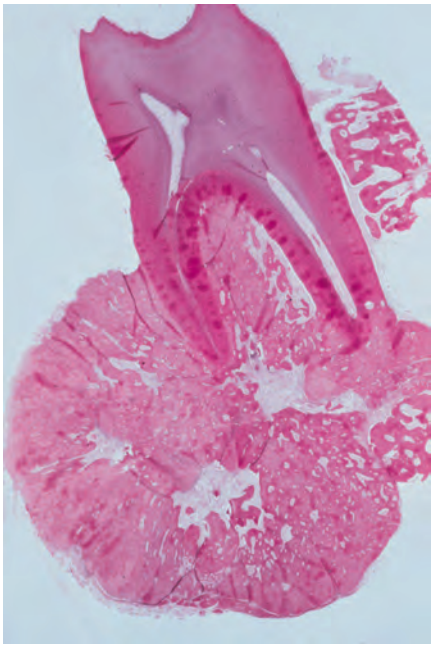
◆ CEMENTOBLASTOMA (TRUE CEMENTOMA)

Cementoblastoma is a benign neoplasm of cementoblasts and represents less than 1% of all odontogenic tumors. Many authorities believe this lesion represents the only true neoplasm of cementum. Alternatively, because cementoblastoma bears a close histopathologic resemblance to osteoblastoma (see previous section), others consider cementoblastoma to be a variant of osteoblastoma. The primary distinguishing

dentlearn.ir

• **Fig. 14.72 Cementoblastoma. A,** A densely mineralized mass is seen at the apex of the distal root of the first molar. The root is partially resorbed. **B,** The surgical specimen shows that the mass is attached to the root. (Courtesy of Dr. John Wright.)

factor is whether or not the lesion is fused to a tooth root. Because of its similarity to osteoblastoma, cementoblastoma is discussed here rather than in Chapter 15.



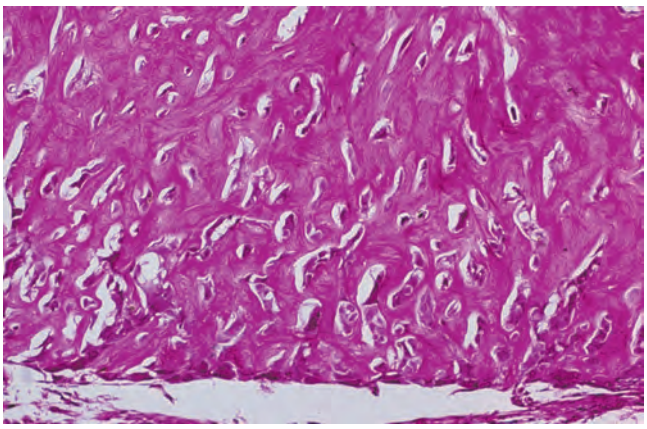
Clinical and Radiographic Features

Nearly 80% of cases arise in the mandible, primarily in the molar and premolar region. In particular, almost 50% of cases involve the mandibular first permanent molar. Impacted, unerupted, or deciduous teeth rarely may be affected as well. There is no sex predilection. The neoplasm predominantly affects young patients, with a mean age of 24 years and a peak in the second and third decades of life. The mean lesion size is about 2 cm (range 0.5 to 8 cm). Pain and swelling are present in approximately 70% of reported cases. The associated tooth usually responds normally to vitality tests, although a loss of vitality is noted in about 20% of cases. Most investigators consider this lesion rather innocuous; however, signs of locally aggressive behavior may be observed, including bony expansion, cortical perforation, displacement of adjacent teeth, envelopment of multiple teeth, maxillary sinus involvement, and infiltration into the pulp chamber and root canals.

Radiographically, the tumor typically appears as a radiopaque mass that is fused to one or more tooth roots and is surrounded by a thin radiolucent rim (Fig. 14.72). In rare instances, the lesion may appear entirely radiolucent. The outline of the root or roots of the involved tooth usually is obscured by root resorption and fusion of the tumor with the tooth. Inferior displacement of the mandibular canal may be evident in about one-fourth of cases.

Histopathologic Features

The histopathologic features of cementoblastoma closely resemble those of osteoblastoma. However, the primary distinguishing feature of cementoblastoma is fusion with the involved tooth (Fig. 14.73). Microscopic examination shows sheets and thick trabeculae of mineralized material with irregularly placed lacunae and prominent basophilic reversal lines. The background stroma is comprised of cellular fibrovascular tissue. Multinucleated giant cells often are present, and prominent blast-like cells frequently line the mineralized trabeculae (Fig. 14.74). Radiating columns of uncalcified matrix typically are seen at the periphery, corresponding to the radiolucent rim seen radiographically. In few instances, the lesion may infiltrate the pulp chamber and root canals of the involved tooth.



• **Fig. 14.73 Cementoblastoma.** Low-power photomicrograph showing the tumor attached to the roots of the tooth.

Treatment and Prognosis

Treatment usually consists of surgical extraction of the tooth and the attached calcified mass. A potential alternative is excision of the mass with root amputation followed by endodontic treatment of the remaining tooth. Some

dentlearn.ir

• **Fig. 14.74 Cementoblastoma.** Mineralized tissue containing numerous plump cementoblasts.

investigators suggest that supplementing extraction or excision with osseous curettage may decrease the risk for recurrence. Unusually large lesions may require surgical resection. The overall recurrence rate is approximately 12%. An increased risk for recurrence has been noted among cases exhibiting bony expansion or cortical perforation.

◆ CHONDROMA

Chondromas are benign tumors of mature hyaline cartilage. They comprise about 16% of benign bone tumors and most often arise in the small bones of the hands and feet. In the craniofacial bones, a diagnosis of chondroma should be viewed with great skepticism because many purported cases have recurred and exhibited malignant behavior. There are only a few individual reports and small series of gnathic chondromas, with most examples thought to arise from cartilage or cartilaginous rests in the condyle, anterior maxilla, mandibular symphysis, and coronoid process.

Chondromas predominantly arise within medullary bone *(enchondromas),* but some may develop just beneath the periosteum *(periosteal chondromas).* Most chondromas are solitary, although multiple lesions (*enchondromatosis*) may develop in the following nonheritable disorders:

- **Ollier disease** (enchondromatosis with predominantly unilateral involvement of the appendicular skeleton)
- **Maffucci syndrome** (enchondromatosis with extraskeletal angiomas)

Enchondromatosis differs from solitary chondroma in that it appears to represent a developmental disorder of endochondral ossification (or "cartilage dysplasia") rather than a true neoplasm.

Chondromas frequently harbor somatic mutations in *IDH1* and *IDH2* (isocitrate dehydrogenase 1 and 2 genes). They also may exhibit mutations or structural alterations of *COL2A1* and *YEATS2*. Such genetic abnormalities may be found in chondrosarcomas as well; however, additional alterations (such as *CDKN2A* amplification) may aid in distinguishing chondrosarcomas from chondromas.

Clinical and Radiographic Features

More than 60% of chondromas are diagnosed in the second, third, and fourth decades of life, and there is no significant sex predilection. Most gnathic examples occur in the condyle or anterior maxilla of adult patients. Usually, the lesions are painless and grow slowly. However, condylar tumors may cause pain, limited mouth opening, and deviation of the mandible from the midline. Lesions arising adjacent to teeth may cause tooth mobility and root resorption. Radiographically, the chondroma typically appears as a well-defined radiolucency with central opacification.

Histopathologic Features

Histopathologically, a chondroma appears as a well-circumscribed, lobular mass of mature hyaline cartilage. The cartilage typically demonstrates well-formed lacunae containing small chondrocytes with pale cytoplasm and small, round nuclei. Microscopic distinction between a chondroma and a low-grade chondrosarcoma of the jaws may be difficult (see page 669).

Treatment and Prognosis

It is wise to consider any jaw lesion diagnosed as a chondroma to represent a potential chondrosarcoma. Treatment typically consists of complete surgical removal.

◆ CHONDROMYXOID FIBROMA

The **chondromyxoid fibroma** is a rare, benign cartilaginous neoplasm that represents less than 1% of all primary bone tumors. Cytogenetic studies have detected frequent abnormalities in chromosome 6, and upregulation of the glutamate receptor metabotropic-1 gene (*GRM1*) located on chromosome 6q24.3 appears to be an important event in tumor development.

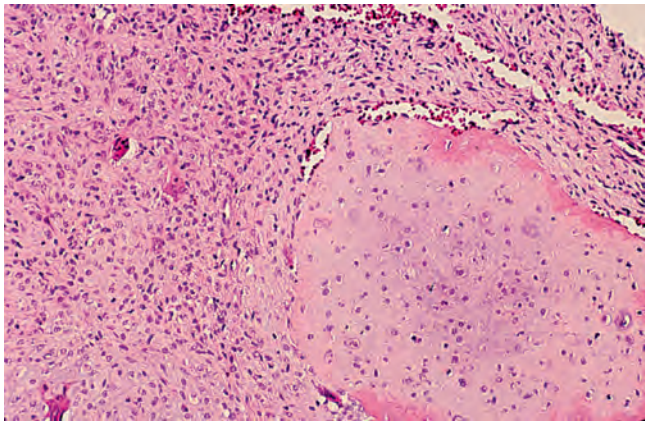
Clinical and Radiographic Features

Chondromyxoid fibromas exhibit a predilection for young adults and most commonly involve the metaphyseal region of long bones, especially the proximal tibia and distal femur. Only about 2% of cases arise in the craniofacial bones, where possible sites of involvement include the sinonasal region, occipital bone, temporal bone, orbital region, and jaws. Depending on tumor location, symptoms may include sinonasal congestion, headache, hearing loss, tinnitus, vertigo, cranial nerve palsy, and visual disturbance.

Among reported jaw lesions, the average age at diagnosis is approximately 28 years (range 9–67 years), with a peak in the second and third decades. There is no significant sex predilection. The lesion occurs more often in the mandible than the maxilla. Initial signs and symptoms often include swelling and pain. However, some cases are asymptomatic and detected incidentally by radiographic examination.

dentlearn.ir

Radiographically, chondromyxoid fibromas of the jaws typically appear as well-circumscribed radiolucencies with sclerotic margins. The lesion borders may appear scalloped, lobulated, or oval. The maximum diameter may range from 1.0 to 6.5 cm (average 3.3 cm). Cortical thinning or destruction (often with a "bite-like" hemispherical pattern) is common, but the periosteum usually remains intact. Internal trabeculation may be evident, and central radiopacities are noted in about 10% of cases.



Histopathologic Features

Microscopic examination shows lobules of spindle-shaped or stellate cells with abundant myxoid or chondroid intercellular substance. The lobules characteristically exhibit increased cellularity at the periphery. Between the lobules there is cellular fibrous tissue with spindle-shaped or round cells and varying numbers of multinucleated giant cells (Fig. 14.75). Coarse, irregular calcifications and residual bone spicules also may be present. Focal hyaline cartilage formation is rare. Occasionally, large pleomorphic cells may cause confusion with chondrosarcoma; however, chondrosarcoma typically shows hypercellularity throughout the tumor lobules and lacks a benign radiographic appearance.

Treatment and Prognosis

There is controversy regarding the most appropriate treatment for chondromyxoid fibroma. Many authors advocate conservative surgical removal, whereas others prefer wide resection. In general, relatively small lesions of the jaws are treated by local enucleation or curettage, but larger lesions often necessitate resection. In addition, some investigators have reported that filling the surgical defect with bone graft material following curettage results in a lower recurrence rate than curettage alone. Radiation therapy is contraindicated because of the risk for inducing malignant transformation or osteoradionecrosis.

Although the chondromyxoid fibroma is a benign tumor, approximately 25% of cases in the long bones recur after curettage alone. Among reported jaw tumors, recurrence has been noted in less than 10% of cases.

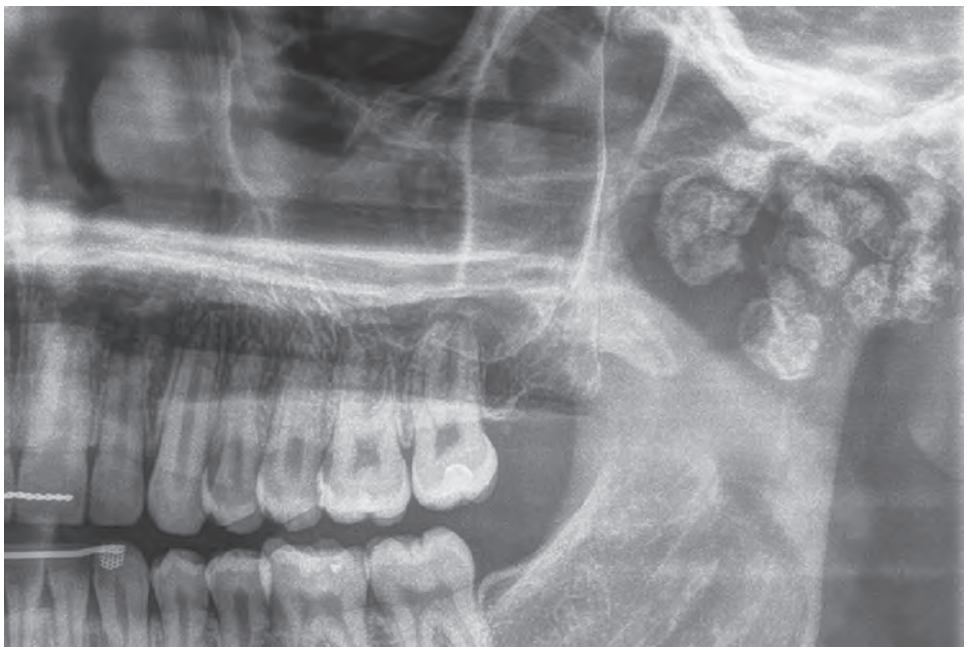
• **Fig. 14.75 Chondromyxoid Fibroma.** Myxoid connective tissue with scattered giant cells and foci of cartilaginous differentiation.

◆ SYNOVIAL CHONDROMATOSIS (SYNOVIAL CHONDROMETAPLASIA; SYNOVIAL OSTEOCHONDROMATOSIS)

Synovial chondromatosis is a rare, benign arthropathy characterized by development of cartilaginous nodules within the synovial membrane. The etiopathogenesis is poorly understood. Traditionally, synovial chondromatosis has been regarded as a reactive, metaplastic process. However, recent studies demonstrating *FN1* (fibronectin 1) and/or *ACVRA2* (activin receptor 2A) gene rearrangement in more than half of examined cases suggest that it may represent a true, benign neoplasm. Examples may be subclassified as *primary synovial chondromatosis* (i.e., cases with no identifiable etiologic factors) or *secondary synovial chondromatosis* (i.e., cases associated with trauma, joint overuse, inflammatory joint disease, or non-inflammatory arthropathy).

The condition typically proceeds through three stages. In the first stage, cartilaginous or osteocartilaginous nodules develop in the synovial lining. Subsequently, these nodules begin to detach, with some lying free in the joint space and others remaining in the synovial membrane. In the final stage, the nodules are found only in the joint space. The detached particles are called **loose bodies** (or "joint mice").

Clinical and Radiographic Features



The disease most commonly affects large joints, such as the knee, elbow, hip, and shoulder. Temporomandibular joint (TMJ) involvement is uncommon, although in recent years there has been an increase in reported cases, possibly because of improved imaging techniques and increased disease awareness.

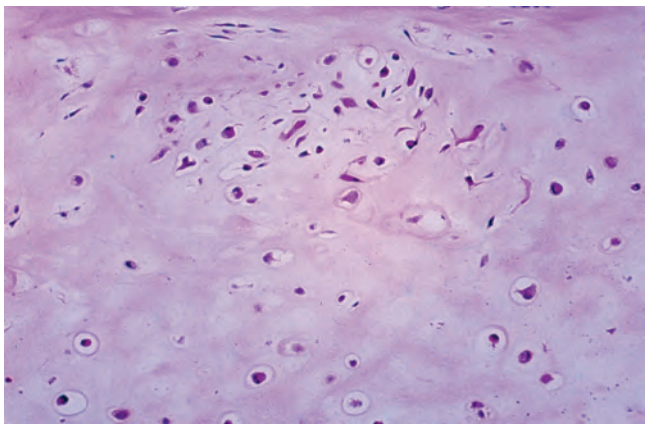
Synovial chondromatosis of the TMJ occurs over a broad age range (12–82 years), with a mean age at diagnosis of approximately 40–50 years. In contrast to the findings in other joints, there is a predilection for females. The clinical presentation is nonspecific and, thus, delay in diagnosis is common. Typical findings include periarticular swelling, pain, crepitus, limited mouth opening, and deviation of the mandible from the midline. Headache, sensory disturbances, and facial nerve paralysis are infrequent. In rare instances, the disease may produce no symptoms.

The process usually is confined to a single joint. However, bilateral involvement and extra-articular extension (e.g., TMJ lesions with erosion of the condylar head, skull base, or intracranial structures) have been reported in a few cases. Within the TMJ, the disease primarily involves the superior compartment, although involvement of the inferior compartment also is possible.

Radiographically, the loose bodies in the joint may appear as round to irregular, radiopaque structures of variable size (Fig. 14.76). Other findings may include

dentlearn.ir

• **Fig. 14.76 Synovial Chondromatosis.** Computed tomography (CT) scan showing opacities of variable size within the temporomandibular joint (TMJ) region. (Courtesy of Dr. Ankur Johri.)



irregularity of the joint surface, widening of the joint space, and sclerosis or hyperostosis of the glenoid fossa or condyle. Similar features, however, may be seen in other degenerative joint diseases. Likewise, failure to detect loose bodies on imaging studies does not preclude a diagnosis of synovial chondromatosis. CT and magnetic resonance imaging (MRI) are more sensitive than plain radiography for demonstrating many of the characteristic features of synovial chondromatosis.

Histopathologic Features

Nodules of hyaline cartilage are present within the synovium and lie loose in the joint space. There may be anywhere from 1 to more than 200 loose bodies. The cartilaginous nodules often become calcified or ossified. Particularly in primary lesions, the chondrocytes may appear atypical with enlarged, hyperchromatic nuclei and binucleation (Fig. 14.77). However, correlation with the clinical and radiographic findings may aid in distinguishing synovial chondromatosis from chondrosarcoma.

Treatment and Prognosis

Synovial chondromatosis of the TMJ typically is treated by partial or complete synovectomy and removal of all loose bodies, at times combined with meniscectomy. Condylectomy is reserved for unusual cases with severe condylar destruction. Surgery is performed most commonly via open arthrotomy, although arthroscopy or arthrocentesis may be used for biopsy and, in select cases, for treatment. A wider approach is typically necessary for rare cases with extensive extra-articular involvement.

• **Fig. 14.77 Synovial Chondromatosis.** Photomicrograph from one of many nodules removed at the time of synovectomy. The cartilage shows some degree of atypia, and in a different clinical setting this histopathology could be interpreted to represent a low-grade chondrosarcoma.

The prognosis is good, with an overall low frequency of recurrence after surgical excision. However, some investigators have noted more aggressive behavior and a higher recurrence rate among primary lesions compared to secondary lesions. Thus periodic follow-up examinations would appear to be prudent. Malignant transformation of synovial chondromatosis of the TMJ is extremely rare.

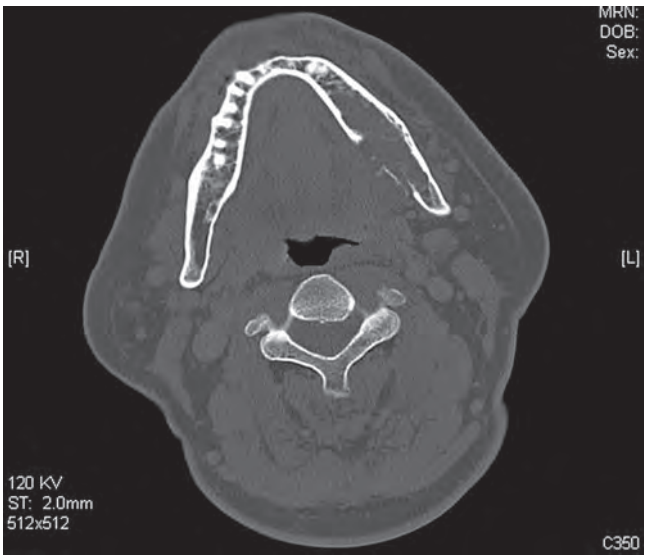
◆ DESMOPLASTIC FIBROMA

The **desmoplastic fibroma** of bone is a benign, locally aggressive, fibroblastic neoplasm that comprises less than 1% of primary bone tumors. Clinicopathologic and

dentlearn.ir

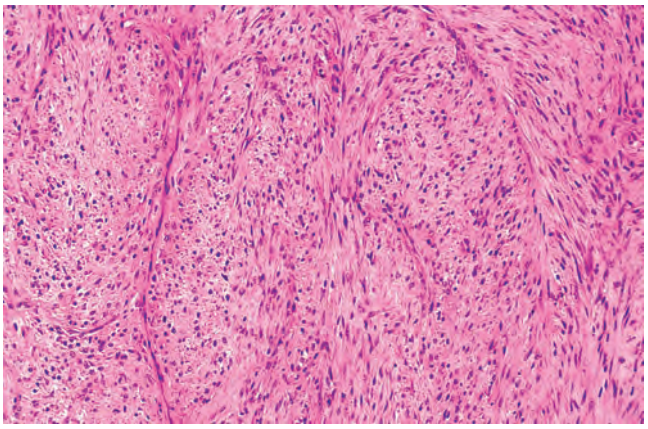
ultrastructural findings suggest that this tumor represents the osseous counterpart of soft tissue fibromatosis (desmoid tumor) (see page 523). Thus far, however, there are only limited genetic studies of desmoplastic fibromas of bone for identification of *CTTNB1* and *APC* mutations; these genes are involved in the Wnt/beta-catenin pathway and have been implicated in the pathogenesis of soft tissue fibromatosis. In addition, immunohistochemical studies for nuclear expression of beta-catenin in desmoplastic fibromas have yielded variable results. In a few cases, desmoplastic fibroma-like lesions of the jaws have been reported in association with tuberous sclerosis.

Clinical and Radiographic Features



Most desmoplastic fibromas of bone arise in patients younger than 30 years old. The most common locations are the mandible, femur, pelvis, tibia, and radius.

Among jaw lesions reported in the English literature, the age range is 6 months to 70 years, with a mean of approximately 14 years. There is no significant sex predilection. More than 80% of cases affect the mandible—most often the posterior body, the angle, and the ramus. Most patients exhibit a painless swelling with slow to rapid growth, although pain has been reported in some examples. Limited opening, malocclusion, tooth mobility, tooth displacement, root resorption, delayed tooth eruption, temporomandibular joint dysfunction, pathologic fracture, proptosis, nasal obstruction, concurrent infection, and dysesthesia also are possible.



Radiographically, the lesion appears as a multilocular or unilocular radiolucency with well- or ill-defined margins (Fig. 14.78). The bone is expanded, and the cortex is thinned; cortical reaction mimicking the appearance of an osteosarcoma is rare. Erosion through the cortex and extension into soft tissue may be evident. In such cases, it may be difficult to determine whether the lesion is a desmoplastic fibroma of bone with soft tissue extension or a soft tissue fibromatosis with extension into bone.

Histopathologic Findings

The tumor is composed of small, elongated fibroblasts and abundant collagen fibers (Fig. 14.79). The degree of cellularity may vary within a given lesion, and the cellular areas may show plump fibroblasts. However, the fibroblasts are not atypical, and mitoses are absent or sparse. Bone spicules may be present at the interface between the tumor and adjacent bone but are never an integral part of the lesion. This reactive bone at the periphery may be mistaken for osteoid production, which may lead to a misdiagnosis of a benign fibro-osseous lesion or low-grade osteosarcoma. Therefore, diagnostic biopsies should be sampled generously from the center rather than the periphery of the lesion. Immunohistochemistry often shows reactivity among the tumor cells for smooth muscle actin and muscle specific actin, and nuclear expression of beta catenin is variable. The Ki-67 proliferation index is less than 5%.

• **Fig. 14.78 Desmoplastic Fibroma.** Ill-defined, destructive radiolucency of the left mandible.

• **Fig. 14.79 Desmoplastic Fibroma.** The tumor consists of a cellular proliferation of fibroblasts arranged in interlacing fascicles.

Treatment and Prognosis

Although the desmoplastic fibroma is a benign tumor, it often behaves in a locally aggressive fashion, with extensive bone destruction and soft tissue extension; thus, radical surgery may be required to control the disease. Most cases are treated by resection, although enucleation or curettage may be adequate for localized lesions without cortical perforation or soft tissue extension. Anecdotal reports of patients treated with chemotherapy (e.g., vincristine, doxorubicin, dacarazine, actinomycin D, cyclophosphamide) have noted variable results.

The recurrence rate is approximately 5% following resection, 30% following enucleation, and as high as 70% following curettage. Given the potential for recurrence, patients should be monitored postoperatively for at least 3 years. The long-term prognosis is good, but there may be considerable morbidity. Malignant transformation is rare.

dentlearn.ir

It may be very difficult to distinguish desmoplastic fibroma of bone from well-differentiated fibrosarcoma. Some authorities suggest that all desmoplastic fibromas of bone be considered potentially malignant.

◆ OSTEOSARCOMA (OSTEOGENIC SARCOMA)

Osteosarcoma is a malignancy characterized by the production of osteoid or immature bone. Excluding hematopoietic neoplasms, osteosarcoma is the most common malignancy to originate within bone. In the United States, approximately 1000 new cases are diagnosed per year, with about half occurring in children and adolescents.

The etiopathogenesis of osteosarcoma is not completely understood. The tumor generally is thought to originate from mesenchymal stem cells or committed osteoblast precursors. A strong association with the adolescent growth spurt and the metaphyses of long bones suggests that rapid bone growth and hormonal factors may play a role. Additional risk factors include radiation exposure, alkylating agents, Paget disease of bone (see page 628), and certain rare heritable syndromes (e.g., Li-Fraumeni syndrome, hereditary retinoblastoma, Rothmund-Thompson syndrome, Bloom syndrome, Werner syndrome, Diamond-Blackfan anemia). Studies have demonstrated a complex genetic profile in most osteosarcomas, with alterations detected in *TP53, RB1, MDM2*, *CDKN2A*, *ATRX*, *DLG2*, and other genes. In addition, some investigators have detected co-amplification of *RASAL1* and *MDM2* in a subtype of high-grade mandibular ostesarcomas; this finding has been noted in the juvenile ossifying fibroma (see page 653) as well.

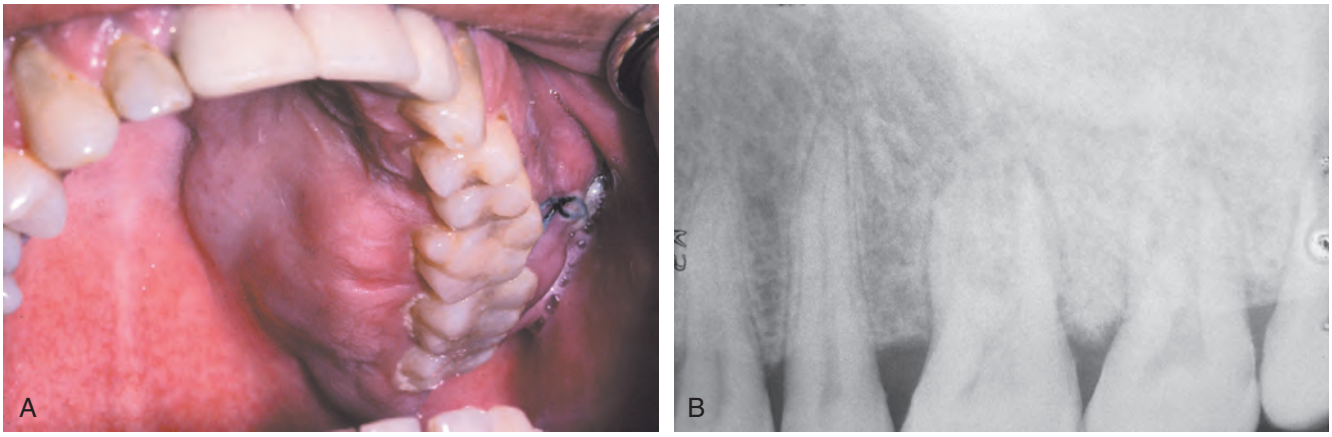
Osteosarcomas may be classified as *central* (arising within the medullary cavity), *surface* (arising in the juxtacortical region), or, vary rarely, *extraskeletal* (arising within soft tissue) (Table 14.5). The vast majority of cases are central. Surface osteosarcomas are discussed in the next section (see page 668). In addition, some authors regard gnathic osteosarcomas as a separate entity, because these lesions exhibit somewhat distinctive clinical features and biologic behavior.

TABLE 14.5 Osteosarcoma Types

Type		Grade
Central (intramedullary)	Conventional: • Osteoblastic • Chondroblastic • Fibroblastic	High
	Other rare variants (e.g., telangiectatic, small cell, epithelioid, giant cell-rich, osteoblastoma-like, and chondroblastoma-like)	High
	Low-grade central	Low
Surface (juxtacortical)	Parosteal	Low
	Periosteal	Intermediate
	High-grade surface	High
Extraskeletal		Low to high

Clinical and Radiographic Features

Extragnathic osteosarcoma demonstrates a bimodal age distribution, with a major peak during adolescence and a lesser peak among adults older than 60 years. The initial peak occurs during the period of greatest bone growth, with most cases arising in the distal femoral and proximal tibial metaphyses. Among tumors involving the extremities, there is a slight male predilection. In older patients, osteosarcoma often is attributed to Paget disease of bone or previous irradiation, and the axial skeleton and flat bones are involved most frequently. In both the axial and appendicular skeleton, the age-adjusted incidence for osteosarcoma in the United States is somewhat greater among blacks compared to Hispanics and whites.



About 6% of all osteosarcomas arise in the jaws. Jaw lesions exhibit no significant gender predilection and occur over a broad age range, with a peak in the third through fifth decades of life. The mean age is approximately 35–41 years, which is about 2 decades older than the mean age for osteosarcomas of the long bones.

Most studies report either a fairly even distribution between the mandible and maxilla or a mandibular predilection. Mandibular tumors arise most frequently in the body, followed by the angle, symphysis, and ramus. Maxillary lesions develop more often in the inferior portion (alveolar ridge, sinus floor, and/or palate) than the superior aspect (zygoma and orbital rim).

Swelling and pain are the most common clinical findings (Figs. 14.80 and 14.81). Tooth mobility, paresthesia, and nasal obstruction (in the case of maxillary tumors) also may be noted. Some patients report symptoms for relatively long periods before diagnosis, which suggests that some osteosarcomas of the jaws grow rather slowly.

Radiographic examination may show a radiopaque, mixed radiolucent-radiopaque, or entirely radiolucent lesion with ill-defined borders (Figs. 14.80, *B,* 14.81, *B,* and 14.82). Cortical destruction, cortical expansion, and a periosteal reaction also may be evident. The latter may appear as a "classic" sunburst pattern (present in about 25% of jaw osteosarcomas) or a triangular elevation of the periosteum (*Codman triangle*). Occasionally, the adjacent teeth exhibit "spiking" root resorption (with tapered narrowing of the root). Symmetrical widening of the periodontal ligament space (*Garrington sign*) (Fig. 14.83) may be an important clue for diagnosis of early osteosarcoma, although this feature also

dentlearn.ir

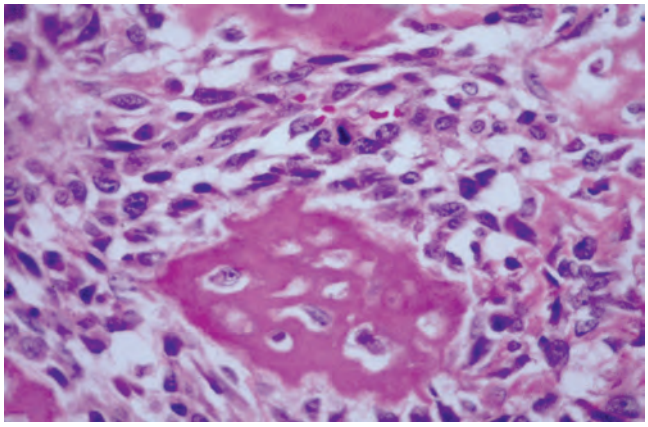
• **Fig. 14.81 Osteosarcoma. A,** This massive tumor had been present for many months before the patient sought treatment. **B,** Intraoral photograph of the tumor mass. **C,** The panoramic radiograph shows a "sunburst" pattern of trabeculation.

may be seen in other malignancies. At times an extensive osteosarcoma may show only subtle variation in the trabecular pattern. Plain radiography and CT often are used for initial evaluation. However, MRI is superior for assessment of primary tumor extent.

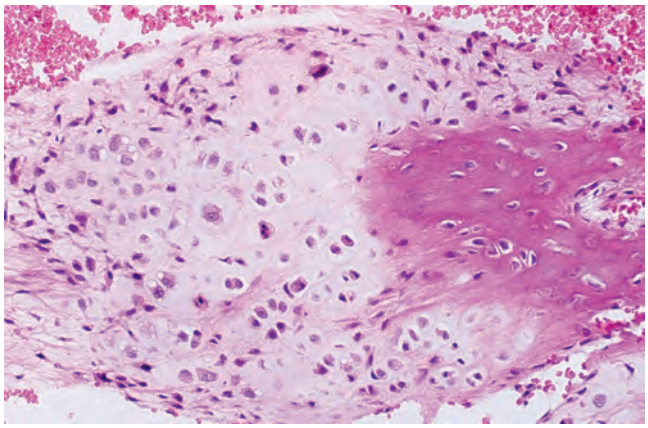
Histopathologic Features

Although osteosarcomas exhibit considerable histopathologic variation, the essential microscopic criterion is direct production of osteoid by malignant mesenchymal cells (Fig. 14.84). In addition to osteoid, the tumor cells may

dentlearn.ir



• **Fig. 14.82 Osteosarcoma.** Computed tomography (CT) scan showing a mottled radiopacity of the mandible with cortical destruction and a focal "sunburst" periosteal reaction. (Courtesy of Dr. Steve Anderson.)



• **Fig. 14.83 Osteosarcoma.** This 26-year-old woman had a 6-cm painful tumor of the anterior mandible. The periapical radiograph shows widening of the periodontal ligament spaces and a mottled radiopacity superimposed on the teeth. (Courtesy of Dr. Charles Ferguson.)

produce chondroid and fibrous connective tissue. Histopathologic findings may range from relatively uniform, round or spindle-shaped cells in low-grade tumors to markedly pleomorphic cells with bizarre nuclear and cytoplasmic shapes in high-grade tumors. The amount of matrix produced by the tumor may vary considerably. In some instances, osteoid production may be very minimal and difficult to demonstrate.

Greater than 90% of ostesarcomas are classified as the conventional type. Depending on whether there is a predominance of osteoid, cartilage, or collagen produced, such

• **Fig. 14.84 Osteosarcoma.** Anaplastic tumor cells forming cellular disorganized bone.

• **Fig. 14.85 Osteosarcoma.** This tumor produced a combination of malignant cartilage and bone.

tumors can be subclassified as osteoblastic, chondroblastic, or fibroblastic. Less common variants are listed in Table 14.5.

Chondroblastic osteosarcomas constitute a substantial proportion of all osteosarcomas of the jaws. Some examples may be composed almost entirely of malignant cartilage growing in lobules with only small foci of direct osteoid production by tumor cells (Fig. 14.85). Such lesions, however, should be classified as osteosarcomas rather than chondrosarcomas. Some investigators have reported that chondroblastic osteosarcomas lack isocitrate dehydrogenase 1 *(IDH1)* gene and isocitrate dehydrogenase 2 *(IDH2)* gene mutations, whereas such mutations are frequent among chondrosarcomas and chondromas.

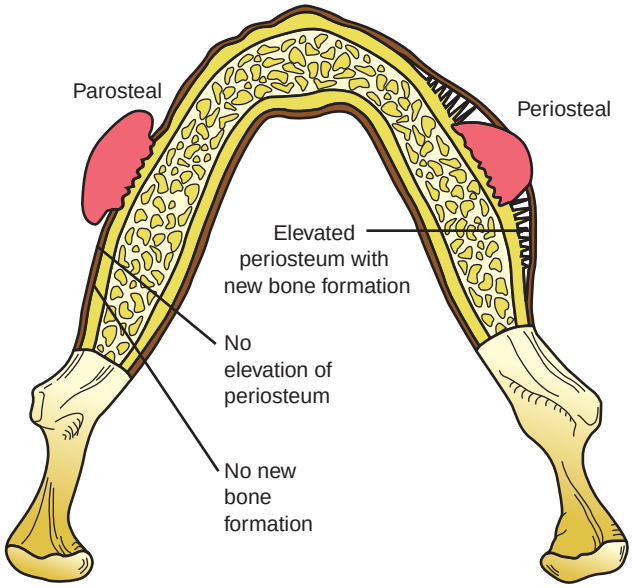
Low-grade osteosarcomas show minimal cellular atypia and may be difficult to differentiate from benign bone lesions, such as fibrous dysplasia or ossifying fibroma. Correlation with imaging studies is essential for accurate diagnosis. Immunohistochemical expression of MDM2 and CDK4 or demonstration of *MDM2* amplification by fluorescence *in situ* hybridization (FISH) also may help to distinguish low-grade osteosarcoma from benign fibro-osseous lesions and other benign bone tumors.

dentlearn.ir

Treatment and Prognosis

The treatment of choice for osteosarcoma of the jaws is wide surgical resection. The additional use of chemotherapy and/or radiotherapy for gnathic osteosarcomas is controversial but may be considered in some cases (e.g., tumors of questionable resectability, surgical margins positive for tumor, and recurrent tumors). For high-grade osteosarcomas of the long bones, management usually consists of neoadjuvant (preoperative) chemotherapy followed by radical surgery and adjuvant (postoperative) chemotherapy. Among patients with localized disease at diagnosis, such treatment has resulted in 5-year survival rates of approximately 60%–80%, compared to less than 20% with surgery alone. However, for patients with gnathic osteosarcomas, such protocols have yielded variable outcomes, and further studies are needed.

The most important prognostic factor is the ability to achieve initial complete surgical removal. Compared to mandibular lesions, maxillary lesions often are more difficult to resect and exhibit a worse prognosis. Additional adverse factors include prior radiation exposure, advanced age, and underlying Paget disease of bone. Interestingly, some investigators have reported a better prognosis for osteosarcoma of the jaws than osteosarcoma of the long bones. This observation may be related to a tendency for gnathic osteosarcomas to exhibit a low rate of metastasis despite often high-grade histopathologic features. However, other studies have shown no significant survival advantage among patients with gnathic osteosarcoma.



For patients with osteosarcoma of the jaws, death results more often from uncontrolled local disease than from distant metastases. Most deaths from uncontrolled local disease occur within 2 years of initial treatment. Metastases most often affect the lungs. According to Surveillance, Epidemiology, and End Results (SEER) data in the United States, the 5-year overall and disease-specific survival rates for osteosarcoma of the jaws from 1973 to 2011 were approximately 53% and 62%, respectively. However, some centers have reported greater than 80% long-term survival.

SURFACE (JUXTACORTICAL) OSTEOSARCOMAS

Although most osteosarcomas arise within the medullary cavity of bone, some cases originate in the periosteal or cortical region with little or no medullary involvement. Such surface lesions typically involve the long bones, although gnathic cases rarely have been reported. Surface osteosarcoma includes the following subtypes:

- Parosteal osteosarcoma
- Periosteal osteosarcoma
- High-grade surface osteosarcoma

Parosteal osteosarcoma appears as a lobulated, exophytic nodule attached to the cortex by a short, broad stalk

• **Fig. 14.86 Peripheral (Juxtacortical) Osteosarcoma.** Illustration comparing different types of peripheral osteosarcoma. Parosteal osteosarcoma presents as a lobulated nodule without a peripheral periosteal reaction. Periosteal osteosarcoma presents as a sessile mass associated with significant periosteal new bone formation.

(Fig. 14.86). There is no elevation of the periosteum and no peripheral periosteal reaction. Radiographs may demonstrate a radiolucent line ("string sign") that corresponds to the periosteum between the sclerotic tumor and the underlying cortex. Histopathologic examination shows a spindle cell fibroblast-like proliferation with well-developed, elongated bony trabeculae, often arranged in a parallel streaming or "pulled steel wool" pattern. A cartilaginous component also may be evident in some examples. Amplification of *CDK4* and *MDM2* has been reported in about 79% of cases. Parosteal osteosarcomas are low-grade tumors, with a low risk for recurrence and metastasis following wide excision. However, long-standing or inadequately excised tumors may become higher grade osteosarcomas.

Periosteal osteosarcoma appears as a sessile lesion that arises between the cortex and the inner (or cambium) layer of the periosteum (see Fig. 14.86). Thus, a periosteal reaction often is evident radiographically. The tumor frequently perforates the periosteum and extends into the surrounding soft tissue. Histopathologically, the tumor demonstrates primitive sarcomatous cells with chondroblastic differentiation. Close inspection reveals focal osteoid or immature bone formation. Treatment typically consists of wide resection alone or combined with chemotherapy. Periosteal osteosarcoma is an intermediate-grade tumor, with a prognosis better than conventional intramedullary osteosarcoma but worse than parosteal osteosarcoma.

High-grade surface osteosarcoma is extremely rare. This variant is similar to conventional intramedullary osteosarcoma in terms of microscopic features and biologic behavior.

dentlearn.ir

POST-IRRADIATION BONE SARCOMA

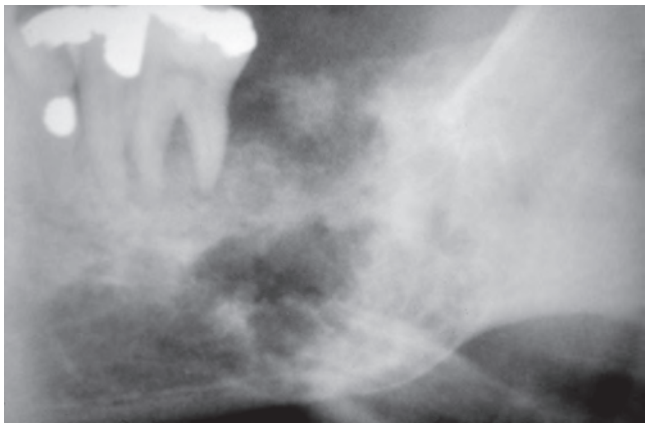
Sarcoma arising in bone previously subjected to radiation therapy is an uncommon but well-recognized phenomenon. Bone sarcomas have been reported to develop 3–55 years after radiation exposure, with a mean latency period of about 4–17 years. Studies estimate that 0.03%–0.2% of irradiated patients develop post-irradiation bone or soft tissue sarcomas. Within the head and neck region, nasopharyngeal cancer represents the most common primary tumor type associated with post-irradiation sarcoma development, and the most frequent locations for such sarcomas include the sinonasal region and mandible.

Some studies indicate that the risk for post-irradiation bone sarcomas increases with cumulative radiation dose. Reported mean and median radiation doses vary from 43 to 64 Gy. However, the radiation dose applied to the primary tumor may be greater than the dose delivered to the area where a sarcoma later arises. Thus, medium- to low-dose radiation may be sufficient and, possibly, even more effective than high-dose radiation for inducing sarcoma development.

Osteosarcoma is the most common post-irradiation bone sarcoma type, accounting for 49%–85% of cases. Other reported types include undifferentiated pleomorphic sarcoma (malignant fibrous histiocytoma), fibrosarcoma, and chondrosarcoma. The lesions tend to be poorly differentiated, and the prognosis is generally poor. According to a systematic review of radiation-induced sarcomas of the head and neck, about 41% of patients died of disease after a mean interval of 14 months. Another review limited to radiation-induced sarcomas of the oral cavity reported a 5-year survival rate of 15%.

◆ CHONDROSARCOMA

Chondrosarcoma is a malignant neoplasm in which the tumor cells form cartilage but not bone. Chondrosarcoma is about half as common as osteosarcoma and twice as common as Ewing sarcoma. Chondrosarcomas comprise about 11% of all primary malignant bone tumors but involve the jaws only rarely. Approximately 1%–12% of all chondrosarcomas arise in the head and neck, and such lesions comprise only 0.1% of all head and neck malignancies.



Chondrosarcoma may develop *de novo (primary chondrosarcoma)* or from a preexisting benign cartilaginous tumor *(secondary chondrosarcoma)*. The histogenesis is controversial; investigators have hypothesized that the tumor may originate from chondrocytes, embryonal chondroid, or pluripotential mesenchymal stem cells. Interestingly, there is an increased risk for chondrosarcoma among patients with Ollier disease and Maffucci syndrome (see page 661). These forms of chondromatosis are associated with somatic mutations in the isocitrate dehydrogenase 1 *(IDH1)* gene and isocitrate dehydrogenase 2 *(IDH2)* gene; likewise, chondromas and chondrosarcomas of bone frequently exhibit mutations in these genes.

Clinical and Radiographic Findings

Although chondrosarcoma develops over a broad age range, most affected patients are older. In the United States, the median age at diagnosis is approximately 53 years, and the male-to-female ratio is 1.3:1. The most frequently involved sites are the ilium, femur, and humerus.

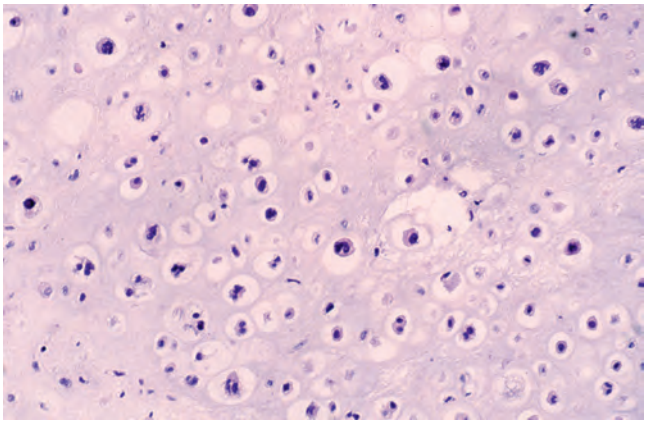
Gnathic chondrosarcomas exhibit a predilection for the anterior maxilla. In contrast, mandibular tumors tend to favor the posterior region. Other possible sites of involvement in the head and neck include the paranasal sinuses, nasal septum, skull base, and cervical vertebrae. Most head and neck chondrosarcomas develop within the bones or joints, but approximately one-third of cases originate in either laryngotracheal cartilage or soft tissue. According to a systematic review of the literature, chondrosarcomas of the jaws occur over a broad age range (2–82 years), with a peak in the third decade and a mean age at diagnosis of approximately 33 years. The male-to-female ratio is approximately 1.2:1. At presentation, the most commonly reported signs or symptoms include swelling, pain, and facial asymmetry. Separation or loosening of teeth also is possible. Infrequent findings include regional lymphadenopathy and paresthesia. Lesions involving the temporomandibular joint can cause trismus. Patients with maxillary tumors may develop nasal obstruction, congestion, epistaxis, photophobia, or visual loss as well.

Radiographically, chondrosarcoma usually appears as an ill-defined radiolucency with radiopaque foci (Fig. 14.87). These radiopaque foci correspond to calcification or ossification of the cartilage matrix. Some cases show extensive calcification and primarily appear radiopaque. Infrequently, there is lobular growth with minimal or no calcification; such lesions may appear as multilocular radiolucencies that mimic a benign process. Penetration of the cortex can result in a sunburst pattern similar to that seen in some osteosarcomas. Jaw tumors may cause root resorption or symmetrical widening of the periodontal ligament space of adjacent teeth.

• **Fig. 14.87 Chondrosarcoma.** Ill-defined radiolucent lesion of posterior mandible containing radiopaque foci. (Courtesy of Dr. Ben B. Henry.)

dentlearn.ir

Chondrosarcomas tend to be highly infiltrative. Although plain radiography typically is used for initial evaluation, MRI is the best method for assessing tumor extent. In addition, CT may help to demonstrate calcifications.



Histopathologic Features

Chondrosarcomas are composed of cartilage showing varying degrees of maturation and cellularity. In most cases, lacunar formation within the chondroid matrix is evident, although this feature may be scarce in poorly differentiated tumors. The tumor often shows a lobular growth pattern. The central areas of the lobules demonstrate the greatest degree of maturation, whereas the peripheral areas tend to exhibit immature cartilage and mesenchymal tissue consisting of round or spindle-shaped cells. Calcification or ossification may occur within the chondroid matrix. Neoplastic cartilage may be replaced by bone in a manner similar to normal endochondral ossification. Distinction between metaplastic bone formation and malignant osteoid production is important for differentiating chondrosarcoma from chondroblastic osteosarcoma.

Chondrosarcomas may be assigned a histopathologic grade of I through III. Low-grade tumors closely resemble normal cartilage and may be very difficult to distinguish from chondromas or synovial chondromatosis. With increasing tumor grade, there is a decreased amount of cartilaginous matrix but increased cellularity, nuclear size, nuclear pleomorphism, binucleated or multinucleated chondrocytes, cellular spindling, mitotic activity, and necrosis. Most chondrosarcomas of the jaws are grade I or II (Fig. 14.88). In general, chondrosarcomas of the head and neck tend to exhibit a lower grade and often are diagnosed at an earlier stage compared to those arising in other regions.

Variants

Uncommon microscopic variants of chondrosarcoma include the following:

• **Fig. 14.88 Chondrosarcoma.** This grade II chondrosarcoma shows a variation in size of chondrocyte nuclei. Occasional double nuclei are seen in the lacunae.

- **Clear cell chondrosarcoma** is a low-grade variant exhibiting cells with abundant clear cytoplasm. This variant may be difficult to differentiate from metastatic clear cell carcinoma.
- **Dedifferentiated chondrosarcoma** is a high-grade variant that shows an admixture of well-differentiated chondrosarcoma and a high-grade sarcoma. This variant is exceedingly rare in the jaws.
- **Myxoid chondrosarcoma** classically is described as a soft tissue tumor, although intraosseous lesions are possible. This variant is characterized by a proliferation of cells with clear, vacuolated, or eosinophilic cytoplasm within a background of mucoid material.
- **Mesenchymal chondrosarcoma** is discussed in the next section.

Treatment and Prognosis

Surgical resection is the mainstay of treatment for chondrosarcoma. Curettage followed by cryosurgery may be an alternative for grade I chondrosarcomas confined within bone, although this technique mainly is used for long bone tumors. Radiation and chemotherapy are less effective for chondrosarcoma than osteosarcoma. However, radiation may be considered for unresectable disease. In addition, for high-grade, clear cell, or extracompartmental (i.e., extending beyond bone) chondrosarcomas, radiation therapy may be administered either preoperatively for tumors deemed borderline resectable or postoperatively for residual disease. Systemic agents typically are reserved for select cases of chondrosarcoma (e.g., dasatinib or pazopanib for widespread metastasis, ivosidenib for *IDH1*-mutant conventional/dedifferentiated tumors).

Major prognostic factors for chondrosarcoma include clinical stage, histopathologic grade, and adequacy of resection. In the United States, the overall relative 5-year survival rate is approximately 78%. The relative 5-year survival rates for patients with localized disease, regional metastasis, and distant metastasis are 91%, 75%, and 22%, respectively. Because recurrence often is a late sequela, patients must be followed for their lifetime.

Head and neck chondrosarcomas typically are locally aggressive with low metastatic potential. Metastasis mainly is seen among rare high-grade tumors. Nevertheless, death may occur by direct extension into vital structures. In particular, maxillary tumors often are large at diagnosis, occur adjacent to the central nervous system, and are difficult to resect; therefore, they are difficult to cure. According to Surveillance, Epidemiology, and End Results (SEER) registry data, 5-year disease-specific and overall survival rates for head and neck chondrosarcomas are 90% and 81%, respectively.

MESENCHYMAL CHONDROSARCOMA

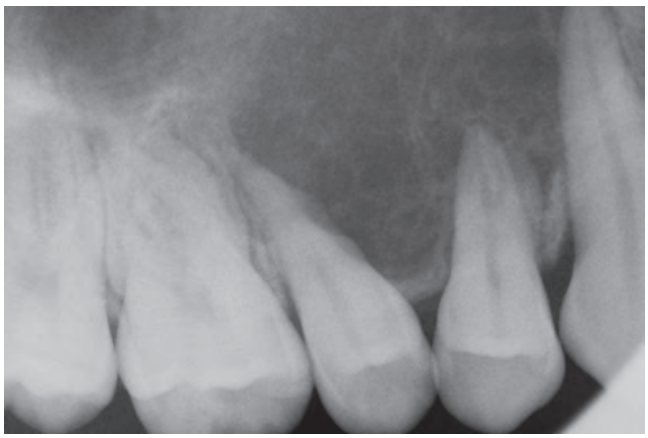
Mesenchymal chondrosarcoma is an aggressive variant of chondrosarcoma with a distinctive biphasic histopathologic pattern. It is considered high-grade based on clinical behavior

dentlearn.ir

rather than histopathologic features. This variant represents only about 2%–9% of all chondrosarcomas. *HEY1-NCOA2* fusion has been identified in approximately 90% of cases; *IRF2BP2-CDX1* fusion also is possible. Unlike conventional chondrosarcomas, mesenchymal chondrosarcomas do not harbor *IDH1* mutations.

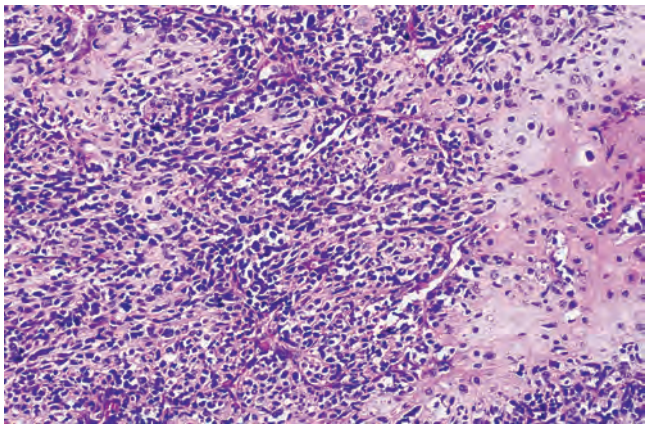
Clinical and Radiographic Features

In contrast to other chondrosarcoma types, the mesenchymal variant is unusual in that it most frequently affects individuals in the second and third decades of life and most often arises in the jaws (22%–27% of cases). Other commonly affected sites are the ribs, shoulder, pelvic girdle, and vertebrae. In addition, approximately 30%–60% of cases arise in soft tissue rather than bone.



Swelling and pain, often of fairly short duration, are the most common symptoms. Radiographically, the tumor typically appears as an ill-defined radiolucency with or without stippled calcification (Fig. 14.89). However, some examples may appear predominantly radiopaque, particularly within the maxilla.

Histopathologic Features



Microscopic examination shows two distinct elements: well-differentiated cartilaginous nodules and sheets of small, undifferentiated, spindled or round cells (Fig. 14.90). The degree of cellularity and atypia within the cartilaginous component may vary from that of a benign chondroma to a low-grade chondrosarcoma. The undifferentiated component may exhibit a branching vascular pattern that mimics solitary fibrous tumor ("hemangiopericytoma"). In addition, the undifferentiated component may appear similar to rhabdomyosarcoma, Ewing sarcoma, lymphoma, or metastatic small cell carcinoma. The undifferentiated cells may exhibit immunohistochemical expression of CD99, SOX9, and NKX3.1, whereas the cartilaginous component expresses S-100 protein.

Treatment and Prognosis

Surgical excision with wide margins is the mainstay of therapy. Some studies have suggested that supplemental radiation therapy and/or chemotherapy may be beneficial, although further investigation is needed. Some individuals are treated with regimens similar to those used for patients with Ewing sarcoma (see next section). Close long-term follow-up is recommended, because local recurrence and metastasis are common and may be discovered more than 20 years after initial therapy. Metastasis most frequently develops in the lungs. According to Surveillance, Epidemiology, and End Results (SEER) registry data, 5- and 10-year overall survival rates are 51% and 43%, respectively; cases arising in the head and neck exhibit better survival compared to those developing in other sites (median survival 95.7 months versus 67.4 months, respectively).

◆ EWING SARCOMA

Ewing sarcoma is a malignant neoplasm composed of small, undifferentiated round cells. In the United States, the annual incidence is approximately 1 per million population. Although rare, Ewing sarcoma is the second most common primary malignant bone tumor in pediatric patients after osteosarcoma. The term *Ewing sarcoma* (or the *Ewing sarcoma family of tumors*) includes classical Ewing sarcoma of bone, extraosseous Ewing sarcoma, primitive neuroectodermal tumor (Ewing sarcoma with neuronal differentiation), and Askin tumor (small round cell tumor of the chest wall). Based on shared histologic, immunohistochemical, and genetic characteristics, authorities currently consider these entities to represent the same tumor type.

The histogenesis of Ewing sarcoma is unknown. Investigators previously have hypothesized that the tumor originates from the neural crest. However, current evidence favors an origin from mesenchymal stem cells with potential for limited neural differentiation. At the molecular level, Ewing sarcoma is defined by balanced chromosomal translocations that result in fusion of the RNA-binding protein

dentlearn.ir

EWS (or the closely related FUS protein) with ETS family transcription factors (e.g., FLI1, ERG, ETV1, ETV4, and FEV). In particular, more than 85% of cases demonstrate the translocation t(11;22) (q24;q12), which encodes the EWS::FLI1 fusion protein.

Recent molecular studies have identified additional rare types of undifferentiated small round cell sarcomas of bone and soft tissue, including round cell sarcoma with *EWSR1*–non-ETS fusions, *CIC*-rearranged sarcoma, and sarcoma with *BCOR* genetic alterations. Such tumors formerly were considered subtypes of Ewing sarcoma (or "Ewing-like sarcoma") but currently are recognized as distinct entities.

Clinical and Radiographic Features

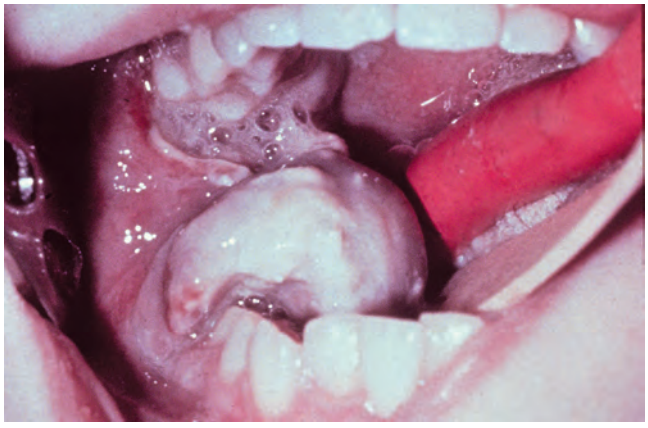
Most patients with Ewing sarcoma are adolescents, and the median age at diagnosis is 15 years. However, advances in molecular diagnosis have led to an increase in the number of cases diagnosed in young adults. There is a slight male predominance, and the majority of patients are white. Osseous lesions most frequently involve the long bones, pelvis, and ribs. Only 1%–2% of cases arise in the gnathic or craniofacial bones. Primary extraosseous lesions are also possible but very rare.

The most common clinical findings are pain and swelling. Fever, leukocytosis, and an elevated erythrocyte sedimentation rate also may be present in advanced disease. The tumor often penetrates the cortex, resulting in a soft tissue mass overlying the affected area of the bone (Fig. 14.91). Jaw involvement is more common in the mandible than the maxilla and may result in tooth displacement, tooth mobility, root resorption, and paresthesia. Cervical lymphadenopathy may be evident as well. The nonspecific clinicoradiographic presentation may lead to a misdiagnosis of odontogenic infection or osteomyelitis.

Radiographically, most osseous lesions appear as ill-defined radiolucencies, although a mixed radiolucent and radiopaque pattern also is possible. Cortical destruction or expansion may or may not be present. The characteristic "onionskin" periosteal reaction, commonly observed in Ewing sarcoma of long bones, seldom is seen in jaw lesions. Although plain radiography often is used for initial evaluation, CT and MRI are superior for assessing lesion extent.

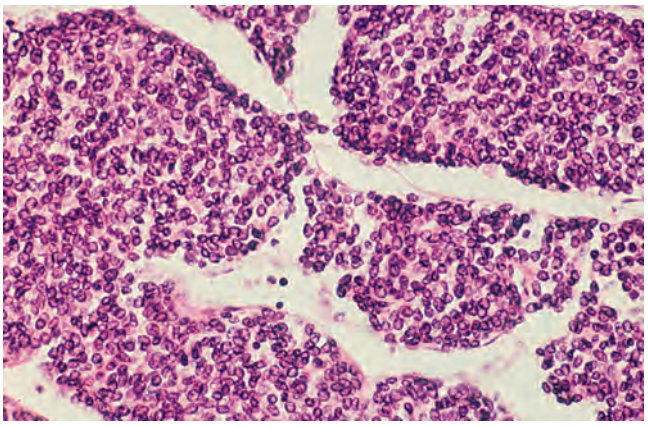
Histopathologic Features

Ewing sarcoma typically is composed of broad sheets of small, monotonous, round cells with well-delineated nuclear outlines and ill-defined cellular borders (Fig. 14.92). In some cases, variable-sized nests of tumor cells are separated by fibrovascular septa, creating a lobular pattern. Extensive necrosis and hemorrhage are common. Cytoplasmic clearing and rosette formation are variable findings.



Diagnosis may be difficult. Ewing sarcoma must be differentiated from other pediatric small round cell tumors, such as metastatic neuroblastoma, malignant lymphoma, small cell osteosarcoma, and alveolar rhabdomyosarcoma. Metastatic small cell carcinoma also may be considered in the differential diagnosis of a suspected Ewing sarcoma in an older patient.

Ewing sarcomas typically exhibit cytoplasmic periodic acid-Schiff (PAS)-positive glycogen granules. Membranous reactivity for CD99 (MIC2) and nuclear reactivity for NKX2.2 usually can be demonstrated by immunohistochemistry. In addition, immunohistochemical expression of FLI1 or ERG may be noted in cases harboring *EWSR1*::*FLI1* or *EWSR1*::*ERG* mutations, respectively. Identification of characteristic chromosomal translocations by reverse transcription polymerase chain reaction (RT-PCR) or fluorescence *in situ* hybridization (FISH) may aid in confirming the diagnosis.



Treatment and Prognosis

Treatment usually consists of multidrug chemotherapy with surgery and/or radiotherapy. Systemic chemotherapy typically is indicated, because seemingly localized disease often is associated with occult micrometastases.

With the development of modern multimodal therapy, the prognosis for patients with Ewing sarcoma has improved dramatically in recent decades. In the United States, overall

• **Fig. 14.92 Ewing Sarcoma.** Broad sheets of small round cells with well-defined nuclear outlines and ill-defined cytoplasmic borders.

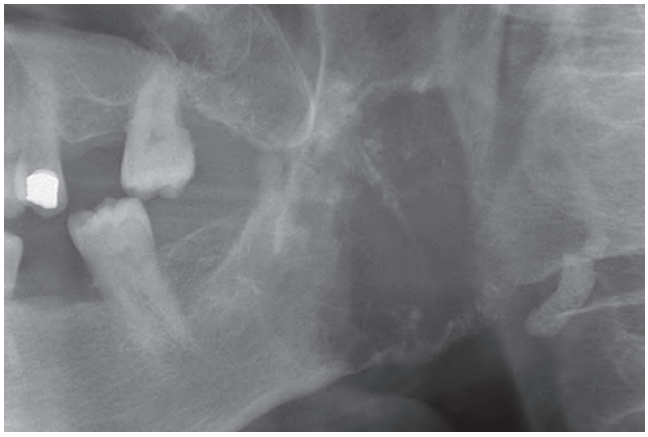
dentlearn.ir

5-year relative survival is approximately 61%, and 5-year survival rates for patients with localized disease, regional metastasis, and distant metastasis at presentation are approximately 81%, 67%, and 38%, respectively. The presence of metastasis is the most important prognostic factor, and metastasis is evident at initial diagnosis in about 25% of patients. The most common sites of metastasis are the lungs and bones; for reasons unknown, patients with extrapulmonary metastasis tend to fare worse than those with metastasis confined to the lungs. There is limited data regarding gnathic Ewing sarcoma, although lesions arising in the jaws appear to exhibit a more favorable prognosis compared to those arising in the long bones and pelvis.

◆ METASTATIC TUMORS TO THE JAWS

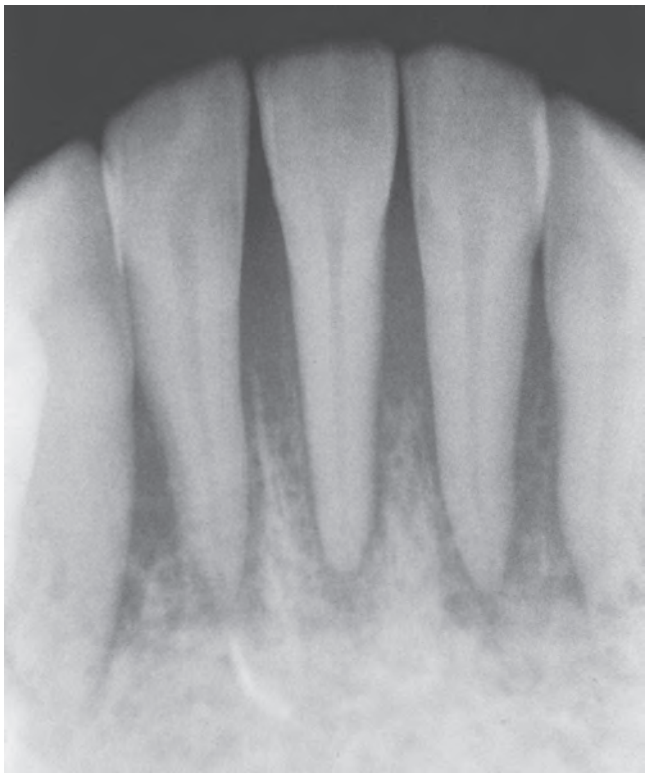
Metastatic carcinoma is the most common form of cancer involving bone. The most common primary sites for carcinomas that metastasize to bone are the breast, lung, thyroid, prostate, and kidney. The bones that most frequently exhibit metastasis include the vertebrae, ribs, pelvis, and skull.

Jaw metastasis is rare but may occur more often than generally appreciated. In an autopsy study of mandibles from patients with various extraoral primary carcinomas, microscopic examination revealed metastasis in 16% of cases, with most of these metastases found to be clinically, radiographically, and grossly undetectable. Metastatic spread of a carcinoma to the jaws usually occurs by the hematogenous route. Sarcomas arising in soft tissues or other bones metastasize to the jaws only very rarely.



Clinical and Radiographic Features

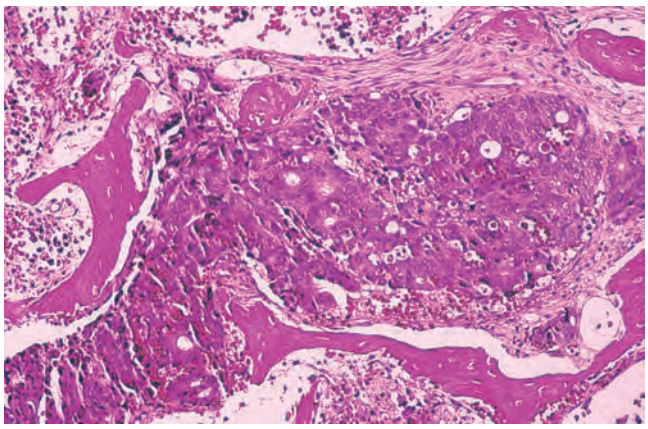
Jaw metastases have been reported over a broad age range but most often affect older adults; the mean age is approximately 43–52 years, with no significant gender bias. There is a marked predilection for the mandible, especially the molar region.



Clinical signs and symptoms of jaw metastasis may include pain, swelling, tooth mobility, trismus, and paresthesia. In particular, mandibular metastasis with involvement of the mental nerve may produce paresthesia in the lower lip and chin **(numb-chin syndrome).** The rarity of jaw metastases and the nonspecific clinical presentation may lead to a mistaken impression of an inflammatory process. Sometimes an osseous metastasis is discovered in a nonhealing extraction site from which a tooth was removed because of local pain or significant mobility. In other instances, the patient may be completely asymptomatic, and the lesion is discovered incidentally by radiographic examination.

Occasionally, diagnosis of a jaw metastasis is the first indication that the patient has a primary malignancy at some other anatomic site. Location of the occult primary tumor may be difficult and may require extensive evaluation.

Most radiographically evident jaw metastases appear as ill-defined or "moth-eaten" radiolucencies (Fig. 14.93). However, some examples—particularly metastatic prostate and breast carcinomas—may appear radiopaque or mixed radiolucent-radiopaque. *Osteolytic* (bone-resorbing) and/or *osteoblastic* (bone-forming) activity may result from various growth factors and other substances produced by tumor cells. Some lesions may mimic periapical inflammatory disease or periodontal disease. Cortical erosion, pathologic fracture, and widening of the periodontal ligament space may be noted as well (Fig. 14.94). Compared to plain radiography,



• **Fig. 14.93 Thyroid Carcinoma Metastatic to the Jaws.** Radiograph showing an ill-defined, destructive radiolucency with irregular borders at the angle of the mandible. (Courtesy of Dr. Terry Day.)

• **Fig. 14.94 Carcinoma Metastatic to the Jaws.** Periapical radiograph showing widening of the periodontal ligament spaces.

dentlearn.ir

• **Fig. 14.95 Carcinoma Metastatic to the Jaws.** Islands of malignant cells can be seen filling the marrow spaces.

bone scintigraphy is more sensitive for detecting osseous metastases.

Histopathologic Features

The microscopic appearance of metastatic carcinoma in bone varies. In some instances, the metastasis exhibits well-differentiated features that suggest an origin from a specific site, such as the kidney, colon, or thyroid. More often, however, metastatic carcinomas are poorly differentiated, and the tumor origin is not readily apparent (Fig. 14.95). Poorly differentiated metastatic carcinoma may be difficult to differentiate from lymphoma, melanoma, or anaplastic sarcoma. In such cases, immunohistochemistry may aid in diagnosis. Definitive diagnosis requires correlation of laboratory studies with a thorough medical history, complete physical examination, and imaging studies.

Treatment and Prognosis

Although a solitary metastatic focus may be treated by excision or radiation therapy, jaw metastasis almost always is associated with widely disseminated disease. Management depends on the specific underlying tumor type and often is palliative in nature. Administration of bisphosphonates may help to slow progression of bone metastases, decrease bone pain, and reduce the risk for pathologic fracture. By definition, osseous metastasis constitutes stage IV disease. Accordingly, the prognosis for metastatic carcinoma to the jaws is poor, and most patients survive less than 1 year.

15
Odontogenic Cysts and Tumors

Odontogenic cysts and tumors constitute an important aspect of oral and maxillofacial pathology. Odontogenic cysts are encountered relatively commonly in dental practice. Odontogenic tumors, by contrast, are uncommon lesions. Even in the specialized oral and maxillofacial pathology laboratory, less than 1% of all specimens received are odontogenic tumors.

ODONTOGENIC CYSTS

With rare exceptions, epithelium-lined cysts in bone are seen only in the jaws. Other than a few cysts that may result from the inclusion of epithelium along embryonic lines of fusion, most jaw cysts are lined by epithelium that is derived from odontogenic epithelium. These are referred to as **odontogenic cysts.** (Non-odontogenic jaw cysts are discussed in Chapter 1.)

Odontogenic cysts are subclassified as developmental or inflammatory in origin. The inciting factors that initiate the formation of **developmental cysts** are unknown, but these lesions do not appear to be the result of an inflammatory reaction. **Inflammatory cysts** are the result of inflammation. Box 15.1 presents categories of odontogenic cysts modified from the 2022 World Health Organization (WHO) classification. (The periapical cyst is discussed in Chapter 3.)

◆ DENTIGEROUS CYST (FOLLICULAR CYST)

The **dentigerous cyst** is defined as a cyst that originates by the separation of the follicle from around the crown of an unerupted tooth. This is the most common type of developmental odontogenic cyst, making up about 20% of all epithelium-lined cysts of the jaws. The dentigerous cyst encloses the crown of an unerupted tooth and is attached to the tooth at the cementoenamel junction (Fig. 15.1). The pathogenesis of this cyst is uncertain, but apparently it develops by accumulation of fluid between the reduced enamel epithelium and the tooth crown.

Although most dentigerous cysts are considered to be developmental in origin, there are some examples that appear to have an inflammatory pathogenesis. For example, it has been suggested that, on occasion, a dentigerous cyst may develop around the crown of an unerupted permanent tooth as a result of periapical inflammation from an overlying primary tooth (Fig. 15.2). Another scenario involves a partially erupted mandibular third molar that develops an inflamed cystlike lesion along the distal or buccal aspect. Although many such lesions probably are due to inflammation associated with recurrent pericoronitis, these lesions are usually diagnosed as examples of dentigerous cyst, especially because it is impossible to determine histopathologically whether the inflammatory component is primary or secondary in nature. The term **paradental cyst** sometimes has been applied to these lesions, but the use of this term in the literature is confusing because it also has been used to describe examples of what is known as the *buccal bifurcation cyst* (see page 704).

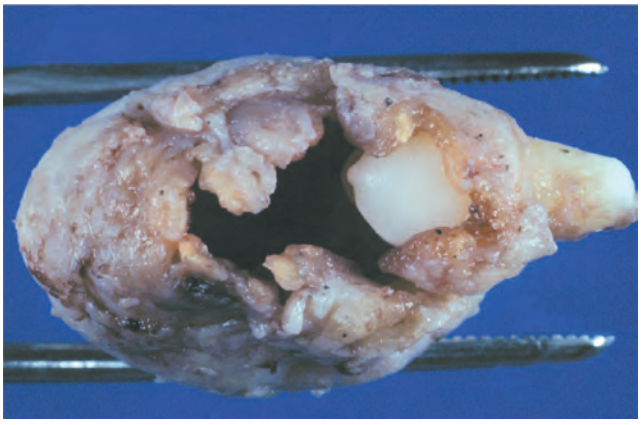
Clinical and Radiographic Features

Although dentigerous cysts may occur in association with any unerupted tooth, most often they involve mandibular third molars, accounting for approximately 65% of all cases. Other relatively frequent sites include maxillary canines, maxillary third molars, and mandibular second premolars. Dentigerous cysts rarely involve unerupted deciduous teeth. Occasionally, they are associated with supernumerary teeth or odontomas. Multiple dentigerous cysts have been reported, although this is an infrequent finding.

Although dentigerous cysts may be encountered in patients across a wide age range, they are discovered most frequently in patients between 10 and 30 years of age. There is a slight male predilection, and the prevalence is higher for whites than for blacks. Small dentigerous cysts are usually completely asymptomatic and are discovered only on a routine radiographic examination or when films are taken to determine the reason for the failure of a tooth to erupt. Dentigerous cysts can grow to a considerable size, and large cysts may be associated with a painless expansion of the bone in the involved area. Extensive lesions may result in facial asymmetry. Large dentigerous cysts are uncommon, and most lesions that are considered to be large dentigerous cysts on radiographic examination prove to be odontogenic keratocysts (OKCs) or ameloblastomas. Dentigerous cysts may become infected and be associated with pain and swelling. Such infections may arise in a dentigerous cyst that is associated with a partially erupted tooth or by extension from a periapical or periodontal lesion that affects an adjacent tooth.

dentlearn.ir

• BOX 15.1 Classification of Odontogenic Cysts

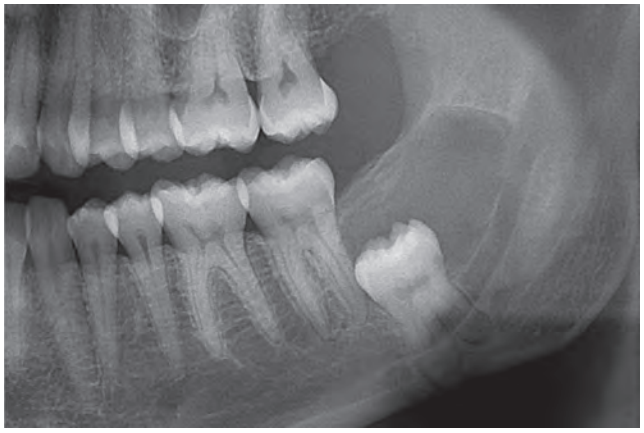


Developmental

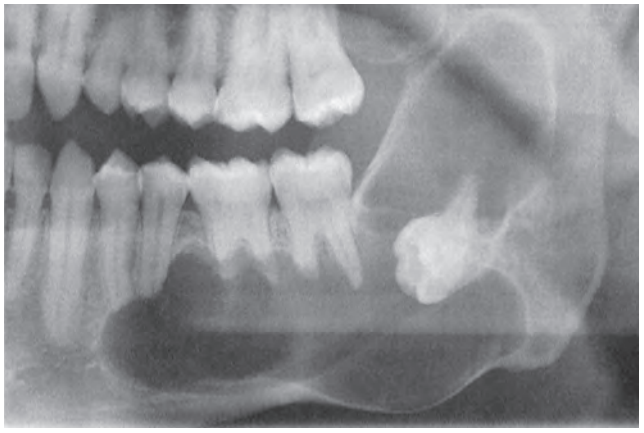
- Dentigerous cyst
- Eruption cyst
- Odontogenic keratocyst (OKC)*
- Orthokeratinized odontogenic cyst
- Gingival (alveolar) cyst of the newborn
- Gingival cyst of the adult
- Lateral periodontal cyst
- Calcifying odontogenic cyst†
- Glandular odontogenic cyst

Inflammatory

- Periapical (radicular) cyst
- Residual periapical (radicular) cyst
- Buccal bifurcation cyst

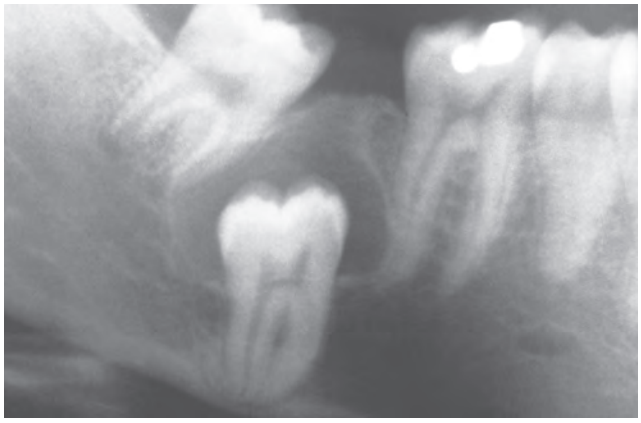


*The OKC currently is included with the odontogenic cysts in the 2022 World Health Organization (WHO) classification; however, some authors and clinicians favor classifying it in the odontogenic tumor category ("keratocystic odontogenic tumor").
†Some odontogenic "ghost cell" lesions occur as solid, neoplastic growths that should be classified as odontogenic tumors ("dentinogenic ghost cell tumor" and "ghost cell odontogenic carcinoma").

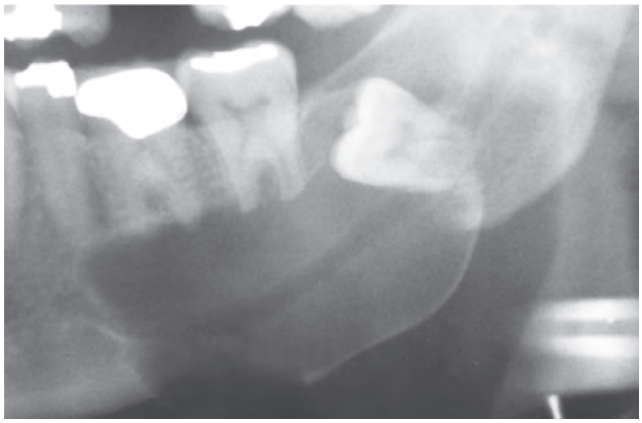


• **Fig. 15.1 Dentigerous Cyst.** Gross specimen of a dentigerous cyst involving a maxillary canine tooth. The cyst has been cut open to show the cyst-to-crown relationship.

• **Fig. 15.2 Dentigerous Cyst.** Well-circumscribed radiolucency surrounding the crown of the mandibular second molar. The overlying primary molar previously had root canal therapy.

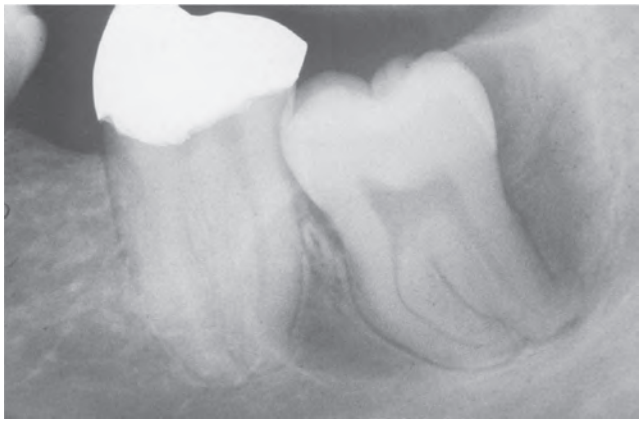


• **Fig. 15.3 Dentigerous Cyst.** Unilocular radiolucency surrounding the crown of an impacted mandibular third molar. (Courtesy of Dr. William Dunlap.)



• **Fig. 15.4 Dentigerous Cyst.** This unusually large dentigerous cyst shows a somewhat multilocular radiographic pattern. Note the root resorption of the adjacent molars and bicuspids. (Courtesy of Dr. John Werther.)

Radiographically, the dentigerous cyst typically shows a unilocular radiolucent area that is associated with the crown of an unerupted tooth (Fig. 15.3). The radiolucency usually has a well-defined and often corticated border, but an infected cyst may show ill-defined borders. A large dentigerous cyst may give the impression of a multilocular process because of the persistence of bone trabeculae within the radiolucency (Fig. 15.4). The cyst-to-crown relationship shows several radiographic variations. In the **central** variety, which is the most common, the cyst surrounds the crown of the tooth and the crown projects into the cyst (Fig. 15.5). The **lateral** variety is usually associated with mesioangular impacted mandibular third molars that are partially erupted. The cyst grows laterally along the root surface and partially surrounds the crown (Fig. 15.6). In the **circumferential** variant, the cyst surrounds the crown and extends for some distance along the root so that a significant portion of the root appears to lie within the cyst (Fig. 15.7). Rarely, a third molar may be displaced to the



dentlearn.ir

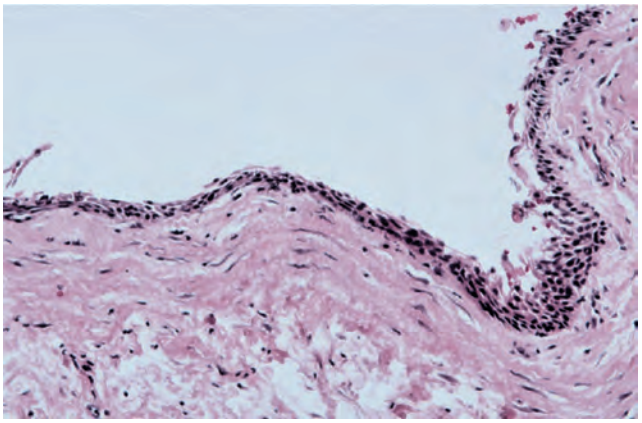
• **Fig. 15.5 Dentigerous Cyst.** Central type showing the crown projecting into the cystic cavity. (Courtesy of Dr. Stephen E. Irwin.)

• **Fig. 15.6 Dentigerous Cyst.** Lateral variety showing a large cyst along the mesial root of the unerupted molar. This cyst exhibited mucous cell prosoplasia. (Courtesy of Dr. John R. Cramer.)

• **Fig. 15.7 Dentigerous Cyst.** Circumferential variety showing cyst extension along the mesial and distal roots of the unerupted tooth. (Courtesy of Dr. Richard Marks.)

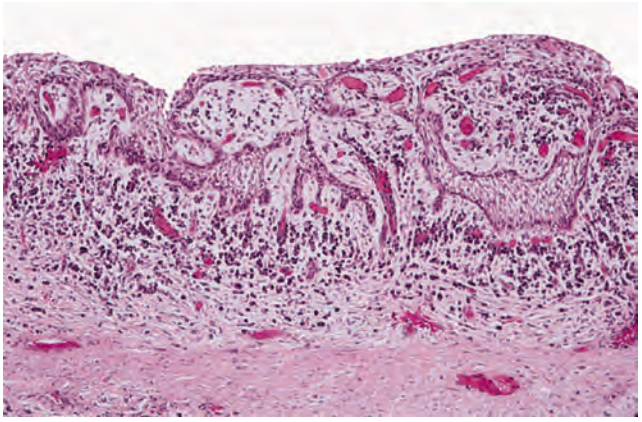
lower border of the mandible or higher up into the ascending ramus. Maxillary anterior teeth may be displaced into the floor of the nose, and other maxillary teeth may be moved through the maxillary sinus to the floor of the orbit. Dentigerous cysts may displace the involved tooth for a considerable distance. Root resorption of adjacent erupted teeth can occur (see Fig. 15.4).

• **Fig. 15.8 Dentigerous Cyst or Enlarged Follicle.** Radiolucent lesion involving the crown of an unerupted mandibular premolar. Distinction between a dentigerous cyst and an enlarged follicle for a lesion of this size by radiographic and even histopathologic means is difficult, if not impossible. (Courtesy of Dr. Wally Austelle.)



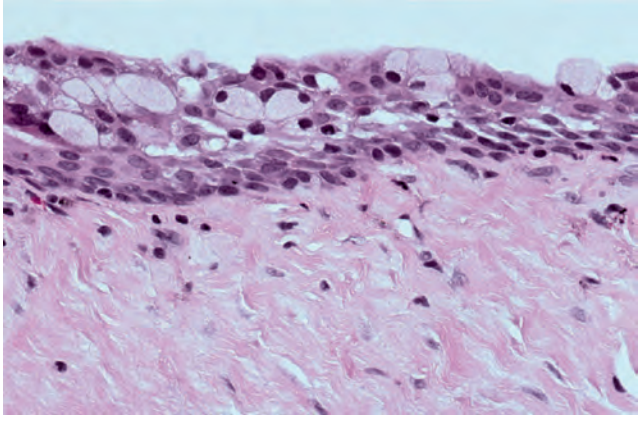
Radiographic distinction between a small dentigerous cyst and an enlarged follicle about the crown of an unerupted tooth is difficult and may be largely an academic exercise (Fig. 15.8). For the lesion to be considered a dentigerous cyst, some investigators believe that the radiolucent space surrounding the tooth crown should be at least 3–4 mm in diameter. Radiographic findings are not diagnostic for a dentigerous cyst, however, because OKCs, unilocular ameloblastomas, and many other odontogenic and nonodontogenic tumors may have radiographic features that are essentially identical to those of a dentigerous cyst.

Histopathologic Features



The histopathologic features of dentigerous cysts vary, depending on whether the cyst is inflamed or not inflamed. In the **noninflamed dentigerous cyst,** the fibrous connective tissue wall is loosely arranged and contains considerable glycosaminoglycan ground substance. Small islands or cords of inactive-appearing odontogenic epithelial rests may be present in the fibrous wall. Occasionally these rests may be numerous, and at times pathologists who are not familiar with oral lesions have misinterpreted this finding as ameloblastoma. The epithelial lining consists of two to four layers of flattened nonkeratinizing cells, and the epithelium and connective tissue interface is flat (Fig. 15.9).

In the fairly common **inflamed dentigerous cyst,** the fibrous wall is more collagenized, with a variable infiltration of chronic inflammatory cells. The epithelial lining may show varying amounts of hyperplasia with the development of rete ridges and more definite squamous features (Fig. 15.10). A keratinized surface is sometimes seen, but these changes must be differentiated from those observed in the OKC. Focal areas of mucous cells may be found in the epithelial lining of dentigerous cysts (Fig. 15.11). Rarely,



dentlearn.ir

• **Fig. 15.9 Dentigerous Cyst.** This noninflamed dentigerous cyst shows a thin, nonkeratinized epithelial lining.

• **Fig. 15.10 Dentigerous Cyst.** This inflamed dentigerous cyst shows a thicker epithelial lining with hyperplastic rete ridges. The fibrous cyst capsule shows a diffuse chronic inflammatory infiltrate.

• **Fig. 15.11 Dentigerous Cyst.** Scattered mucous cells can be seen within the epithelial lining.

ciliated columnar cells are present. Small nests of sebaceous cells rarely may be noted within the fibrous cyst wall. These mucous, ciliated, and sebaceous elements are believed to represent the multipotentiality of the odontogenic epithelial lining in a dentigerous cyst.

Gross examination of the wall of a dentigerous cyst may reveal one or several areas of nodular thickening on the luminal surface. These areas must be examined microscopically to rule out the presence of early neoplastic change.

Because a thin layer of reduced enamel epithelium normally lines the dental follicle surrounding the crown of an unerupted tooth, it can be difficult to distinguish a small dentigerous cyst from simply a normal or enlarged dental follicle based on microscopic features alone. Again, this distinction often represents largely an academic exercise; the most important consideration is ensuring that the lesion does not represent a more significant pathologic process (e.g., OKC or ameloblastoma).

Treatment and Prognosis

The usual treatment for a dentigerous cyst is careful enucleation of the cyst together with removal of the unerupted tooth. If eruption of the involved tooth is considered feasible, then the tooth may be left in place after partial removal of the cyst wall. Patients may need orthodontic treatment to assist eruption. Large dentigerous cysts also may be treated by marsupialization. This permits decompression of the cyst, with a resulting reduction in the size of the bone defect. The cyst can then be excised at a later date, with a less extensive surgical procedure. In situations where the tooth roots are in close proximity to the inferior alveolar nerve, coronectomy and cyst removal can be performed. This procedure allows the roots to remain in place, thereby reducing the risk of damage to the neurovascular bundle.

The prognosis for most dentigerous cysts is excellent, and recurrence seldom is noted after complete removal of the cyst. However, several potential complications must be considered. Much has been written about the possibility that the lining of a dentigerous cyst might undergo neoplastic transformation to an **ameloblastoma.** Although undoubtedly this can occur, the frequency of such neoplastic transformation is low. Rarely, a **squamous cell carcinoma** may arise in the lining of a dentigerous cyst (see page 705). It is likely that some **intraosseous mucoepidermoid carcinomas** (see page 496) develop from mucous cells in the lining of a dentigerous cyst.

◆ ERUPTION CYST (ERUPTION HEMATOMA)

The **eruption cyst** is the soft tissue analogue of the dentigerous cyst. The cyst develops as a result of separation of the dental follicle from around the crown of an erupting tooth that is within the soft tissues overlying the alveolar bone.

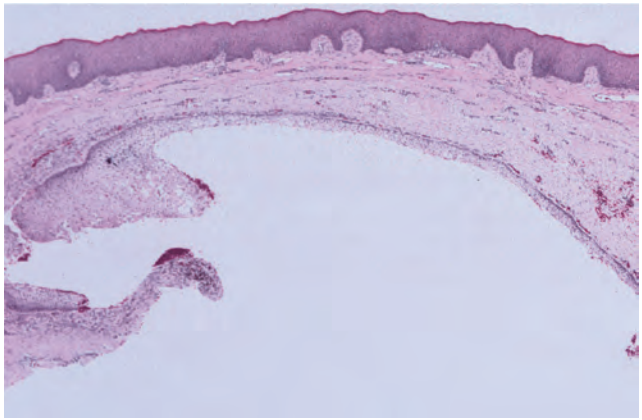
Clinical Features

The eruption cyst appears as a soft, often translucent swelling in the gingival mucosa overlying the crown of an erupting deciduous or permanent tooth. Most examples are seen in children younger than age 10. Although the cyst can occur around any tooth, the lesion most commonly has been associated with the central incisors and first molars in both dentitions. On occasion, bilateral cysts may be observed. Surface

dentlearn.ir

trauma may result in a considerable amount of blood in the cystic fluid, which imparts a blue to purple-brown color. Such lesions sometimes are referred to as **eruption hematomas** (Fig. 15.12).

Histopathologic Features



Intact eruption cysts seldom are submitted to the oral and maxillofacial pathology laboratory, and most examples consist of the excised roof of the cyst, which has been removed to facilitate tooth eruption. These show surface oral epithelium on the superior aspect. The underlying lamina propria shows a variable inflammatory cell infiltrate. The deep portion of the specimen, which represents the roof of the cyst, shows a thin layer of nonkeratinizing squamous epithelium (Fig. 15.13).

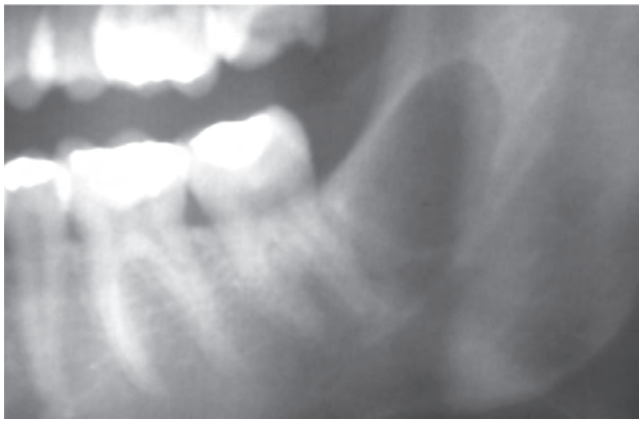
Treatment and Prognosis

Treatment may not be required because the cyst usually ruptures spontaneously, permitting the tooth to erupt. If this does not occur, then simple excision of the roof of the cyst generally permits speedy eruption of the tooth.

• **Fig. 15.12 Eruption Cyst.** This soft gingival swelling contains considerable blood and can also be designated as an eruption hematoma.

• **Fig. 15.13 Eruption Cyst.** A cystic epithelial cavity can be seen below the mucosal surface.

◆ PRIMORDIAL CYST



The concept and meaning of the term **primordial cyst** often have been controversial and confusing. In the older classification of cysts used in the United States, the primordial cyst was considered to originate from cystic degeneration of the enamel organ epithelium before the development of dental hard tissue. Therefore, the primordial cyst would occur in place of a tooth.

In the mid-1950s, oral and maxillofacial pathologists in Europe introduced the term **odontogenic keratocyst (OKC)** to denote a cyst with specific histopathologic features and clinical behavior, which was believed to arise from the dental lamina (i.e., the dental primordium). Subsequently, this concept was widely accepted, and the terms *odontogenic keratocyst* and *primordial cyst* were used synonymously. The 1972 WHO classification used the designation *primordial cyst* as the preferred term for this lesion. The 1992 WHO classification, however, listed *odontogenic keratocyst* as the preferred designation.

Almost all examples of so-called primordial cysts (i.e., a cyst that develops in the place of a tooth) microscopically will be OKCs (Fig. 15.14). Whether there could be such a radiographic presentation that is not microscopically an OKC is still unsettled. If such a lesion exists, then it must be exceedingly rare.

◆ ODONTOGENIC KERATOCYST (KERATOCYSTIC ODONTOGENIC TUMOR)

The **odontogenic keratocyst (OKC)** is a distinctive form of developmental odontogenic cyst that deserves special consideration because of its specific histopathologic features and potentially aggressive clinical behavior. There is general agreement that the OKC arises from cell rests of the dental lamina. This cyst shows a different growth mechanism and biologic behavior from the more common dentigerous cyst and radicular cyst.

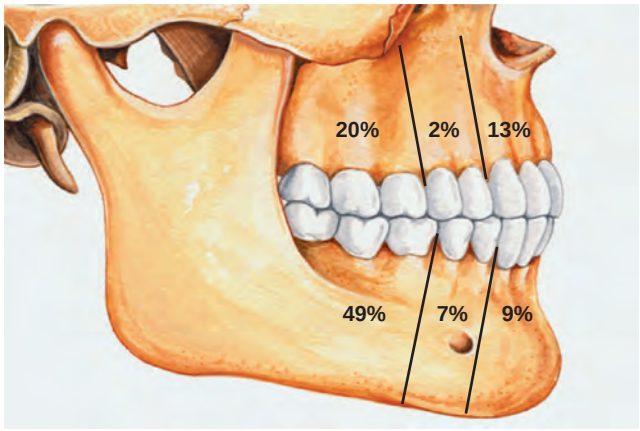
• **Fig. 15.14 Primordial Cyst.** This patient gave no history of extraction of the third molar. A cyst is located in the third molar area. The cyst was excised, and histopathologic examination revealed an odontogenic keratocyst (OKC).

dentlearn.ir

Some investigators have suggested that the OKC be regarded as a benign cystic neoplasm rather than a cyst. Indeed, in the 2005 WHO monograph on head and neck tumors, this lesion was reclassified under the name **keratocystic odontogenic tumor (KCOT).** However, subsequent editions of the WHO classification reverted to using OKC as the preferred designation. The arguments to support classification as a tumor largely rely on studies that have shown certain molecular genetic alterations that are also present in some neoplasms. Recent studies have reported that 93% of sporadic OKCs, as well as 90% of OKCs associated with the nevoid basal cell carcinoma syndrome, show inactivating mutations of the *PTCH1* gene, an important component of the Hedgehog signaling pathway. When compared to other odontogenic cysts, the OKC shows significantly greater expression of proliferating cell nuclear antigen (PCNA) and Ki-67, especially in the suprabasilar layer. Also, genetic analyses have demonstrated loss of heterozygosity for various other tumor suppressor genes (*p16, p53, MCC, TSLC1, LATS2*, and *FHIT*) in many OKCs.

Whether such molecular findings warrant reclassification of the OKC as a neoplasm (KCOT) remains a hotly debated topic in oral and maxillofacial pathology circles. The authors currently favor retaining "odontogenic keratocyst" as the primary term for this lesion, although both terms are acceptable and should be considered synonymous. Regardless of which term is preferred, these lesions are significant for three reasons:

1. Greater growth potential than most other odontogenic cysts
2. Higher recurrence rate
3. Possible association with the nevoid basal cell carcinoma syndrome



Although there are wide variations in the reported frequency of OKCs compared with that of other types of odontogenic cysts, most studies indicate that OKCs make up 3%–11% of all odontogenic cysts.

Clinical and Radiographic Features

OKCs may be found in patients who range in age from infancy to old age, but about 60% of all cases are diagnosed in people between 10 and 40 years of age. There is a slight male predilection. The mandible is involved in 60%–80% of cases, with a marked tendency to involve the posterior body and ramus (Fig. 15.15).

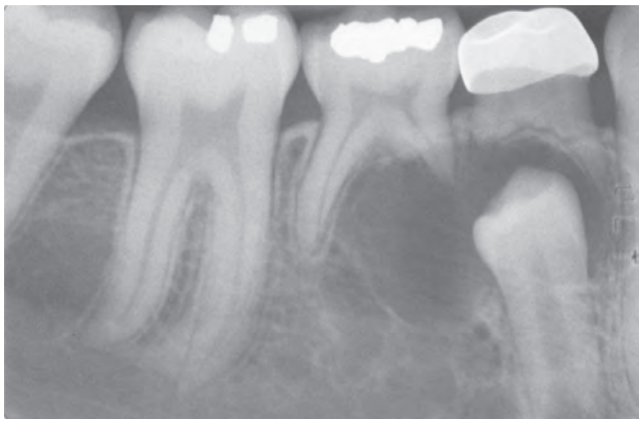
Small OKCs are usually asymptomatic and discovered only during the course of a radiographic examination. Larger OKCs may be associated with pain, swelling, or drainage. Some extremely large cysts, however, may cause no symptoms.

OKCs tend to grow in an anteroposterior direction within the medullary cavity of the bone without causing obvious bone expansion. This feature may be useful in differential clinical and radiographic diagnosis because dentigerous and radicular cysts of comparable size are usually associated with bony expansion. Multiple OKCs may be present, and

• **Fig. 15.15 Odontogenic Keratocyst (OKC).** Relative distribution of OKCs in the jaws.

• **Fig. 15.16 Odontogenic Keratocyst (OKC).** Large, multilocular cyst involving most of the angle and ramus of the right mandible. (Courtesy of Dr. Dan Cook.)

such patients should be evaluated for other manifestations of the **nevoid basal cell carcinoma (Gorlin) syndrome** (see page 694).



OKCs demonstrate a well-defined radiolucent area with smooth and often corticated margins. Large lesions, particularly in the posterior body and ramus of the mandible, may appear multilocular (Fig. 15.16). An unerupted tooth is involved in the lesion in 25%–40% of cases; in such instances, the radiographic features suggest the diagnosis of dentigerous cyst (Figs. 15.17 and 15.18). In these cases, the cyst has presumably arisen from dental lamina rests near an unerupted tooth and has grown to envelop the unerupted tooth. Resorption of the roots of erupted teeth adjacent to OKCs is less common than that noted with dentigerous and radicular cysts.

The diagnosis of OKC is based on the histopathologic features. The radiographic findings, although often highly suggestive, are not diagnostic. The radiographic findings in an OKC may simulate those of a dentigerous cyst, a radicular cyst, a residual cyst, a lateral periodontal cyst (Fig. 15.19), or the so-called globulomaxillary cyst (which is no longer considered to be a true entity). OKCs of the anterior midline

maxillary region can mimic nasopalatine duct cysts (Fig. 15.20). For unknown reasons, this particular subset of keratocyst usually occurs in older individuals with a mean age of nearly 70 years. Rare examples of peripheral OKCs within the gingival soft tissues have been reported.

Histopathologic Features

The OKC typically shows a thin, friable wall, which is often difficult to enucleate from the bone in one piece. The cystic lumen may contain a clear liquid that is similar to a transudate of serum, or it may be filled with a cheesy material that, on microscopic examination, consists of keratinaceous debris. Microscopically, the thin fibrous wall is usually devoid of significant inflammation. The epithelial lining is composed of a uniform layer of stratified squamous epithelium, usually four to eight cells in thickness. The epithelium and connective tissue interface is usually flat, and rete ridge formation is inconspicuous. Detachment of portions of the cyst-lining epithelium from the fibrous wall is commonly

• **Fig. 15.19 Odontogenic Keratocyst (OKC).** This cyst cannot be radiographically differentiated from a lateral periodontal cyst. (Courtesy of Dr. Keith Lemmerman.)

dentlearn.ir

observed. The luminal surface shows flattened parakeratotic epithelial cells, which exhibit a wavy or corrugated appearance (Fig. 15.21). On occasion, isolated foci of orthokeratin production may be found in addition to the parakeratin. The basal epithelial layer is composed of a palisaded layer of cuboidal or columnar epithelial cells, which are often hyperchromatic. Small satellite cysts, cords, or islands of odontogenic epithelium may be seen within the fibrous wall. Rare examples of a so-called solid variant of odontogenic keratocyst have been described, which are characterized by a combination of both solid islands of odontogenic epithelium and keratin-filled cystic spaces. In rare instances, cartilage has been observed in the wall of an OKC.

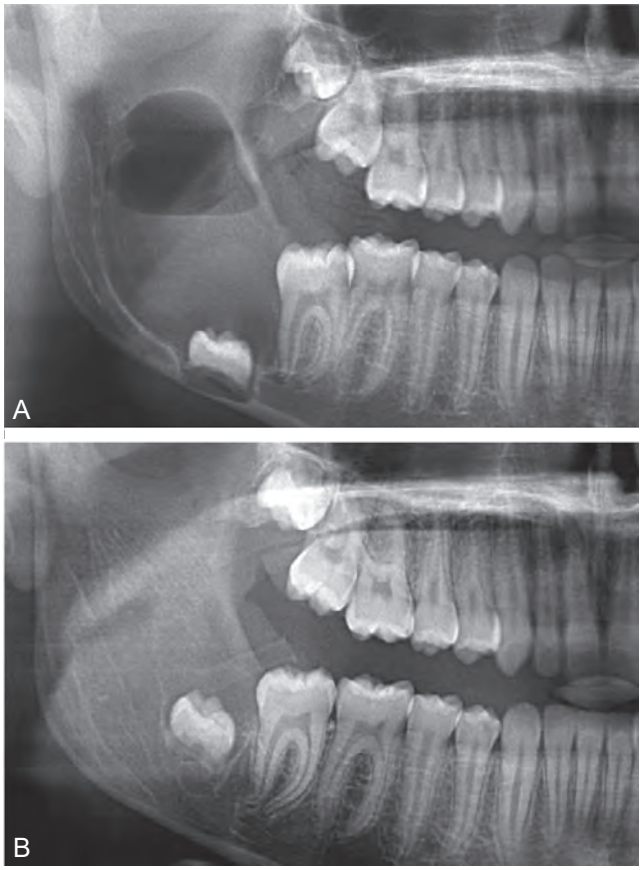
In the presence of inflammatory changes, the typical features of the OKC may be altered. The parakeratinized luminal surface may disappear, and the epithelium may proliferate to form rete ridges with the loss of the characteristic palisaded basal layer (Fig. 15.22). When these changes involve most of the cyst lining, the diagnosis of OKC cannot be confirmed unless other sections show the typical features described earlier.

• **Fig. 15.21 Odontogenic Keratocyst (OKC).** The epithelial lining is 6–8 cells thick, with a hyperchromatic and palisaded basal cell layer. Note the corrugated parakeratotic surface.

• **Fig. 15.22 Odontogenic Keratocyst (OKC).** The characteristic microscopic features have been lost in the central area of this portion of the cystic lining because of the heavy chronic inflammatory cell infiltrate.

In the past, some investigators recognized a purely orthokeratotic variant of the OKC. However, these cysts do not demonstrate a hyperchromatic and palisaded basal cell layer, which is so characteristic of true OKCs. In addition, the clinical behavior of these orthokeratinized cysts differs markedly from that of the typical parakeratinized cysts described in this section. Therefore, these orthokeratinizing cysts should be classified as a separate entity (see following section).

Treatment and Prognosis



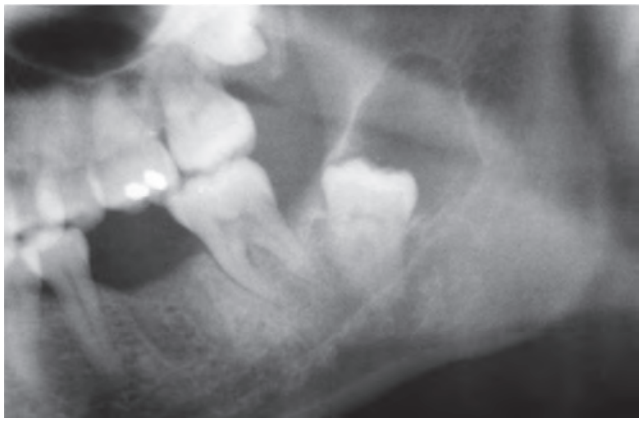
Although the presence of an OKC may be suspected on clinical or radiographic grounds, histopathologic confirmation is required for the diagnosis. Consequently, most OKCs are treated similarly to other odontogenic cysts—i.e., by enucleation and curettage. Complete removal of the cyst in one piece is often difficult because of the thin, friable nature of the cyst wall. In contrast to other odontogenic cysts, OKCs often tend to recur after treatment. Whether this is due to fragments of the original cyst that were not removed at the time of the operation or a "new" cyst that has developed from dental lamina rests in the general area of the original cyst cannot be determined with certainty.

The reported frequency of recurrence in various studies ranges from 5% to 62%. This wide variation may be related to the total number of cases studied, the length of follow-up periods, and the inclusion or exclusion of orthokeratinized cysts in the study group. Several reports that include large numbers of cases indicate a recurrence rate of approximately 21%–30%. Recurrence is encountered more often in mandibular OKCs, particularly those in the posterior body and ramus. Multiple recurrences are not unusual. Although many OKCs recur within 5 years of the original surgery, a significant number of recurrences may not be manifested until 10 or more years after the original surgical procedure. Long-term clinical and radiographic follow-up, therefore, is necessary.

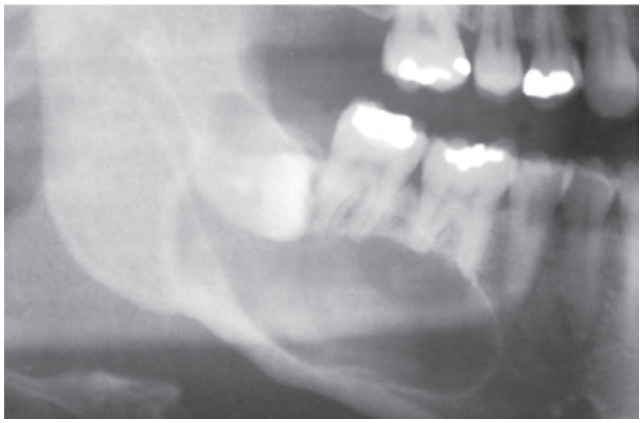
Many surgeons recommend peripheral ostectomy of the bony cavity with a bone bur to reduce the frequency of recurrence. Others advocate chemical cauterization of the bony cavity with Carnoy's solution after cyst removal (although use of Carnoy's solution may not be permitted by many hospitals). Intraluminal injection of Carnoy's solution also has been used to free the cyst from the bony wall, thereby allowing easier removal with a lower recurrence rate. After cystotomy and incisional biopsy, some surgeons have treated large OKCs by insertion of a polyethylene drainage tube to allow decompression and subsequent reduction in size of the cystic cavity (Fig. 15.23). Such decompression treatment results in thickening of the cyst lining, allowing easier removal with an apparently lower recurrence rate.

Other than the tendency for recurrences, the overall prognosis for most OKCs is good. Occasionally, a locally aggressive OKC cannot be controlled without local resection and bone grafting. In extremely rare instances, keratocysts have been seen to extend up into the skull base region. A few examples of carcinoma arising in an OKC have been

dentlearn.ir



• **Fig. 15.23 Decompression of an Odontogenic Keratocyst (OKC). A,** Large unilocular radiolucency associated with the right mandibular third molar. **B,** Six months after insertion of a polyethylene drainage tube to allow decompression, the cyst has shrunk and the third molar has migrated upward. (Courtesy of Dr. Brad Gregory.)



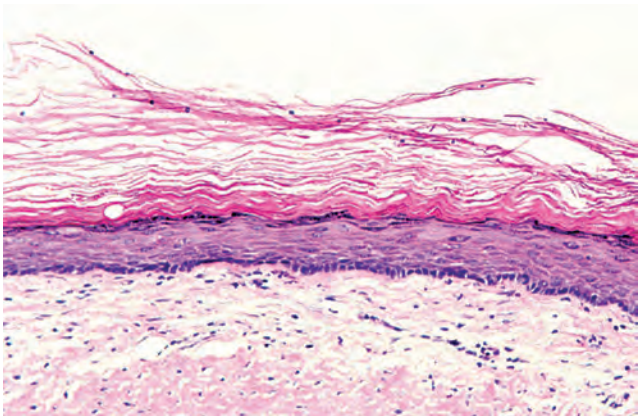
reported, but the propensity for an OKC to undergo malignant alteration is no greater and is possibly less than that for other types of odontogenic cysts. Patients with OKCs should be evaluated for manifestations of the nevoid basal cell carcinoma syndrome (see page 694), particularly if the patient is in the first or second decade of life or if multiple keratocysts are identified.

◆ ORTHOKERATINIZED ODONTOGENIC CYST

The designation **orthokeratinized odontogenic cyst** does not denote a specific clinical type of odontogenic cyst but refers only to an odontogenic cyst that microscopically has an orthokeratinized epithelial lining. Although such lesions were originally called the *orthokeratinized variant of odontogenic keratocyst,* it is generally accepted that they are clinicopathologically different from the more common parakeratinized odontogenic keratocyst (OKC) and should be placed into a different category. Orthokeratinized odontogenic cysts represent 7%–17% of all keratinizing jaw cysts.

• **Fig. 15.24 Orthokeratinized Odontogenic Cyst.** Small unilocular radiolucency associated with the impacted mandibular left third molar. (Courtesy of Dr. Tom McDonald.)

• **Fig. 15.25 Orthokeratinized Odontogenic Cyst.** A large cyst involving a horizontally impacted lower third molar. (Courtesy of Dr. Carroll Gallagher.)



Clinical and Radiographic Features

Orthokeratinized odontogenic cysts occur predominantly in young adults and show a 2.6:1 male-to-female ratio. The lesion occurs more frequently in the mandible than the maxilla (3:1 ratio), with a tendency to involve the posterior areas of the jaws. They have no clinical or radiographic features that differentiate them from other inflammatory or developmental odontogenic cysts. The lesion usually appears as a unilocular radiolucency, but occasional examples have been multilocular. About two-thirds of orthokeratinized odontogenic cysts are encountered in a lesion that appears clinically and radiographically to represent a dentigerous cyst; they most often involve an unerupted mandibular third molar tooth (Figs. 15.24 and 15.25). The size can vary from less than 1 cm to large lesions greater than 7 cm in diameter. Occasional examples of multiple orthokeratinized odontogenic cysts have been described.

Histopathologic Features

The cyst lining is composed of stratified squamous epithelium, which shows an orthokeratotic surface of varying thickness. Keratohyaline granules may be prominent in the superficial

dentlearn.ir

• **Fig. 15.26 Orthokeratinized Odontogenic Cyst.** Microscopic features showing a thin epithelial lining. The basal epithelial layer does not demonstrate palisading. Keratohyaline granules are present, and a thick layer of orthokeratin is seen on the luminal surface.

epithelial layer subjacent to the orthokeratin. In rare instances, focal sebaceous differentiation has been reported. The epithelial lining may be relatively thin, and a prominent palisaded basal layer, characteristic of the OKC, is not present (Fig. 15.26).

Treatment and Prognosis

Enucleation with curettage is the usual treatment for orthokeratinized odontogenic cysts. Recurrence has rarely been noted, and the reported frequency is around 2%, which is in marked contrast with the 30% or higher recurrence rate associated with OKCs. It has been suggested that cysts with an orthokeratinized surface may be at slightly greater risk for malignant transformation, but evidence for this is scant. Orthokeratinized odontogenic cysts typically are not associated with nevoid basal cell carcinoma syndrome, even in rare situations when multiple cysts are identified.

◆ NEVOID BASAL CELL CARCINOMA SYNDROME (GORLIN SYNDROME)

Nevoid basal cell carcinoma syndrome (Gorlin syndrome; NBCCS) is an autosomal dominant inherited condition that exhibits high penetrance and variable expressivity. The syndrome usually is caused by mutations in **patched** *(PTCH),* a tumor suppressor gene mapped to chromosome 9q22.3-q31, which plays an important role in the sonic hedgehog (SHH) signaling pathway. A much smaller percentage of cases have been related to germline mutations of *SUFU,* another member of the SHH pathway. Approximately 20%–30% of affected patients represent new mutations. One of the most common clinical features is development of OKCs, which can lead to early diagnosis. The prevalence of Gorlin syndrome is estimated to be anywhere from 1 in 19,000 to 1 in 164,000, depending on the population studied.

Clinical and Radiographic Features

There is great variability in the expressivity of NBCCS, and no single component is present in all patients. The most common and significant features are summarized in Box 15.2. The patient often has a characteristic facies, with frontal and temporoparietal bossing, which results in an increased cranial circumference (more than 60 cm in adults). The eyes may appear widely separated, and many patients have true mild ocular hypertelorism. Mild mandibular prognathism is also commonly present (Fig. 15.27).

Basal cell carcinomas of the skin are a major component of the syndrome. These tumors usually begin to appear at puberty or in the second and third decades of life, although they can develop in young children. The lesions may vary from flesh-colored papules to ulcerating plaques. They often appear on skin that is not exposed to sunlight, but they are most commonly located in the midface area (Fig. 15.28). Tumors on the neck and eyelids often are pedunculated and can be mistaken for skin tags (acrochordons). The number of skin tumors may vary from only a few to many hundreds. Blacks with the syndrome tend to develop basal cell carcinomas less frequently than whites (40% versus 90%), and they have fewer of these lesions, probably because of protective skin pigmentation. Less than 15% of dark-skinned patients develop more than two basal cell carcinomas.

Palmar and plantar pits are present in about 65%–85% of patients (Fig. 15.29). These punctate lesions represent a localized impairment of the maturation of basal epithelial cells, resulting in a focally depressed area as the result of a

• BOX 15.2 Major Clinical Features of the Nevoid Basal Cell Carcinoma Syndrome

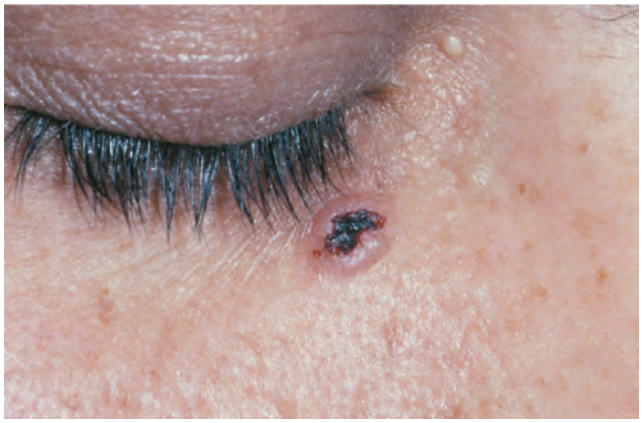
50% or Greater Frequency

- Multiple basal cell carcinomas
- Odontogenic keratocysts (OKCs)
- Epidermal cysts of the skin
- Palmar/plantar pits
- Calcified falx cerebri
- Enlarged head circumference
- Rib anomalies (splayed, fused, partially missing, and/or bifid)
- Mild ocular hypertelorism
- Spina bifida occulta of cervical or thoracic vertebrae

15%–49% Frequency

- Calcified ovarian fibromas
- Short fourth metacarpals
- Kyphoscoliosis or other vertebral anomalies
- Pectus excavatum or carinatum
- Strabismus (exotropia)

Less Than 15% Frequency (But Not Random)



- Medulloblastoma
- Meningioma
- Lymphomesenteric cysts
- Cardiac fibroma
- Fetal rhabdomyoma
- Marfanoid build
- Cleft lip and/or palate
- Hypogonadism in males
- Intellectual disability

• **Fig. 15.28 Nevoid Basal Cell Carcinoma Syndrome.** An ulcerating basal cell carcinoma is present on the upper face.

markedly thinned keratin layer. Basal cell carcinomas rarely may develop at the base of the pits.

Ovarian cysts and fibromas have been reported in 25%–50% of women with this syndrome. A number of other tumors also have been reported to occur with lesser frequency. These include desmoplastic medulloblastoma within the first 4 years of life, meningioma, cardiac fibroma, and fetal rhabdomyoma. The risk for medulloblastoma is approximately 2%–5% for patients with *PTCH* mutations, but this risk can be as high as 33% for those with *SUFU* mutations.

• **Fig. 15.29 Nevoid Basal Cell Carcinoma Syndrome.** Plantar pits.

• **Fig. 15.30 Nevoid Basal Cell Carcinoma Syndrome.** Chest film showing presence of bifid ribs *(arrows).*

Skeletal anomalies are present in 60%–75% of patients with this syndrome. The most common anomaly is a bifid rib or splayed ribs (Fig. 15.30). This anomaly may involve several ribs and may be bilateral. Kyphoscoliosis has been observed in about 30%–40% of patients, and a number of other anomalies, such as spina bifida occulta and shortened metacarpals, seem to occur with unusual frequency. A distinctive lamellar calcification of the falx cerebri, noted on an anteroposterior skull radiograph or computed tomography (CT) image, is a common finding and is present in most affected patients (Fig. 15.31).

Jaw cysts are one of the most constant features of the syndrome and are present in 90% of the patients. The cysts are OKCs, although there are some differences between the cysts in patients with NBCCS and in those with isolated OKCs. The cysts are frequently multiple; some patients have had as many as ten separate cysts. The patient's age when the first

dentlearn.ir

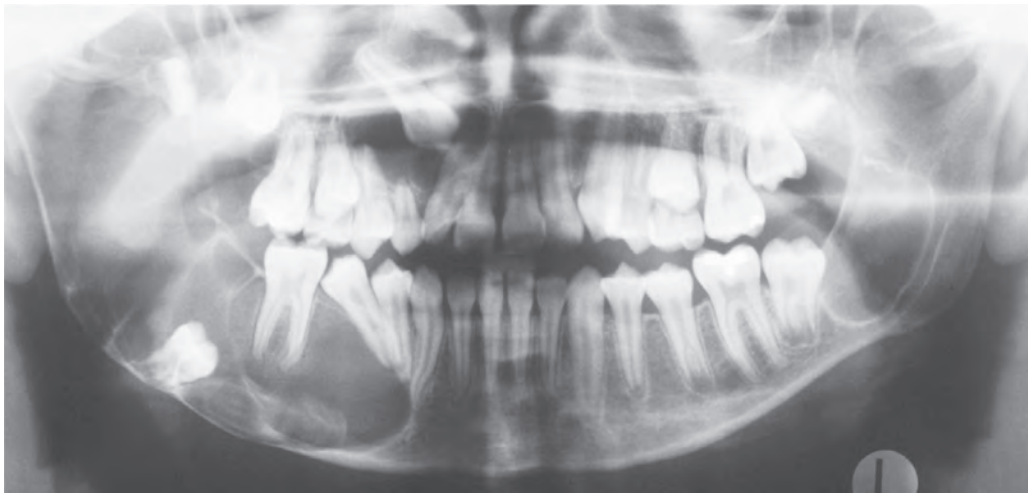
OKC is removed is significantly younger in those affected by this syndrome than in those with isolated OKCs. For most patients with this syndrome, their first OKC is removed before age 19. About one-third of patients with NBCCS have only a solitary cyst at the time of the initial presentation, but in most cases additional cysts will develop over periods ranging from 1 to 20 years. Interestingly, OKCs may not occur in individuals with *SUFU*-related NBCCS.

Radiographically, the cysts in patients with NBCCS do not differ significantly from isolated OKCs. The cysts in patients with this syndrome are often associated with the crowns of unerupted teeth; on radiographs they may mimic dentigerous cysts (Fig. 15.32).

• **Fig. 15.31 Nevoid Basal Cell Carcinoma Syndrome.** Anteroposterior skull film showing calcification of the falx cerebri. (Courtesy of Dr. Ramesh Narang.)

Diagnostic criteria for NBCCS are provided in Box 15.3.

Histopathologic Features



The cysts in NBCCS histopathologically are invariably OKCs. The keratocysts in patients with this syndrome tend to have more satellite cysts, solid islands of epithelial proliferation, and odontogenic epithelial rests within the fibrous capsule than do isolated keratocysts (Fig. 15.33). Foci of calcification also appear to be more common. These features, however, are not diagnostic for NBCCS because they may be seen in isolated keratocysts.

The basal cell tumors of the skin cannot be distinguished from ordinary basal cell carcinomas. They exhibit a wide spectrum of histopathologic findings, from superficial basal cell lesions to aggressive, noduloulcerative basal cell carcinomas.

Treatment and Prognosis

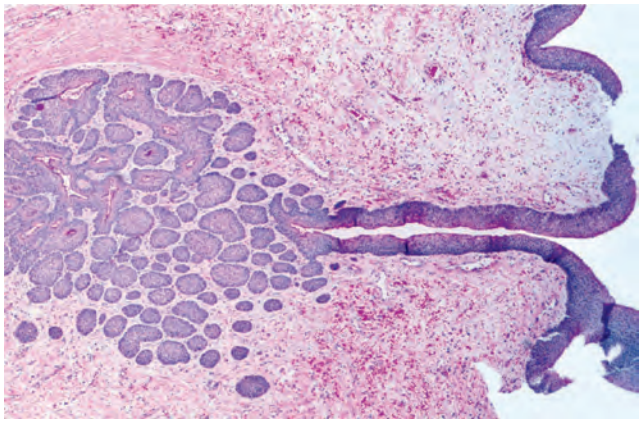
Most of the anomalies in NBCCS are minor and usually not life threatening. The prognosis generally depends on the behavior of the skin tumors. In a few cases, aggressive basal cell carcinomas have caused the death of the patient as a result of tumor invasion of the brain or other vital structures (Figs. 15.34 and 15.35). Because the development of the basal cell carcinomas seems to be triggered by ultraviolet (UV) light exposure, patients should take appropriate precautions to avoid sunlight. For the same reason, radiation therapy should be avoided if at all possible. The jaw cysts are treated in the same manner as isolated OKCs, but in many patients additional cysts will continue to develop. Varying degrees of jaw deformity may result from the operations for multiple cysts. Infection of the cysts in patients with this syndrome is also relatively common.

The recent development of SHH pathway inhibitors, such as vismodegib, has shown promise in the management of basal cell carcinomas in patients with NBCCS. In

• **Fig. 15.32 Nevoid Basal Cell Carcinoma Syndrome.** Large cysts are present in the right and left mandibular molar regions, together with a smaller cyst involving the right maxillary canine in the same patient shown in Fig. 15.27. (Courtesy of Dr. Richard DeChamplain.)

dentlearn.ir

• BOX 15.3 Diagnostic Criteria for the Nevoid Basal Cell Carcinoma Syndrome

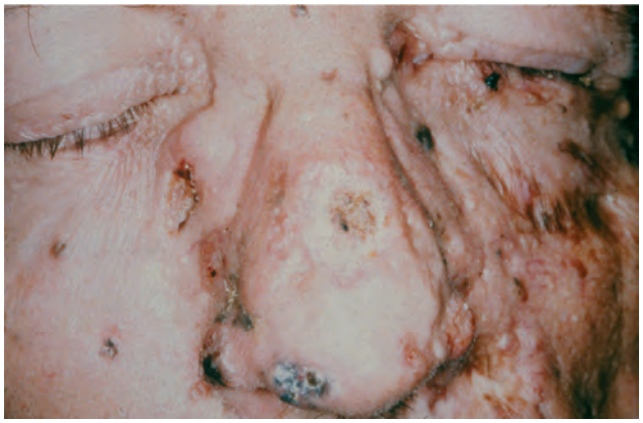


A diagnosis can be made if the patient has:
1. Two major criteria
2. One major and two minor criteria
3. One major criterion and genetic confirmation

Major Criteria

1. Lamellar (sheet-like) calcification of the falx cerebri
2. Odontogenic keratocyst (OKC)
3. Two or more palmar or plantar pits
4. Five or more basal cell carcinomas *or* one before the age of 30 years
5. First degree relative with the nevoid basal cell carcinoma syndrome

Minor Criteria



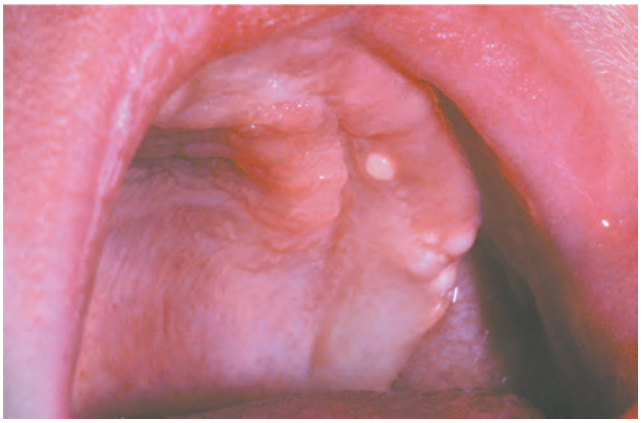
1. Childhood medulloblastoma
2. Lymphomesenteric or pleural cysts
3. Macrocephaly
4. Cleft lip or palate
5. Rib or vertebral anomalies: bifid, splayed, or extra ribs; bifid vertebrae
6. Preaxial or postaxial polydactyly
7. Ovarian or cardiac fibromas
8. Ocular anomalies (e.g., cataracts, developmental defects, and pigmentary changes of the retinal epithelium)

• **Fig. 15.33 Nevoid Basal Cell Carcinoma Syndrome.** Odontogenic keratocyst (OKC) showing numerous odontogenic epithelial rests in the cyst wall.

addition, vismodegib has been shown to be effective in inducing shrinkage of odontogenic keratocysts in some syndrome patients. Unfortunately, this medication often is associated with intolerable side effects that can cause patients to discontinue therapy. However, continuing research into this class of SHH pathway inhibitors may result in better medications for the treatment of these lesions.

Some investigators have suggested that affected children should have magnetic resonance imaging (MRI) studies every 6 months until 7 years of age to monitor for the development of medulloblastoma. Fortunately, this malignancy appears to have a better prognosis in syndrome patients than in patients without the syndrome. Genetic counseling is appropriate for affected individuals.

• **Fig. 15.34 Nevoid Basal Cell Carcinoma Syndrome.** This 52-year-old man had more than 100 basal cell carcinomas removed from his face over a 30-year period. Several basal cell carcinomas are present in this photograph. The lesion at the inner canthus of the left eye was deeply invasive and was eventually fatal as a result of brain invasion.



• **Fig. 15.35 Nevoid Basal Cell Carcinoma Syndrome.** Facial deformity secondary to multiple surgical procedures to remove basal cell carcinomas.

◆ GINGIVAL (ALVEOLAR) CYST OF THE NEWBORN

Gingival cysts of the newborn are small, superficial, keratin-filled cysts that are found on the alveolar mucosa of infants. These cysts arise from remnants of the dental

dentlearn.ir

• **Fig. 15.36 Gingival Cyst of the Newborn.** Multiple whitish papules on the alveolar ridge of a newborn infant.

• **Fig. 15.37 Gingival Cyst of the Adult.** Tense, fluid-filled swelling on the facial gingiva.

lamina. They are common lesions, having been reported in 25%–53% of all newborns. However, because they disappear spontaneously by rupture into the oral cavity, the lesions seldom are noticed or sampled for biopsy. Similar inclusion cysts (e.g., **Epstein's pearls** and **Bohn's nodules**) are also found in the midline of the palate or laterally on the hard and soft palate (see page 25).

Clinical Features

Gingival cysts of the newborn appear as small, usually multiple whitish papules on the mucosa overlying the alveolar processes of neonates (Fig. 15.36). The individual cysts are usually no more than 2–3 mm in diameter. The maxillary alveolus is more commonly involved than the mandibular.

Histopathologic Features

Examination of an intact gingival cyst of the newborn shows a thin, flattened epithelial lining with a parakeratotic luminal surface. The lumen contains keratinaceous debris.

Treatment and Prognosis

No treatment is indicated for gingival cysts of the newborn because the lesions spontaneously involute as a result of the rupture of the cysts and resultant contact with the oral mucosal surface. The lesions are rarely seen after 3 months of age.

◆ GINGIVAL CYST OF THE ADULT

The **gingival cyst of the adult** is an uncommon lesion. It is considered to represent the soft tissue counterpart of the **lateral periodontal cyst** (see next topic), being derived from rests of the dental lamina (rests of Serres). The diagnosis of gingival cyst of the adult should be restricted to lesions with the same histopathologic features as those of the lateral periodontal cyst. On rare occasions, a cyst may develop in the gingiva at the site of a gingival graft; however, such lesions probably represent *epithelial inclusion cysts* that are a result of the surgical procedure.

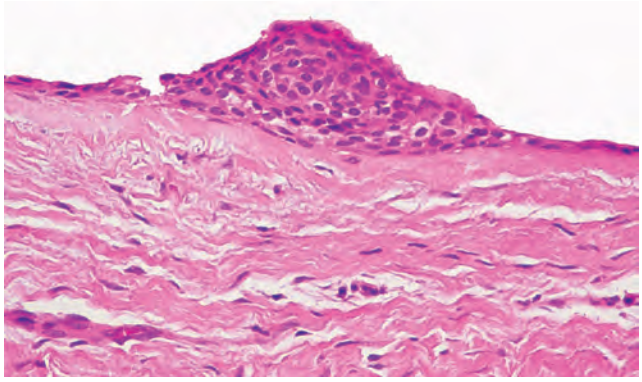
Clinical Features

Like the lateral periodontal cyst, the gingival cyst of the adult shows a striking predilection to occur in the mandibular canine and premolar area (60%–75% of cases). Gingival cysts of the adult are most commonly found in patients in the fifth through the seventh decades of life. They are almost invariably located on the facial gingiva or alveolar mucosa. Maxillary gingival cysts are usually found in the incisor, canine, and premolar areas.

Clinically, the cysts appear as painless, domelike swellings, usually less than 0.5 cm in diameter, although rarely they may be somewhat larger (Fig. 15.37). They are often bluish or blue-gray. In some instances, the cyst may cause a superficial "cupping out" of the alveolar bone, which is usually not detected on a radiograph but is apparent when the cyst is excised. If more bone is missing, one could argue that the lesion may be a lateral periodontal cyst that has eroded the cortical bone rather than a gingival cyst that originated in the mucosa.

Histopathologic Features

The histopathologic features of the gingival cyst of the adult are similar to those of the lateral periodontal cyst, consisting of a thin, flattened epithelial lining with or without focal plaques that contain clear cells (Figs. 15.38 and 15.39). Small nests of these glycogen-rich clear cells, which represent rests of the dental lamina, also may be seen in the surrounding connective tissue. Sometimes the cystic lining is so thin that it is easily mistaken for the endothelial lining of a dilated blood vessel.



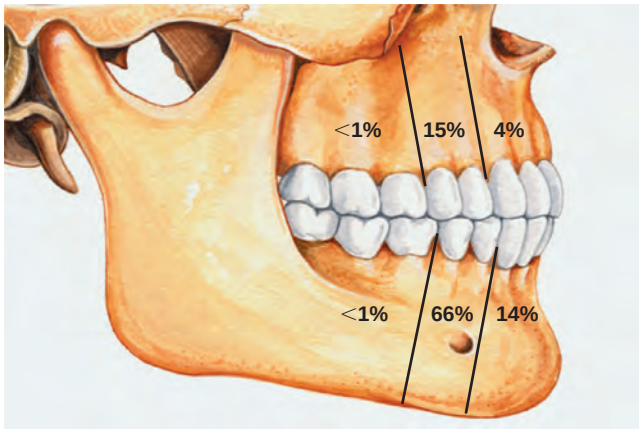
Treatment and Prognosis

The gingival cyst of the adult responds well to simple surgical excision. The prognosis is excellent.

dentlearn.ir

• **Fig. 15.38 Gingival Cyst of the Adult.** Low-power photomicrograph showing a thin-walled cyst in the gingival soft tissue.

• **Fig. 15.39 Gingival Cyst of the Adult.** High-power photomicrograph showing a plaquelike thickening of the epithelial lining.



◆ LATERAL PERIODONTAL CYST (BOTRYOID ODONTOGENIC CYST)

The **lateral periodontal cyst** is an uncommon type of developmental odontogenic cyst that typically occurs along the lateral root surface of a tooth. It is believed to arise from rests of the dental lamina, and it represents the intrabony counterpart of the gingival cyst of the adult. The lateral periodontal cyst accounts for less than 2% of all epithelium-lined jaw cysts.

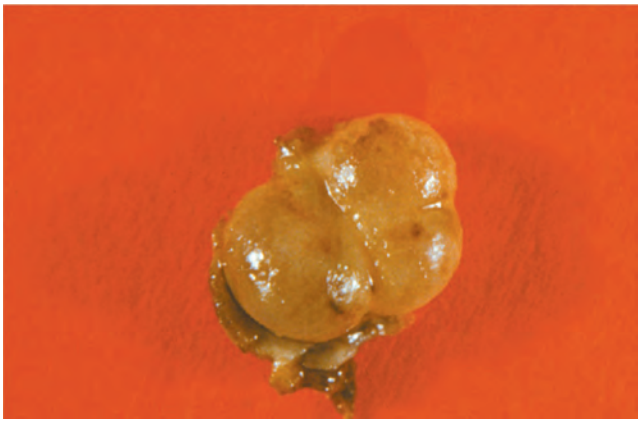
In the past, the term *lateral periodontal cyst* was used to describe any cyst that developed along the lateral root surface, including lateral radicular cysts (see page 126) and OKCs (see page 689). However, the lateral periodontal cyst has distinctive clinical and microscopic features that distinguish it from other lesions that sometimes develop in the same location.

Clinical and Radiographic Features

The lateral periodontal cyst is most often an asymptomatic lesion that is detected only during a radiographic examination. It most frequently occurs in patients in the fifth through the seventh decades of life; rarely does it occur in someone younger than age 30. Around 75%–80% of cases occur in the mandibular premolar-canine-lateral incisor area. Maxillary examples also usually involve this same tooth region (Fig. 15.40).

• **Fig. 15.40 Lateral Periodontal Cyst.** Relative distribution of lateral periodontal cysts in the jaws.

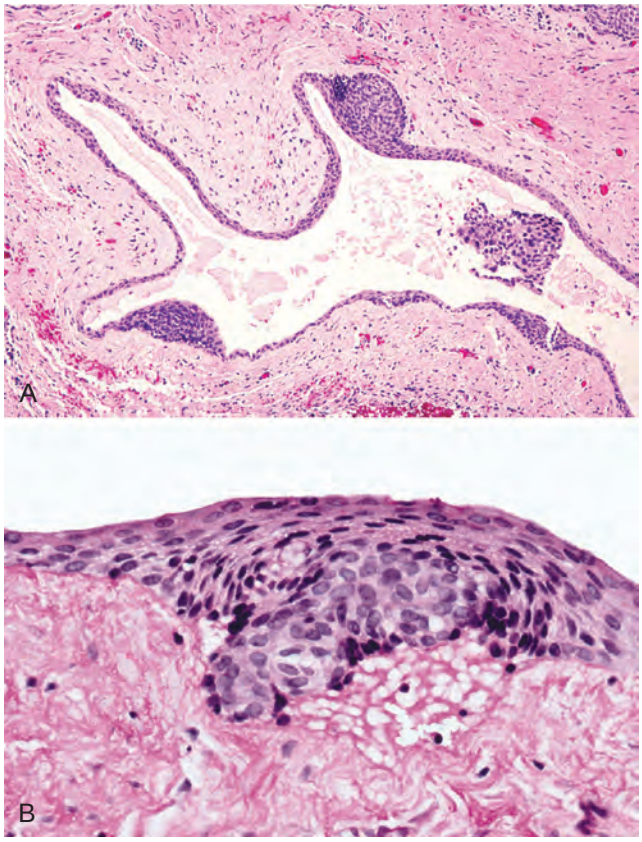
• **Fig. 15.41 Lateral Periodontal Cyst.** Radiolucent lesion between the roots of a vital mandibular canine and first premolar.



Radiographically, the cyst usually appears as a well-circumscribed radiolucent area located laterally to the root or roots of vital teeth. Most such cysts are less than 1.0 cm in greatest diameter (Figs. 15.41 and 15.42). In rare instances, multifocal lateral periodontal cysts have been described. In addition, some examples can develop in edentulous sites.

Occasionally, the lesion may have a polycystic appearance; such examples have been termed **botryoid odontogenic cysts.** Grossly and microscopically, they show a grapelike cluster of small individual cysts (Fig. 15.43). These

dentlearn.ir



• **Fig. 15.42 Lateral Periodontal Cyst.** A larger lesion causing root divergence.

• **Fig. 15.43 Lateral Periodontal Cyst.** Gross specimen of a botryoid variant. Microscopically, this grapelike cluster revealed three separate cavities.

lesions are generally considered to represent a variant of the lateral periodontal cyst, possibly the result of cystic degeneration and subsequent fusion of adjacent foci of dental lamina rests. The botryoid variant often shows a multilocular radiographic appearance, but it also may appear unilocular.

The radiographic features of the lateral periodontal cyst are not diagnostic; an OKC that develops between the roots of adjacent teeth may show identical radiographic findings. An inflammatory radicular cyst that occurs laterally to a root in relation to an accessory foramen or a cyst that arises from periodontal inflammation also may simulate a lateral periodontal cyst radiographically (see page 126). In one study of 46 cases of cystic lesions in the lateral periodontal region, only 13 met the histopathologic criteria for the lateral

• **Fig. 15.44 Lateral Periodontal Cyst. A,** This photomicrograph shows a thin epithelial lining with focal nodular thickenings. **B,** These thickenings often show a swirling appearance of the cells.

periodontal cyst; eight were OKCs, 20 were inflammatory cysts, and five were of undetermined origin.

Histopathologic Features

The lateral periodontal cyst has a thin, generally noninflamed, fibrous wall, with an epithelial lining that is only one to three cells thick in most areas. This epithelium usually consists of flattened squamous cells, but sometimes the cells are cuboidal in shape. Foci of glycogen-rich clear cells may be interspersed among the lining epithelial cells. Some cysts show focal nodular thickenings of the lining epithelium, which are composed chiefly of clear cells (Fig. 15.44). Clear cell epithelial rests sometimes are seen within the fibrous wall. Rarely, lateral periodontal cysts exhibit focal areas that histopathologically are suggestive of the glandular odontogenic cyst (see page 703).

Treatment and Prognosis

Conservative enucleation of the lateral periodontal cyst is the treatment of choice. Usually, this can be accomplished without damage to the adjacent teeth. Recurrence is unusual, although it has been reported with the botryoid variant, presumably because of its polycystic nature. An exceedingly rare

dentlearn.ir

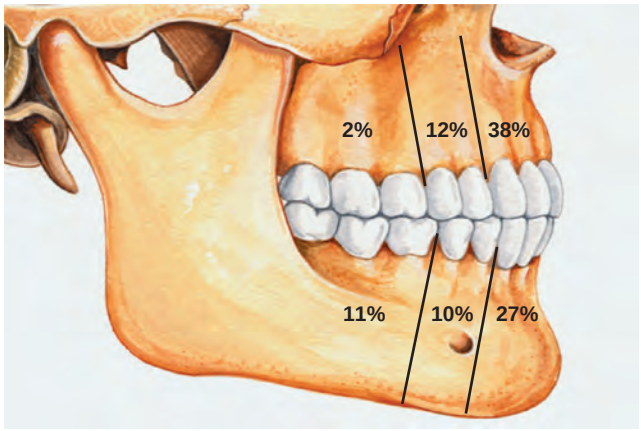
case of squamous cell carcinoma, which apparently originated in a lateral periodontal cyst, also has been reported.

◆ CALCIFYING ODONTOGENIC CYST (CALCIFYING CYSTIC ODONTOGENIC TUMOR; GORLIN CYST; DENTINOGENIC GHOST CELL TUMOR; GHOST CELL ODONTOGENIC CARCINOMA)

First described in 1962 by Gorlin and associates, the **calcifying odontogenic cyst** is part of a spectrum of lesions characterized by odontogenic epithelium containing "ghost cells," which then may undergo calcification. Most examples grow in a cystic fashion, although some lesions occur as solid tumorlike growths. Therefore, in the 2022 WHO classification system, ghost cell lesions have been categorized under three separate headings (based on the cystic, solid, or malignant nature of the lesion):

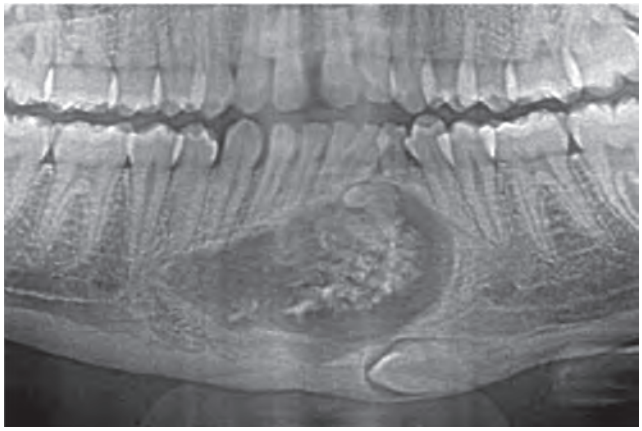
1. Calcifying odontogenic cyst
2. Dentinogenic ghost cell tumor
3. Ghost cell odontogenic carcinoma

At this point, it is uncertain whether these categories are variations of the same pathologic process or represent distinct, separate lesions. Molecular studies have shown that calcifying odontogenic cysts harbor mutations of *CTNNB1,* which encodes for β-catenin. Similar mutations also have been described in the dentinogenic ghost cell tumor and ghost cell odontogenic carcinoma.



The overwhelming majority of intraosseous ghost cell odontogenic lesions grow as cystic lesions, and less than 5% of cases can be classified as solid dentinogenic ghost cell tumors or ghost cell odontogenic carcinomas. Approximately one-third of peripheral lesions will be solid in nature, although these peripheral examples are not as aggressive as their intraosseous counterparts.

The calcifying odontogenic cyst may be associated with other recognized odontogenic tumors, most commonly **odontomas.** However, **adenomatoid odontogenic tumors** and **ameloblastomas** also have been associated with calcifying odontogenic cysts.

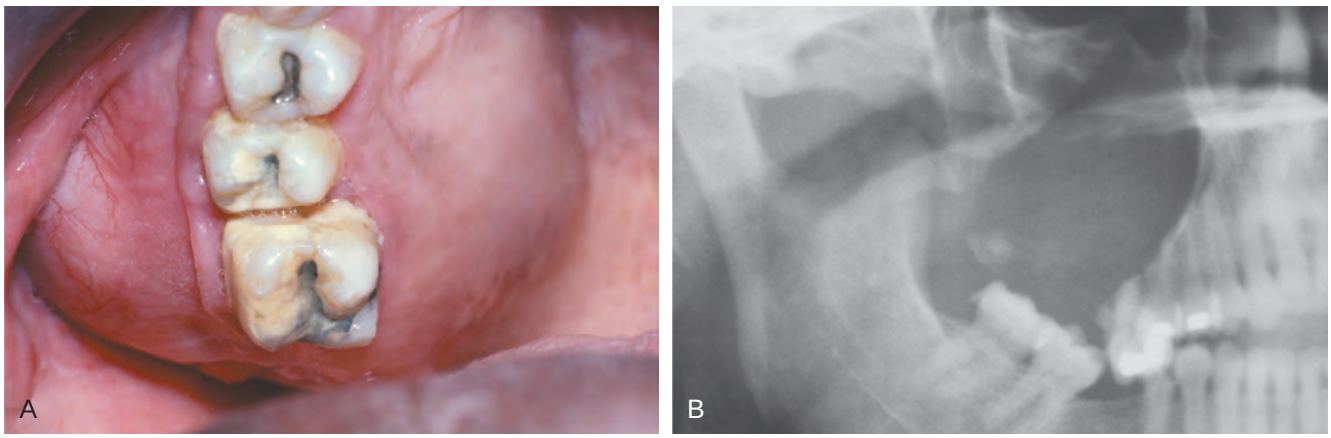


Clinical and Radiographic Features

Intraosseous calcifying odontogenic cysts occur with about equal frequency in the maxilla and mandible. About 65% of cases are found in the incisor and canine areas (Fig. 15.45). The mean age is 30 years, and most cases are diagnosed in the second to fourth decades of life. Calcifying odontogenic cysts that are associated with odontomas tend to occur in younger patients, with a mean age of 17 years.

The central calcifying odontogenic cyst is usually a unilocular, well-defined radiolucency, although the lesion occasionally may appear multilocular. Radiopaque structures within the lesion, either irregular calcifications or toothlike densities, are present in about one-third to one-half of cases (Fig. 15.46). In approximately one-third of cases, the radiolucent lesion is associated with an unerupted tooth, most often a canine. Most calcifying odontogenic cysts are between 2.0 and 4.0 cm in greatest diameter, but lesions as large as 12.0 cm have been noted. Root resorption or divergence of adjacent teeth is seen with some frequency (Fig. 15.47).

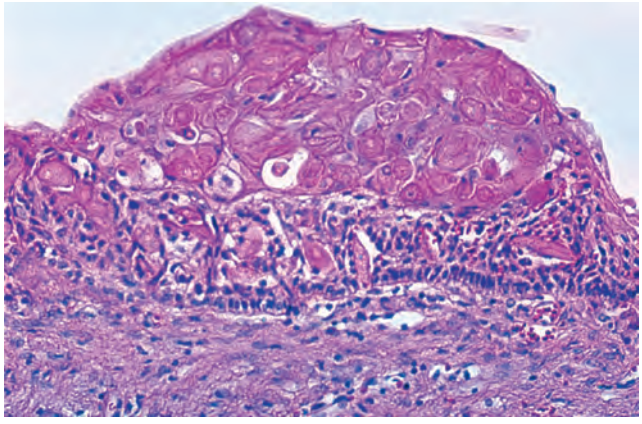
• **Fig. 15.45 Calcifying Odontogenic Cyst.** Relative distribution of calcifying odontogenic cysts in the jaws.



• **Fig. 15.46 Calcifying Odontogenic Cyst.** Well-circumscribed mixed radiolucent/radiopaque lesion in the anterior mandible. This cyst was associated with an odontoma. (Courtesy of Dr. Michael Border).

Intraosseous dentinogenic ghost cell tumors are most common in the third through the fifth decades of life, occurring most often in the posterior areas of both jaws. These solid tumors are capable of acting more aggressively than their cystic counterparts, sometimes resulting in root resorption, perforation of the cortical plate, or sinus destruction.

Extraosseous odontogenic ghost cell lesions comprise from 5% to 17% of all cases, appearing as localized sessile or pedunculated gingival masses with no distinctive clinical features (Fig. 15.48). They can resemble common gingival fibromas, gingival cysts, or peripheral giant cell granulomas. Peripheral examples tend to occur later in life, with peak prevalence during the sixth to eighth decades.



dentlearn.ir

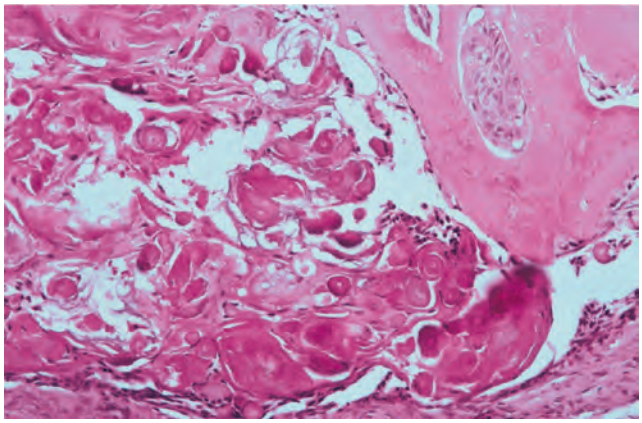
• **Fig. 15.48 Peripheral Calcifying Odontogenic Cyst.** Nodular mass of the maxillary facial gingiva. (Courtesy of Dr. Kenneth Rasenberger.)

• **Fig. 15.49 Calcifying Odontogenic Cyst.** The cyst lining shows ameloblastoma-like epithelial cells, with a columnar basal layer. Large eosinophilic ghost cells are present within the epithelial lining.

Ghost cell odontogenic carcinomas are extremely rare, aggressive neoplasms that may arise *de novo* or from malignant degeneration of calcifying odontogenic cyst or dentinogenic ghost cell tumor. Such tumors have been reported more often in the maxilla than in the mandible.

Histopathologic Features



The calcifying odontogenic cyst most commonly occurs as a well-defined cystic lesion with a fibrous capsule and a lining of odontogenic epithelium of four to ten cells in thickness. The basal cells of the epithelial lining may be cuboidal or columnar and are similar to ameloblasts. The overlying layer of loosely arranged epithelium may resemble the stellate reticulum of an ameloblastoma.

The most characteristic histopathologic feature of the calcifying odontogenic cyst is the presence of variable numbers of "ghost cells" within the epithelial component. These eosinophilic ghost cells are altered epithelial cells that are characterized by the loss of nuclei with preservation of the basic cell outline (Fig. 15.49).

The nature of the ghost cell change is controversial. Some believe that this change represents coagulative necrosis or accumulation of enamel protein; others contend it is a form of normal or aberrant keratinization of odontogenic epithelium. Masses of ghost cells may fuse to form large sheets of amorphous, acellular material. Calcification within the ghost cells is common. This first appears as fine basophilic granules that may increase in size and number to form extensive masses of calcified material. Areas of an eosinophilic matrix material that are considered by some authors to represent dysplastic dentin (dentinoid) also may be present adjacent to the epithelial component. This is believed to be the result of an inductive effect by the odontogenic epithelium on the adjacent mesenchymal tissue (Fig. 15.50).

Several variants of the cystic type of calcifying odontogenic cyst are seen. In some cases, the epithelial lining proliferates into the lumen so that the lumen is largely filled with

dentlearn.ir

• **Fig. 15.50 Calcifying Odontogenic Cyst.** Eosinophilic dentinoid material is present adjacent to a sheet of ghost cells.

masses of ghost cells and dystrophic calcifications. Multiple daughter cysts may be present within the fibrous wall, and a foreign body reaction to herniated ghost cells may be conspicuous.

In another variant, unifocal or multifocal epithelial proliferation of the cyst lining into the lumen may resemble ameloblastoma. These proliferations are intermixed with varying numbers of ghost cells. These epithelial proliferations superficially resemble, but do not meet, the strict histopathologic criteria for ameloblastoma.

About 20% of calcifying odontogenic cysts are associated with odontomas. This variant is usually a unicystic lesion that shows the features of a calcifying odontogenic cyst together with those of a small complex or compound odontoma.

Solid dentinogenic ghost cell tumors may occur intraosseously or extraosseously. The **extraosseous** forms appear to be more common. These show varying-sized islands of odontogenic epithelium in a fibrous stroma. The epithelial islands show peripheral palisaded columnar cells and central stellate reticulum, which resemble ameloblastoma. Nests of ghost cells, however, are present within the epithelium, and juxtaepithelial dentinoid is commonly present. These features differentiate this lesion from the peripheral ameloblastoma.

The rare **intraosseous** dentinogenic ghost cell tumor is a solid neoplasm that consists of ameloblastoma-like strands and islands of odontogenic epithelium in a mature fibrous connective tissue stroma. Variable numbers of ghost cells and juxtaepithelial dentinoid are present.

Ghost cell odontogenic carcinomas grow as solid tumors but also exhibit malignant features, such as cellular pleomorphism, increased mitotic activity, necrosis, and invasion of the surrounding tissues.

Treatment and Prognosis

The prognosis for a patient with a calcifying odontogenic cyst is good; only a few recurrences after simple enucleation have been reported. Peripheral examples appear to have the same prognosis as a peripheral ameloblastoma, with a minimal chance of recurrence after simple surgical excision.

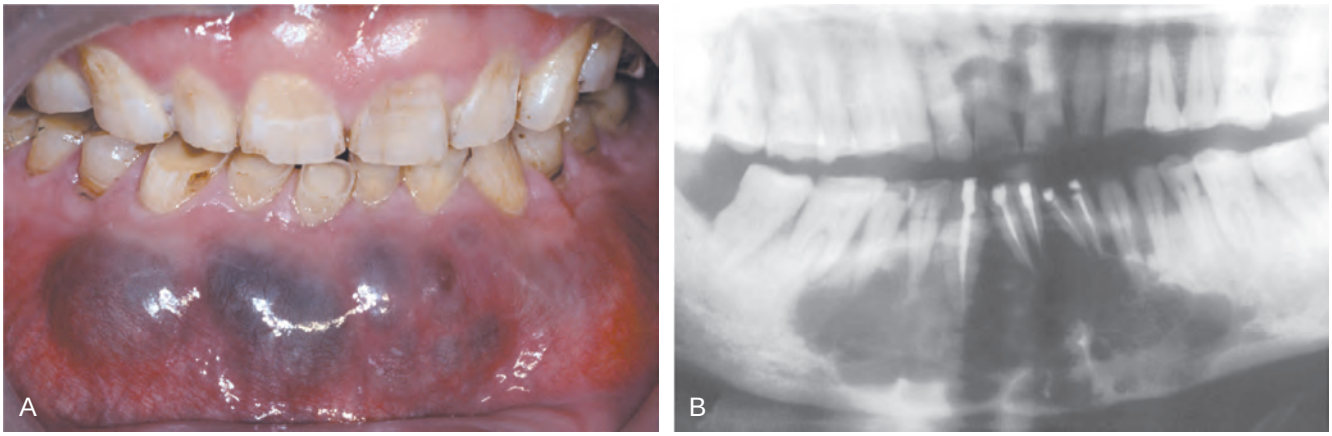
However, intraosseous dentinogenic ghost cell tumors are potentially aggressive neoplasms. One study reported a recurrence rate of 73% for lesions treated in a conservative fashion (enucleation or curettage), whereas the recurrence rate was 33% for lesions treated more aggressively (marginal or segmental resection). Although few cases of ghost cell odontogenic carcinoma have been reported, such tumors have an unpredictable behavior. Recurrences are common, and a few patients have died from either uncontrolled local disease or metastases. An overall 5-year survival rate of 73% has been calculated for reported cases.

◆ GLANDULAR ODONTOGENIC CYST (SIALO-ODONTOGENIC CYST)

The **glandular odontogenic cyst** is a rare type of developmental odontogenic cyst that can show aggressive behavior. Although it is generally accepted as being of odontogenic origin, it also shows glandular or salivary features that presumably are an indication of the pluripotentiality of odontogenic epithelium.

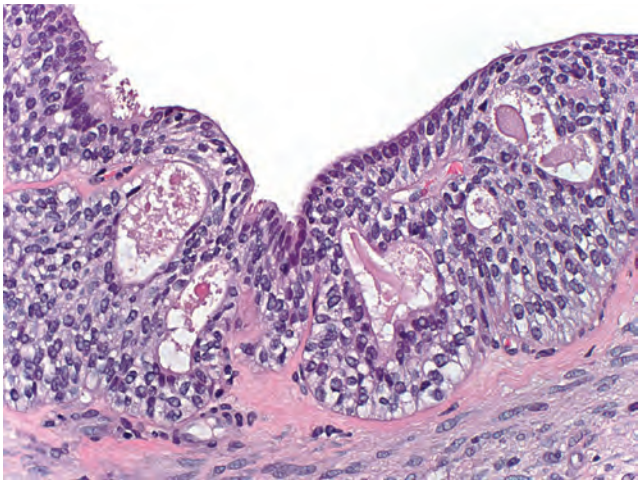
Clinical and Radiographic Features

The glandular odontogenic cyst occurs most commonly in middle-aged adults, with a mean age of 46–48 years at the time of diagnosis; rarely does it occur before the age of 20. Approximately 68%–75% of reported cases have occurred in the mandible. The cyst has a strong predilection for the anterior region of the jaws, and many mandibular lesions will cross the midline.



The size of the cyst can vary from small lesions less than 1 cm in diameter to large destructive lesions that may involve most of the jaw. Small cysts may be asymptomatic; however, large cysts often produce clinical expansion, which sometimes can be associated with pain or paresthesia (Fig. 15.51).

Radiographically, the lesion presents as either a unilocular or multilocular radiolucency. The margins of the radiolucency are usually well defined with a corticated rim.



Histopathologic Features

The glandular odontogenic cyst is lined by squamous epithelium of varying thickness. The interface between the epithelium and the fibrous connective tissue wall is generally flat. The fibrous cyst wall is usually devoid of any inflammatory cell infiltrate. The superficial epithelial cells that line the cyst cavity tend to be cuboidal to columnar, resulting in an uneven hobnail and sometimes papillary surface (Fig. 15.52). The surface layer often includes mucin-producing goblet cells, occasionally with the presence of cilia. Glandular, ductlike spaces within the epithelial lining are another characteristic finding. These spaces are lined by cuboidal cells and often contain mucicarmine-positive fluid. In focal areas,

dentlearn.ir

• **Fig. 15.51 Glandular Odontogenic Cyst. A,** Expansile lesion of the anterior mandible. **B,** The panoramic radiograph shows a large multilocular radiolucency. (Courtesy of Dr. Cheng-Chung Lin.)

• **Fig. 15.52 Glandular Odontogenic Cyst.** The cyst is lined by stratified squamous epithelium that exhibits surface columnar cells with cilia. Numerous microcysts containing mucinous material are present.

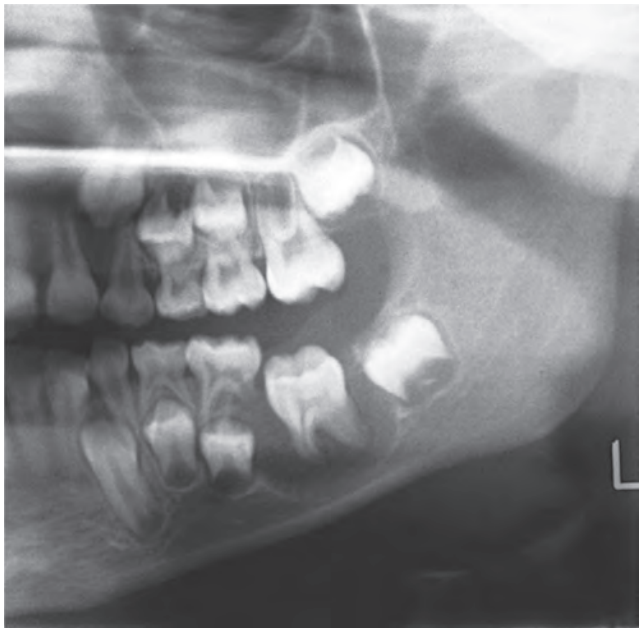
the epithelial lining cells may form spherical nodules, similar to those seen in lateral periodontal cysts.

There is some histopathologic overlap between the features of the glandular odontogenic cyst and those of some intraosseous, low-grade, predominantly cystic mucoepidermoid carcinomas (see page 496). In selected microscopic fields, the microscopic features may be identical. Examination of multiple sections, however, usually permits the differentiation of these lesions. Also, glandular odontogenic cysts will not show *MAML2* gene rearrangements, which often are found in central mucoepidermoid carcinomas.

Treatment and Prognosis

Most cases of glandular odontogenic cyst have been treated by enucleation or curettage. However, this cyst shows a propensity for recurrence, which is observed in approximately 22%–30% of all cases. Recurrence appears to be more common among the lesions that present in a multilocular fashion. Because of its potentially aggressive nature and tendency for recurrence, some authors have advocated *en bloc* resection, particularly for multilocular lesions. Marsupialization and decompression may be attempted for larger lesions to promote shrinkage prior to surgery. One example of central mucoepidermoid carcinoma apparently arising from a recurrent glandular odontogenic cyst has been reported.

◆ BUCCAL BIFURCATION CYST (INFLAMMATORY COLLATERAL CYST)



The **buccal bifurcation cyst** is an uncommon inflammatory odontogenic cyst that characteristically develops on the buccal aspect of the mandibular first permanent molar, although some cases have involved the second molar. The pathogenesis of this cyst is uncertain. One theory suggests that early tooth eruption may be associated with inflammation of the buccal sulcular or junctional epithelium, resulting in epithelial proliferation and cyst formation. In addition, a few of these lesions have been associated with teeth that demonstrate cervical enamel extensions into the bifurcation area (see page 90). Such extensions may predispose these teeth to buccal pocket formation, which could then enlarge to form a cyst in response to pericoronitis.

The term **paradental cyst** sometimes has been used synonymously for the buccal bifurcation cyst. Such lesions typically occur distal or buccal of partially erupted mandibular third molars with a history of pericoronitis. The pathogenesis of the so-called paradental cyst also is uncertain. However, the distinction of paradental cysts from secondarily inflamed dentigerous cysts is difficult, if not impossible, in many instances (see page 685).

Clinical and Radiographic Features

The buccal bifurcation cyst typically occurs in children from 5 to 13 years of age. The patient has slight-to-moderate tenderness on the buccal aspect of the mandibular first or second molar, which may be in the process of erupting. The patient often notes associated clinical swelling and a foul-tasting discharge. Periodontal probing usually reveals pocket formation

dentlearn.ir

• **Fig. 15.54 Buccal Bifurcation Cysts.** Coronal computed tomography (CT) image showing bilateral cysts buccal to the roots of the mandibular first molars. (Courtesy of Dr. Brent Newby.)

on the buccal aspect of the involved tooth. Around one-third of patients have been reported to have bilateral involvement of the first molars.

Radiographs typically show a well-circumscribed unilocular radiolucency involving the buccal bifurcation and root area of the involved tooth (Fig. 15.53). The average size of the lucent defect is 1.2 cm, but the lesion may be as large as 2.5 cm in diameter. An occlusal radiograph or cone-beam computed tomography (CBCT) can be helpful in demonstrating the buccal location of the lesion. The root apices of the molar are characteristically tipped toward the lingual mandibular cortex (Fig. 15.54). Many cases are associated with proliferative periostitis (see page 141) of the overlying buccal cortex, which is characterized by a single or multiple layers of reactive bone formation.

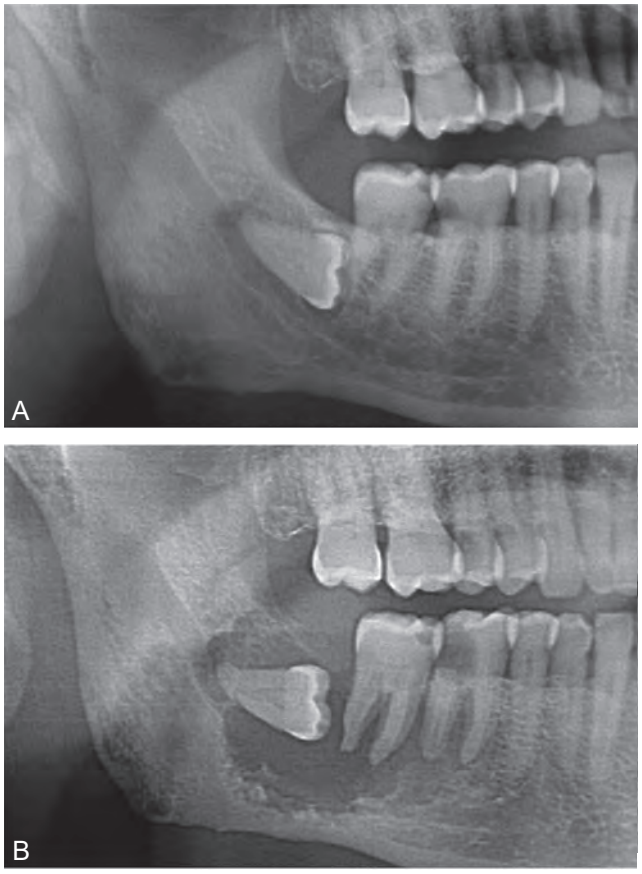
Histopathologic Features

The microscopic features are nonspecific and show a cyst that is lined by nonkeratinizing stratified squamous epithelium with areas of hyperplasia. A prominent chronic inflammatory cell infiltrate is present in the surrounding connective tissue wall.

Treatment and Prognosis

The buccal bifurcation cyst is usually treated by enucleation; extraction of the associated tooth is unnecessary. Within 1 year of surgery, there is usually complete healing with normalization of periodontal probing depths and radiographic evidence of bone fill. Several reports have described cases that resolved without surgery—either with no treatment at all or by daily irrigation of the buccal pocket with saline and hydrogen peroxide.

◆ CARCINOMA ARISING IN ODONTOGENIC CYSTS



Carcinoma arising within bone is a rare lesion that is essentially limited to the jaws. Because the putative source of the epithelium giving rise to the carcinoma is odontogenic, these intraosseous jaw carcinomas are collectively known as **odontogenic carcinomas.** Odontogenic carcinomas may arise in an ameloblastoma, rarely from other odontogenic tumors, *de novo* (without evidence of a preexisting lesion), or from the epithelial lining of odontogenic cysts. Some intraosseous mucoepidermoid carcinomas (see page 496) also may arise from mucous cells lining a dentigerous cyst.

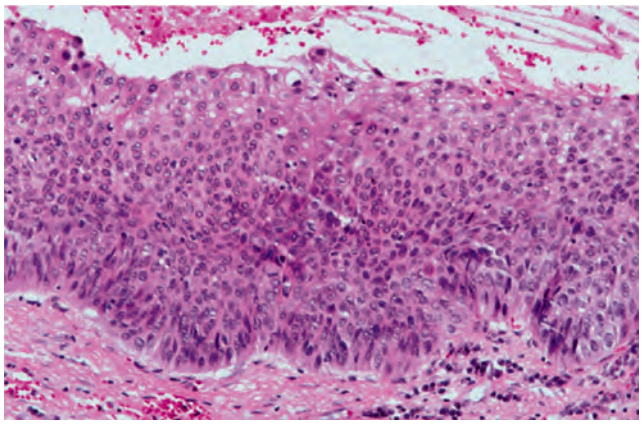
Most intraosseous carcinomas apparently arise in odontogenic cysts. Although infrequently documented in the literature, carcinomatous transformation of the lining of an odontogenic cyst may be more common than is generally appreciated. Several studies have shown that 1%–2% of all oral cavity carcinomas seen in some oral and maxillofacial pathology services may originate from odontogenic cysts. The pathogenesis of carcinomas arising in odontogenic cysts is unknown. Occasionally, areas within the lining of odontogenic cysts histopathologically demonstrate varying degrees of epithelial dysplasia, and such changes likely give rise to the carcinoma.

Clinical and Radiographic Features

Although carcinomas arising in cysts may be seen in patients across a wide age range, they are encountered most often in older patients. The mean reported age is 60 years. This lesion is over twice as common in men as in women. Pain and swelling are the most common complaints. However, many

dentlearn.ir

• **Fig. 15.55 Carcinoma Arising in a Dentigerous Cyst. A,** Impacted mandibular third molar surrounded by a narrow radiolucent rim. **B,** Radiographic appearance 5 years later, which shows a large destructive radiolucency with ragged borders. (Courtesy of Dr. Matthew Lee.)

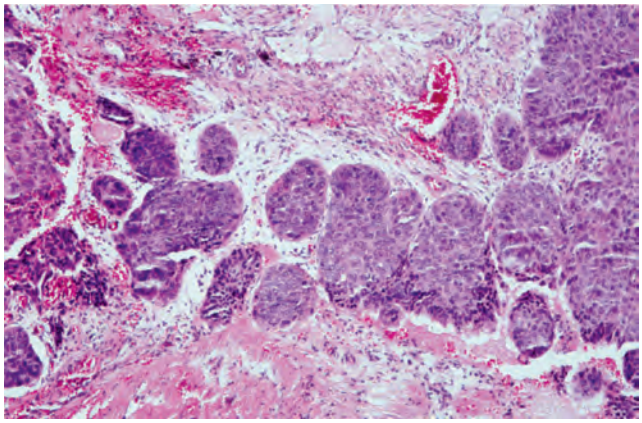


• **Fig. 15.56 Carcinoma Arising in a Cyst.** There is a massive carcinoma of the mandible, with extension into the parotid gland, the face, and the base of the brain. Nineteen years previously, a large odontogenic keratocyst (OKC) with areas of epithelial dysplasia had been removed from the ascending ramus. The patient had suffered multiple recurrences, with eventual change into invasive carcinoma.

patients have no symptoms, and the diagnosis of carcinoma is made only after microscopic examination of a presumed odontogenic cyst.

Radiographic findings may mimic those of any odontogenic cyst, although the margins of the radiolucent defect are usually irregular and ragged. CT scans of the lesion may demonstrate a destructive pattern that is not appreciated on viewing plain radiographs. A lesion considered to be a **residual periapical cyst** is apparently the most common type associated with carcinomatous transformation, although routine periapical cysts can also exhibit malignant change. These account for 60% of reported cases. In about 16% of cases, the carcinoma appeared to have arisen in a **dentigerous cyst** (Fig. 15.55). Examples of malignant transformation of calcifying odontogenic cysts also have been reported. In one patient, the carcinoma was thought to originate from a **lateral periodontal cyst.**

A number of examples of carcinoma arising in an OKC also have been documented (Fig. 15.56). However, some reported examples do not appear to have arisen in true parakeratinized OKCs, but rather in **orthokeratinized odontogenic cysts.**



• **Fig. 15.57 Carcinoma Arising in a Cyst.** High-power view of a dentigerous cyst from a 53-year-old man. The lining demonstrates full-thickness epithelial dysplasia.

Histopathologic Features

Most carcinomas arising in cysts histopathologically have been **well-differentiated** or **moderately well-differentiated squamous cell carcinomas.** Sometimes it is possible to identify a transition from a normal-appearing cyst lining to invasive squamous cell carcinoma (Figs. 15.57 and 15.58).

dentlearn.ir

• **Fig. 15.58 Carcinoma Arising in a Cyst.** Same case as Fig. 15.57 showing islands of invasive epithelial cells in the cyst wall.

Treatment and Prognosis

The treatment of patients with carcinomas arising in cysts has varied from local block excision to radical resection, with or without radiation or adjunctive chemotherapy. The prognosis is difficult to evaluate because most reports consist of isolated cases. Metastases to regional lymph nodes have been demonstrated in a few cases. One review showed an overall 2-year survival rate of 62%, but the 5-year survival rate dropped to 38%.

Before a given lesion can be accepted as an example of primary intraosseous carcinoma, the possibility that the tumor represents metastatic spread from an intraoral or extraoral site must be ruled out by appropriate studies.

ODONTOGENIC TUMORS

Odontogenic tumors comprise a complex group of lesions of diverse histopathologic types and clinical behavior. Some of these lesions are true neoplasms and may rarely exhibit malignant behavior. Others may represent tumorlike malformations (hamartomas).

Odontogenic tumors, like normal odontogenesis, demonstrate varying inductive interactions between odontogenic epithelium and odontogenic ectomesenchyme. This ectomesenchyme was formerly referred to as *mesenchyme* because it was thought to be derived from the mesodermal layer of the embryo. It is now accepted that this tissue differentiates from the ectodermal layer in the cephalic portion of the embryo. **Tumors of odontogenic epithelium** are composed only of odontogenic epithelium without any participation of odontogenic ectomesenchyme.

Other odontogenic neoplasms, sometimes referred to as **mixed odontogenic tumors,** are composed of odontogenic epithelium and ectomesenchymal elements. Dental hard tissue may or may not be formed in these lesions.

A third group, **tumors of odontogenic ectomesenchyme,** is composed principally of ectomesenchymal elements. Although odontogenic epithelium may be included within these lesions, it does not appear to play any essential role in their pathogenesis.

• BOX 15.4 Classification of Odontogenic Tumors

I. Tumors of odontogenic epithelium
  A. Ameloblastoma and ameloblastoma, unicystic type
    1. Metastasizing (malignant) ameloblastoma
    2. Ameloblastic carcinoma
  B. Clear cell odontogenic carcinoma
  C. Adenomatoid odontogenic tumor
  D. Calcifying epithelial odontogenic tumor
  E. Squamous odontogenic tumor
II. Mixed odontogenic tumors
  A. Ameloblastic fibroma
  B. Ameloblastic fibro-odontoma
  C. Ameloblastic fibrosarcoma
  D. Compound odontoma
  E. Complex odontoma
  F. Primordial odontogenic tumor
III. Tumors of odontogenic ectomesenchyme
  A. Odontogenic fibroma
  B. Granular cell odontogenic tumor
  C. Odontogenic myxoma
  D. Cementoblastoma

Box 15.4 presents categories of odontogenic tumors, listing the most common and important odontogenic tumors that are discussed in this textbook.

Because many of these lesions are quite rare, it is sometimes difficult to assess certain epidemiologic features accurately, as well as recommendations regarding treatment. It should be kept in mind that reports in the literature may be biased due to geopolitical/economic variations in submission of biopsies or the tendency of journal editors to publish reports of lesions that are unusual or aggressive.

TUMORS OF ODONTOGENIC EPITHELIUM

Epithelial odontogenic tumors are composed of odontogenic epithelium without participation of odontogenic ectomesenchyme. Several distinctly different tumors are included in the group; ameloblastoma is the most important and common of them.

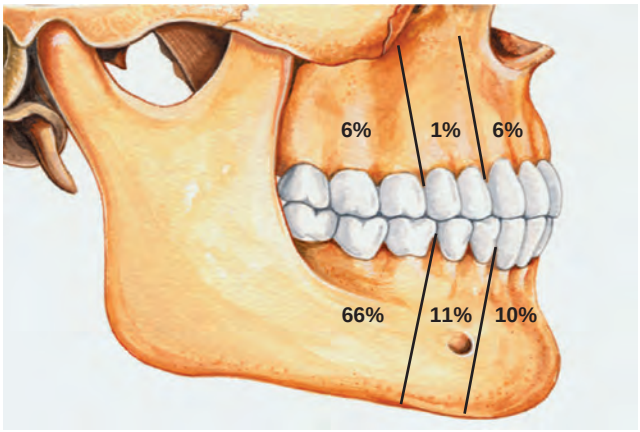
◆ AMELOBLASTOMA

The **ameloblastoma** is the most common clinically significant odontogenic tumor. Its relative frequency equals the combined frequency of all other odontogenic tumors, excluding odontomas. Ameloblastomas are tumors of odontogenic epithelial origin. Theoretically, they may arise from rests of dental lamina, from a developing enamel organ, from the epithelial lining of an odontogenic cyst, or from the basal cells of the oral mucosa. As many as 80% of ameloblastomas will show mutations in *BRAF* p.V600E, a gene involved in the mitogen-activated protein kinase (MAP kinase) cell signaling pathway.

Ameloblastomas are slow-growing, locally invasive tumors that run a benign course in most cases. They typically

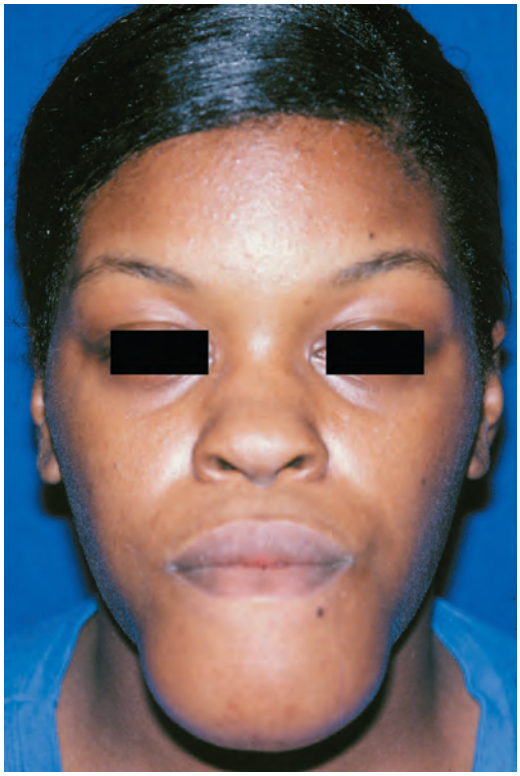
dentlearn.ir

have been described as having three different clinicoradiographic presentations, which deserve separate consideration because of potentially differing therapeutic considerations and prognosis:



1. Conventional solid or multicystic (about 75%–86% of all cases)
2. Unicystic (about 13%–21% of all cases)
3. Peripheral (extraosseous) (about 1%–4% of all cases)

CONVENTIONAL SOLID OR MULTICYSTIC INTRAOSSEOUS AMELOBLASTOMA



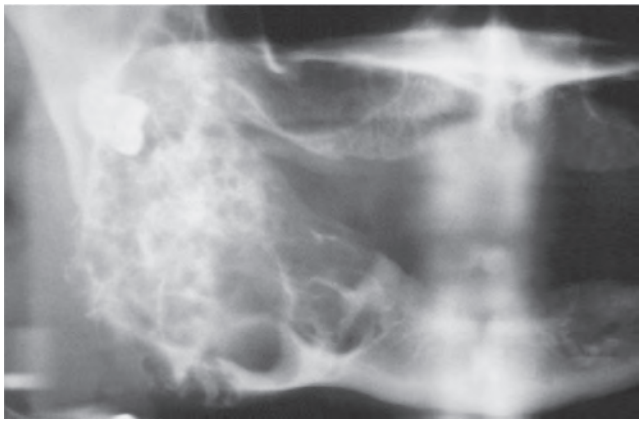
Clinical and Radiographic Features

Conventional solid or **multicystic intraosseous ameloblastoma** is encountered in patients across a wide age range. It is rare in children younger than age 10 and relatively uncommon in the 10- to 19-year-old group. The tumor shows an approximately equal prevalence in the third to seventh decades of life. There is no significant sex predilection. Some studies indicate a greater frequency in blacks; others show no racial predilection. About 80%–85% of conventional ameloblastomas occur in the mandible, most often in the molar-ascending ramus area. About 15%–20% of ameloblastomas occur in the maxilla, usually in the posterior regions (Fig. 15.59). The tumor is often asymptomatic, and smaller lesions are detected only during a radiographic examination. A painless swelling or expansion of the jaw is the usual clinical presentation (Figs. 15.60 and 15.61). If untreated, then the lesion may grow slowly to massive or grotesque proportions (Fig. 15.62). Pain and paresthesia are uncommon, even with large tumors.

The most typical radiographic feature is that of a multilocular radiolucent lesion, although one large international study suggested that a unilocular presentation was just as likely. Multilocular lesions are described as having a "soap bubble" appearance (when the radiolucent loculations are large) or as being "honeycombed" (when the loculations are small) (Figs. 15.63–15.65). Buccal and lingual cortical expansion is frequently present. Resorption of the roots of teeth adjacent to the tumor is common. In many cases an unerupted tooth, most often a mandibular third molar, is associated with the radiolucent defect (Fig. 15.66). Solid ameloblastomas may radiographically appear as unilocular radiolucent defects, which may resemble almost any type of cystic lesion (Fig. 15.67). The margins of these radiolucent lesions, however, often show irregular scalloping. Although the radiographic features, particularly of the typical multilocular defect, may be highly suggestive of ameloblastoma, a variety of odontogenic and non-odontogenic lesions may show similar radiographic features (see Appendix).

• **Fig. 15.59 Ameloblastoma.** Relative distribution of ameloblastomas in the jaws.

• **Fig. 15.60 Ameloblastoma.** Large expansile mass of the anterior mandible. (Courtesy of Dr. Michael Tabor.)



• **Fig. 15.61 Ameloblastoma.** Prominent expansion of the lingual alveolus caused by a large ameloblastoma of the mandibular symphysis.

dentlearn.ir

• **Fig. 15.62 Ameloblastoma.** Massive tumor of the anterior mandible. (Courtesy of Dr. Ronald Baughman.)

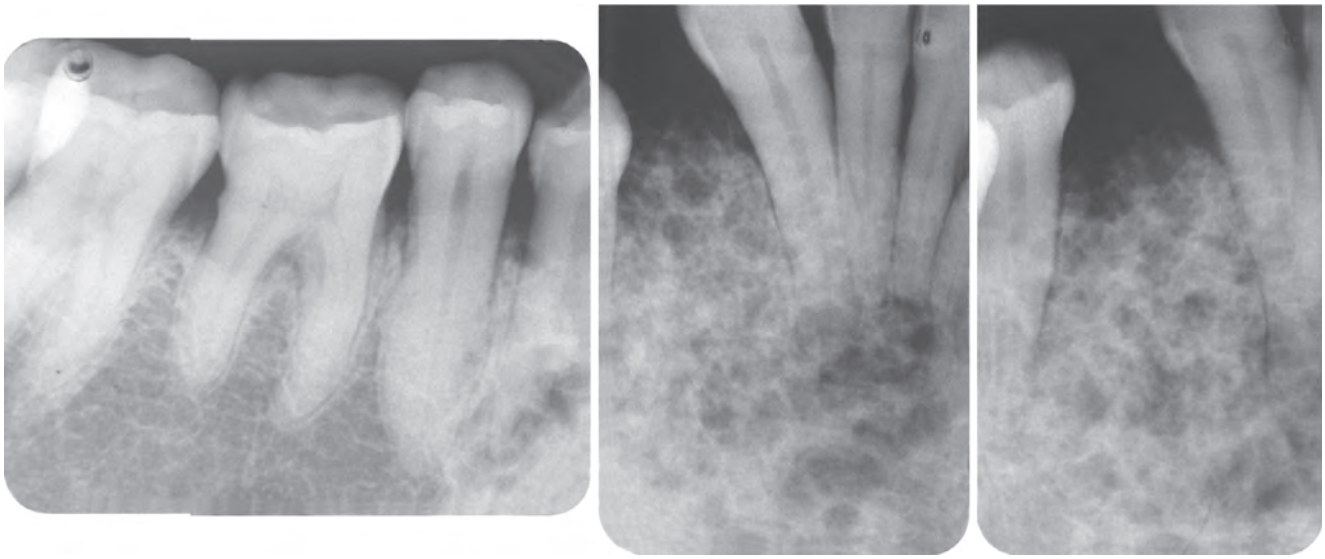
• **Fig. 15.63 Ameloblastoma.** Large multilocular lesion involving the mandibular angle and ascending ramus. The large loculations show the "soap bubble" appearance. An unerupted third molar has been displaced high into the ramus.

One histopathologic form of ameloblastoma that does not have these characteristic features is the desmoplastic ameloblastoma, a variant that Eversole and colleagues documented initially in the literature in 1984. The desmoplastic ameloblastoma has a marked predilection to occur in the anterior regions of the jaws, with equal distribution between the mandible and the maxilla. Radiographically, this type may not suggest the diagnosis of ameloblastoma; the majority of these tumors resemble a fibro-osseous lesion because of their mixed radiolucent and radiopaque appearance (Fig. 15.68). This mixed radiographic appearance is due to osseous metaplasia within the dense fibrous septa that characterize the lesion, not because the tumor itself is producing a mineralized product.

Histopathologic Features

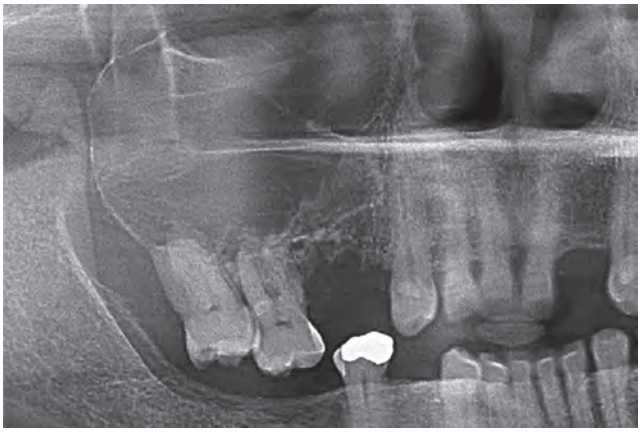
Conventional solid or multicystic intraosseous ameloblastomas show a remarkable tendency to undergo cystic change; grossly, most tumors have varying combinations of cystic and solid features. The cysts may be seen only at the microscopic level or may be present as multiple large cysts that include most of the tumor. Several microscopic subtypes of conventional ameloblastoma are recognized, but these microscopic patterns generally have little bearing on the behavior of the tumor. Large tumors often show a combination of microscopic patterns.

The **follicular** and **plexiform** patterns are the most common. Less common histopathologic patterns include the **acanthomatous, granular cell, desmoplastic,** and **basal cell** types.



Follicular Pattern

The follicular histopathologic pattern is the most common and recognizable. Islands of epithelium resemble enamel organ epithelium in a mature fibrous connective tissue stroma. The epithelial nests consist of a core of loosely arranged angular cells resembling the stellate reticulum of an enamel organ. A single layer of tall columnar ameloblast-like cells surrounds this central core. The nuclei of these cells are located at the opposite pole to the basement membrane (**reversed polarity**). In other areas, the peripheral cells may be more cuboidal and resemble basal cells. Cyst formation is common and may vary from microcysts, which form within the epithelial islands, to large macroscopic cysts, which may be several centimeters in diameter (Figs. 15.69 and 15.70). If an incisional biopsy is taken from the latter area, an inappropriate diagnosis of "unicystic ameloblastoma" may be rendered by the pathologist.



Plexiform Pattern

The plexiform type of ameloblastoma consists of long, anastomosing cords or larger sheets of odontogenic epithelium. The cords or sheets of epithelium are bounded by columnar or cuboidal ameloblast-like cells surrounding more loosely arranged epithelial cells. Occasionally the cuboidal cells may form structures resembling ducts, resulting in what has been termed an adenoid pattern. Such lesions may be misdiagnosed as adenomatoid odontogenic tumor or adenocarcinoma by the pathologist who is not familiar with this pattern. The supporting stroma in the plexiform pattern of ameloblastoma tends to be loosely arranged and vascular. Cyst formation is relatively uncommon in this variety. When it occurs, it is more often associated with stromal degeneration rather than cystic change within the epithelium (Fig. 15.71).

• **Fig. 15.65 Ameloblastoma.** Expansile, radiolucent mass of the right posterior maxilla, which fills the maxillary sinus. (Courtesy of Dr. Doug Oliver.)

If the duct-like structures are accompanied by dentinoid deposition, then the diagnosis of a rare, relatively recently described, ameloblastoma-like tumor called adenoid ameloblastoma may be appropriate. One report has suggested that the characteristic mutations of *BRAF* p.V600E gene are not present in this lesion.

Acanthomatous Pattern

When extensive squamous metaplasia, often associated with keratin formation, occurs in the central portions of the epithelial islands of a follicular ameloblastoma, the term **acanthomatous ameloblastoma** is sometimes applied. This change does not indicate a more aggressive course for the lesion; histopathologically, however, such a lesion may be confused with squamous cell carcinoma or squamous odontogenic tumor (Fig. 15.72).

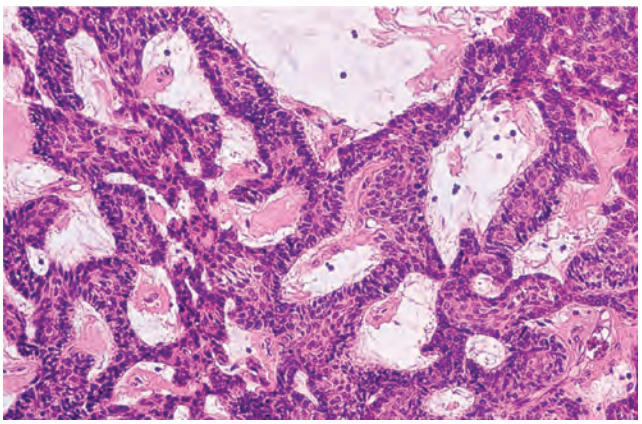
• **Fig. 15.68 Desmoplastic Ameloblastoma.** Large mixed radiolucent and radiopaque lesion of the anterior and right body of the mandible. (Courtesy of Dr. Román Carlos.)

Granular Cell Pattern



Ameloblastomas may sometimes show transformation of groups of lesional epithelial cells to granular cells. These cells have abundant cytoplasm filled with eosinophilic granules that resemble lysosomes ultrastructurally and histochemically. Although originally considered to represent an aging or degenerative change in long-standing lesions, this variant has been seen in young patients. When this granular cell change is extensive in an ameloblastoma, the designation of **granular cell ameloblastoma** is appropriate (Fig. 15.73).

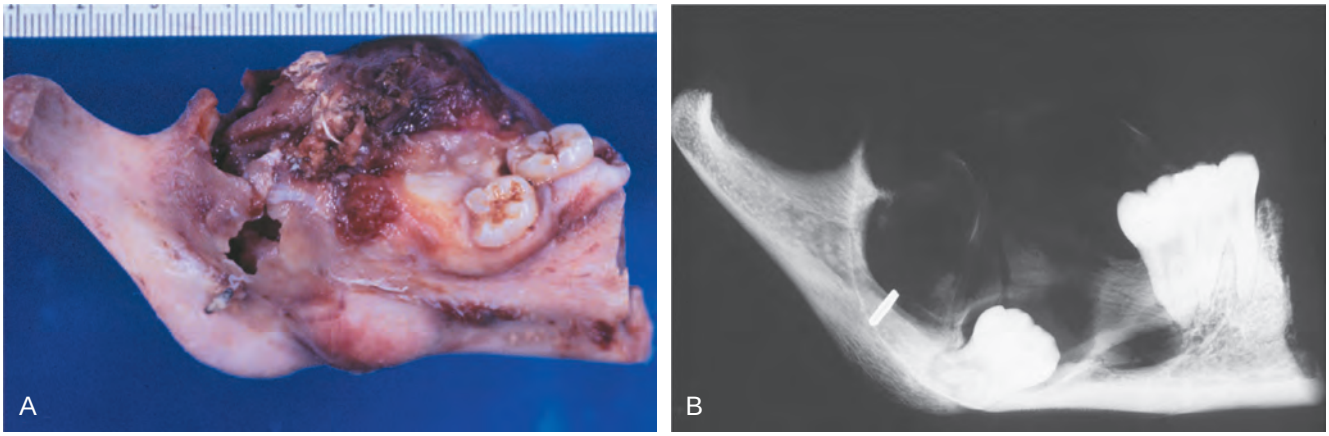
production of the cytokine known as *transforming growth factor-β (TGF-β)* in association with this lesion, suggesting that this may be responsible for the desmoplasia. Peripheral columnar ameloblast-like cells are inconspicuous about the epithelial islands (Fig. 15.74).

Basal Cell Pattern



The basal cell variant of ameloblastoma is the least common type. These lesions are composed of nests of uniform basaloid cells, and they histopathologically are very similar to basal cell carcinoma of the skin. No stellate reticulum is present in the central portions of the nests. The peripheral cells about the nests tend to be cuboidal rather than columnar (Fig. 15.75).

Treatment and Prognosis

Patients with conventional solid or multicystic intraosseous ameloblastomas have been treated by a variety of means. These range from simple enucleation and curettage to *en bloc* resection (Fig. 15.76). The optimal method of treatment has been the subject of controversy for many years, primarily because this tumor is rather uncommon, and designing well-controlled, randomized clinical trials with sufficient follow-up periods is a logistical challenge. The conventional ameloblastoma tends to infiltrate between intact cancellous bone trabeculae at the periphery of the lesion before bone resorption becomes radiographically evident. Therefore, the actual margin of the tumor often extends beyond its apparent radiographic or clinical margin. Attempts to remove the tumor by curettage often leave small islands of tumor within the bone, which later manifest as recurrences. Recurrence rates of 50%–90% have been reported in various studies after curettage. Recurrence often takes many years to become clinically manifest, and 5-year disease-free periods do not indicate a cure.

Marginal resection is the most widely used treatment, but recurrence rates of up to 15% have been reported after marginal or block resection. Some surgeons advocate a more conservative approach to treatment by planning surgery after careful evaluation of CT scans of the tumor. Removal of

dentlearn.ir

• **Fig. 15.76 Ameloblastoma. A,** Gross photograph of a mandibular resection specimen. **B,** The radiograph of the specimen shows a large radiolucent defect associated with an inferiorly displaced third molar. (Courtesy of Dr. Mary Richardson.)

the tumor, followed by peripheral ostectomy, often reduces the need for extensive reconstructive surgery. Some tumors may not be amenable to this approach because of their size or growth pattern.

Other surgeons advocate that the margin of the resection should be at least 1.0–2.0 cm past the radiographic limits of the tumor. Ameloblastomas of the posterior maxilla are particularly dangerous because of the difficulty of obtaining an adequate surgical margin around the tumor. Orbital invasion by maxillary ameloblastomas occasionally has been described. Although some studies suggest that the ameloblastoma may be radiosensitive, radiation therapy has seldom been used as a treatment modality because of the intraosseous location of the tumor and the potential for secondary radiation-induced malignancy developing in a relatively young patient population.

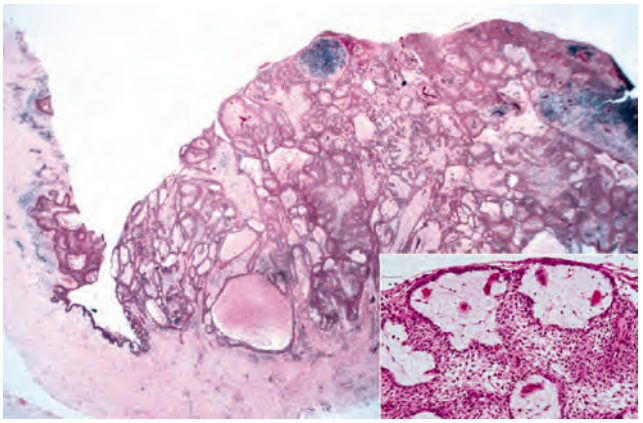
The conventional ameloblastoma is a persistent, infiltrative neoplasm that very seldom may kill the patient by progressive spread to involve vital structures. Most of these tumors, however, are not life-threatening lesions. Rarely, an ameloblastoma exhibits frank malignant behavior. These are discussed separately.

UNICYSTIC AMELOBLASTOMA

The **unicystic ameloblastoma** has for several decades been given separate consideration based on its clinical, radiographic, and pathologic features. Although its response to treatment in reports from the 1970s and 1980s suggested that this lesion might behave in a less aggressive fashion, recent reports have disputed this concept. Unicystic ameloblastomas account for 10%–46% of all intraosseous ameloblastomas in various studies. Whether the unicystic ameloblastoma originates *de novo* as a neoplasm or whether it is the result of neoplastic transformation of nonneoplastic cyst epithelium has been long debated. Both mechanisms probably occur, but proof of which is involved in an individual patient is virtually impossible to obtain.

• **Fig. 15.77 Unicystic Ameloblastoma.** Radiolucency associated with the crown of the developing mandibular second molar. (Courtesy of Dr. Joseph Van Sickels.)

Clinical and Radiographic Features



Unicystic ameloblastomas are seen most often in younger patients, with about 50% of all such tumors diagnosed during the second decade of life. The average age in one large series was 23 years. More than 90% of unicystic ameloblastomas are found in the mandible, usually in the posterior regions. The lesion is often asymptomatic, although large lesions may cause a painless swelling of the jaws.

In many patients, this lesion typically appears as a circumscribed radiolucency that surrounds the crown of an unerupted mandibular third molar (Figs. 15.77 and 15.78), clinically resembling a dentigerous cyst. Other tumors simply appear as sharply defined radiolucent areas and are usually considered to be a primordial, radicular, or residual cyst, depending on the relationship of the lesion to teeth in the area. In some instances, the radiolucent area may have scalloped margins but is still a unicystic ameloblastoma. Whether a unicystic ameloblastoma can have a truly multilocular radiographic presentation is arguable.

• **Fig. 15.79 Unicystic Ameloblastoma (Luminal Type).** The cyst is lined by ameloblastic epithelium showing a hyperchromatic, polarized basal layer. The overlying epithelial cells are loosely cohesive and resemble stellate reticulum.

• **Fig. 15.81 Unicystic Ameloblastoma (Mural Type).** The epithelial lining of the cystic component can be seen on the left edge of the photomicrograph. Islands of follicular ameloblastoma are infiltrating into the fibrous connective tissue wall on the right.

The surgical findings may also suggest that the lesion in question is a cyst, and the diagnosis of ameloblastoma is made only after microscopic study of the specimen.

Histopathologic Features

Three histopathologic variants of unicystic ameloblastoma have been described. In the first type **(luminal unicystic ameloblastoma),** the tumor is confined to the luminal surface of the cyst. The lesion consists of a fibrous cyst wall with a lining composed totally or partially of ameloblastic epithelium. The lining demonstrates a basal layer of columnar or cuboidal cells with hyperchromatic nuclei that show reverse polarity and basilar cytoplasmic vacuolization (Fig. 15.79). The upper epithelial cells are loosely cohesive and resemble stellate reticulum. This finding does not seem to be related to inflammatory edema.

In the second microscopic variant, one or more nodules of ameloblastoma project from the cystic lining into the lumen of the cyst. This type is called an **intraluminal unicystic ameloblastoma.** These nodules may be relatively small or largely fill the cystic lumen. In some cases, the nodule of tumor that projects into the lumen demonstrates an edematous, plexiform pattern that resembles the plexiform pattern seen in conventional ameloblastomas (Fig. 15.80). These lesions are sometimes referred to as **plexiform unicystic ameloblastomas.** The intraluminal cellular proliferation does not always meet the strict histopathologic criteria for ameloblastoma, and this may be secondary to inflammation that nearly always accompanies this pattern. Typical ameloblastoma, however, may be found in other, less inflamed parts of the specimen.

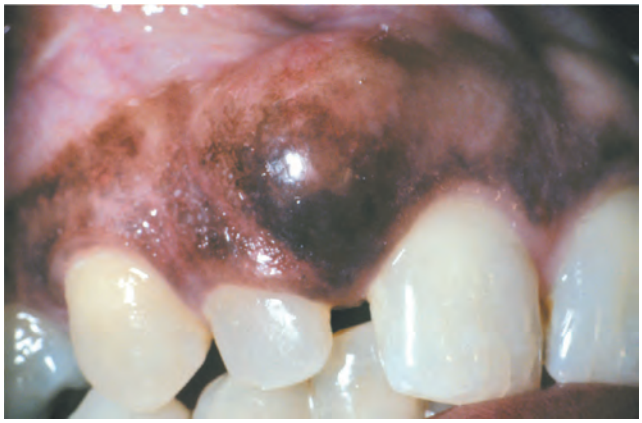
In the third variant, known as **mural unicystic ameloblastoma,** the fibrous wall of the cyst is infiltrated by typical follicular or plexiform ameloblastoma. The extent and depth of the ameloblastic infiltration may vary considerably. With any presumed unicystic ameloblastoma, multiple sections through many levels of the specimen are necessary to rule out the possibility of mural invasion of tumor cells (Fig. 15.81).

dentlearn.ir

Treatment and Prognosis

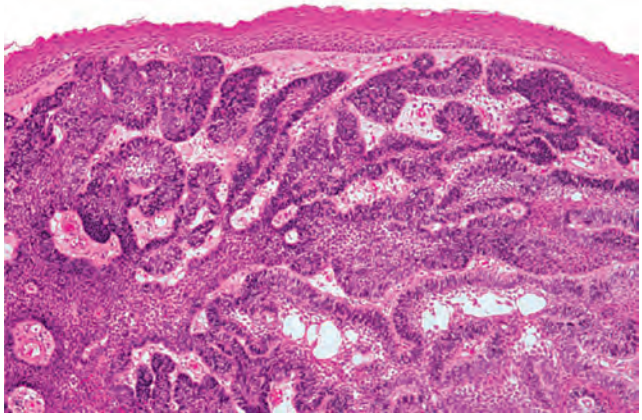
The clinical and radiographic findings in most cases of unicystic ameloblastoma suggest that the lesion is an odontogenic cyst. These tumors are usually treated as cysts by enucleation. The diagnosis of ameloblastoma is made only after microscopic examination of the presumed cyst. If the ameloblastic elements are confined to the lumen of the cyst with or without intraluminal tumor extension, then the cyst enucleation has probably been adequate treatment. The patient, however, should be kept under long-term follow-up. If the specimen shows extension of the tumor into the fibrous cyst wall for any appreciable distance, then subsequent management of the patient is more controversial. Some surgeons believe that local resection of the area is indicated as a prophylactic measure; others prefer to keep the patient under close radiographic observation and delay further treatment until there is evidence of recurrence.

Recurrence rates of 10%–20% were described after enucleation and curettage of unicystic ameloblastomas in many of the earlier series of cases. This range is considerably less than the 50%–90% recurrence rates noted after curettage of conventional solid and multicystic intraosseous ameloblastomas. A systematic review of the literature up to 2018 determined that 21% of these lesions recurred after enucleation, and only 3% recurred following radical resection. It is possible that some of those tumors that are designated as "unicystic" may, in fact, have a more characteristic invasive component that has not been detected histopathologically because it is essentially impossible to examine these lesions in every 360-degree plane of section.



PERIPHERAL (EXTRAOSSEOUS) AMELOBLASTOMA

The **peripheral ameloblastoma** is uncommon and accounts for about 1%–4% of all ameloblastomas. This tumor probably arises from rests of dental lamina beneath the oral mucosa or from the basal epithelial cells of the surface epithelium. Histopathologically, these lesions have the same features as the intraosseous form of the tumor.



Clinical Features

The peripheral ameloblastoma is usually a painless, nonulcerated sessile or pedunculated gingival or alveolar mucosal lesion. The clinical features are non-specific, and most lesions are clinically considered to represent a fibroma or pyogenic granuloma. Most examples are smaller than 1.5 cm, but larger lesions have been reported (Fig. 15.82). The tumor has been found in patients across a wide age range, but most are seen in middle-aged persons, with an average reported age of 52 years.

Peripheral ameloblastomas are most commonly found on the posterior gingival and alveolar mucosa, and they are somewhat more common in mandibular than in maxillary areas. In some cases, the superficial alveolar bone becomes slightly eroded, but significant bone involvement does not occur. A few examples of a microscopically identical lesion have been reported in the buccal mucosa at some distance from the alveolar or gingival soft tissues.

• **Fig. 15.82 Peripheral Ameloblastoma.** Sessile gingival mass. (Courtesy of Dr. Dean K. White.)

• **Fig. 15.83 Peripheral Ameloblastoma.** Interconnecting cords of ameloblastic epithelium filling the lamina propria.

Histopathologic Features

Peripheral ameloblastomas have islands of ameloblastic epithelium that occupy the lamina propria underneath the surface epithelium (Fig. 15.83). The proliferating epithelium may show any of the features described for the intraosseous ameloblastoma; plexiform or follicular patterns are the most common. Connection of the tumor with the basal layer of the surface epithelium is seen in about 50% of cases. This may represent origin of the tumor from the basal layer of the epithelium in some cases, but in other instances the tumor could develop in the gingival connective tissue and merge with the surface epithelium.

Basal cell carcinomas of the gingival mucosa have been reported, but most of these would be designated best as peripheral ameloblastomas. A **peripheral odontogenic fibroma** may be confused microscopically with a peripheral ameloblastoma, particularly if a prominent epithelial

dentlearn.ir

component is present in the former. The presence of dysplastic dentin or cementum-like elements in the peripheral odontogenic fibroma and the lack of peripheral columnar epithelial cells showing reverse polarity of their nuclei should serve to distinguish the two lesions.

Treatment and Prognosis

Unlike the intraosseous ameloblastoma, the peripheral ameloblastoma shows an innocuous clinical behavior. Patients respond well to local surgical excision. Although local recurrence has been noted in 15%–20% of cases, further local excision almost always results in a cure. Several examples of malignant change in a peripheral ameloblastoma have been reported, but this is rare.

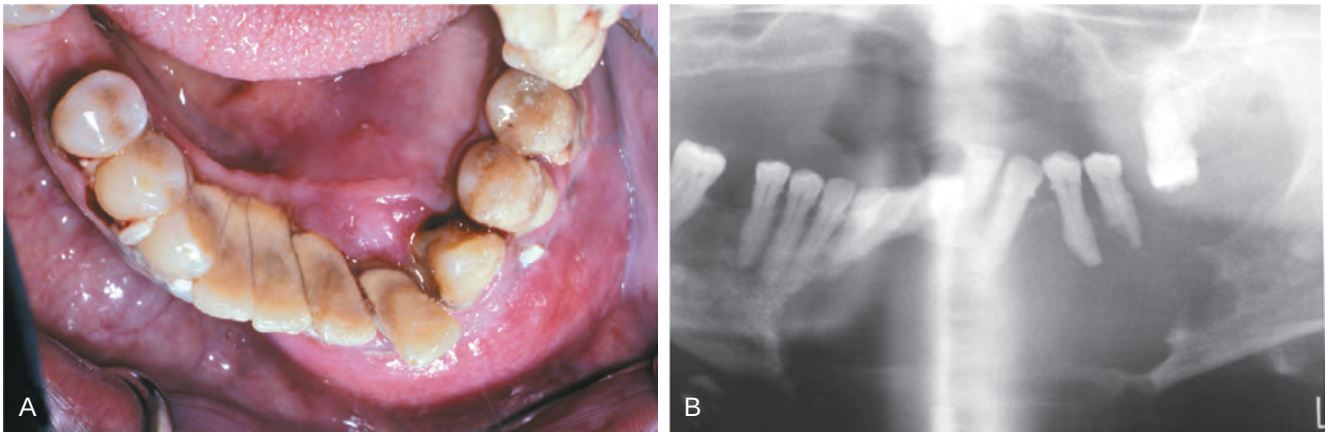
◆ MALIGNANT AMELOBLASTOMA AND AMELOBLASTIC CARCINOMA

Rarely, an ameloblastoma exhibits frank malignant behavior with development of metastases. The frequency of malignant behavior in ameloblastomas is difficult to determine but probably occurs in far less than 1% of all ameloblastomas.

The terminology for these lesions is somewhat confusing, but should not be considered controversial. The term *malignant ameloblastoma*, also known as *metastasizing ameloblastoma*, is used for a tumor that shows the histopathologic features of ameloblastoma, both in the primary tumor and in the metastatic deposits. This is a very rare neoplasm, with fewer than 30 well-documented cases described in the literature. The term *ameloblastic carcinoma* should be reserved for an ameloblastoma that has cytologic features of malignancy in the primary tumor, in a recurrence, or in any metastatic deposit. This is also a rare condition, although approximately 200 cases have been reported. These lesions may follow a markedly aggressive local course, but metastases do not necessarily occur. Other malignancies of odontogenic differentiation that are quite rare, but deserve mention, include sclerosing odontogenic carcinoma, primary intraosseous carcinoma, ghost cell odontogenic carcinoma, odontogenic carcinosarcoma, odontogenic carcinoma with dentinoid, and odontogenic sarcomas.

Clinical and Radiographic Features

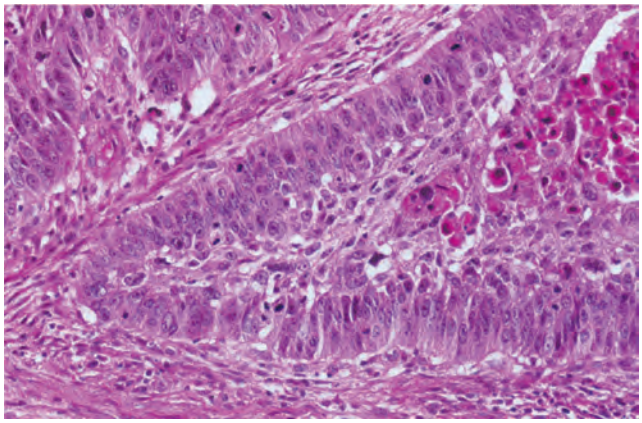
Malignant ameloblastomas have been observed in patients who range in age from 6 to 61 years (mean age, 30 years), and no sex predilection is seen. For patients with documented metastases, the interval between the initial treatment of the ameloblastoma and first evidence of metastasis varies from 3 to 45 years. In nearly one-third of cases, metastases do not become apparent until 10 years after treatment of the primary tumor. Ameloblastic carcinomas, in contrast, tend to develop later in life, with the mean age at diagnosis typically being in the sixth decade of life. Men are affected twice as frequently as women.



Metastases from ameloblastomas are found most often in the lungs. These have sometimes been regarded as aspiration or implant metastases. However, the peripheral location of some of these lung metastases suggests that they must have occurred by blood or lymphatic routes rather than aspiration.

Cervical lymph nodes are the second most common site for metastasis of an ameloblastoma. Spread to vertebrae, other bones, and viscera has also occasionally been confirmed.

The radiographic findings of malignant ameloblastomas may be essentially the same as those in typical nonmetastasizing ameloblastomas. Ameloblastic carcinomas are often more aggressive lesions, with ill-defined margins and cortical destruction (Fig. 15.84).



Histopathologic Features

With malignant ameloblastomas, the primary jaw tumor and the metastatic deposits show no microscopic features that differ from those of ameloblastomas with a completely

• **Fig. 15.84 Ameloblastic Carcinoma. • **Fig. 15.86 Clear Cell Odontogenic Carcinoma.** A radiolucent defect at the apex of the mandibular first molar. (Courtesy of Dr. John Werther.)

benign local course. With ameloblastic carcinomas, the metastatic deposit or primary tumor shows the microscopic pattern of ameloblastoma in addition to cytologic features of malignancy. These include an increased nuclear-to-cytoplasmic ratio, nuclear hyperchromatism, and the presence of mitoses (Fig. 15.85). Necrosis in tumor islands and areas of dystrophic calcification may also be present.

Treatment and Prognosis

The prognosis of patients with malignant ameloblastomas appears to be poor, but the paucity of documented cases with long-term follow-up does not permit accurate assumptions to be made. About 50% of the patients with documented metastases and long-term follow-up have died of their disease. Lesions designated as *ameloblastic carcinoma* have demonstrated a uniformly aggressive clinical course, with perforation of the cortical plates of the jaw and extension of the tumor into adjacent soft tissues. One review of the literature identified a mean 5-year survival rate of nearly 70% when ameloblastic carcinoma was treated by surgical resection having disease-free margins. Radiation therapy has been used infrequently to treat this malignancy, although isolated reports indicate some benefit for those patients who are not candidates for extensive surgical procedures.

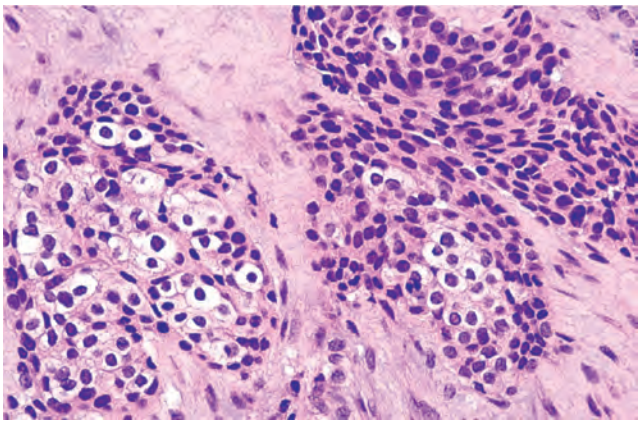
◆ CLEAR CELL ODONTOGENIC CARCINOMA (CLEAR CELL ODONTOGENIC TUMOR)

Clear cell odontogenic carcinoma is a rare jaw tumor that was first described in 1985. To date, approximately 120 examples have been documented. The tumor appears to be of odontogenic origin, but its histogenesis is uncertain. Histochemical and ultrastructural studies have suggested that the clear cells, which are the prominent feature of this neoplasm, may have similarities to glycogen-rich presecretory ameloblasts. Molecular studies of clear cell odontogenic carcinoma, however, have identified translocation of the *EWSR1* gene, which is often fused with the *ATF1* gene. This genetic alteration can be found in a variety of tumors, but it is often seen in hyalinizing clear cell carcinoma, a rare salivary gland malignancy.

Clinical and Radiographic Features

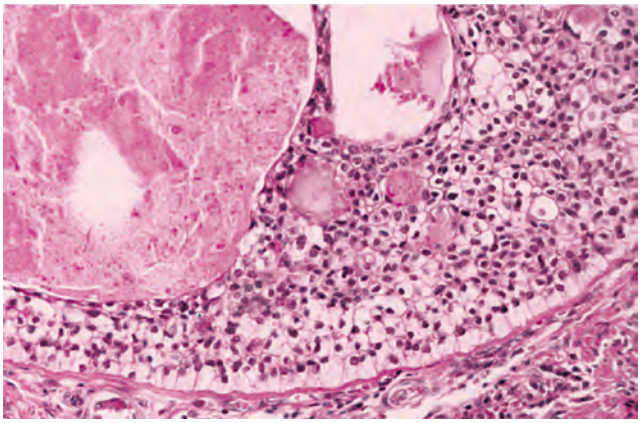
The clear cell odontogenic carcinoma exhibits a variable clinical pattern. A wide age range (from 17 to 89 years of age; mean age—55 years) has been described, and 65% of cases are diagnosed in females. Slightly more than 80% of the lesions develop in the mandible. Approximately 50% of patients complain of pain or lower lip paresthesia, and bony swelling has been described as a presenting sign in 80% of affected patients. Other patients are relatively symptom free. A significant number of patients will have evidence of soft tissue involvement by the tumor at the time of diagnosis because the lesion perforates bone.

Radiographically, the lesions appear as unilocular or multilocular radiolucencies. The margins of the radiolucency are often somewhat ill-defined or irregular (Fig. 15.86).



Histopathologic Features

Three histopathologic patterns have been described for clear cell odontogenic carcinoma. The biphasic pattern consists of varying-sized nests of epithelial cells, with a clear or faintly eosinophilic cytoplasm admixed with more eosinophilic polygonal epithelial cells (Fig. 15.87). The second pattern is more monophasic, characterized by only clear cells that are arranged in nests and cords. Thin strands of hyalinized connective tissue often separate the clear cell nests. The third pattern has a resemblance to ameloblastoma in that the peripheral cells of the clear cell islands may infrequently demonstrate palisading (Fig. 15.88). Often the lesional cells do not exhibit a significant degree of nuclear or cytologic pleomorphism. Furthermore, mitoses are generally sparse and necrosis is not a prominent feature. The clear cells contain



dentlearn.ir

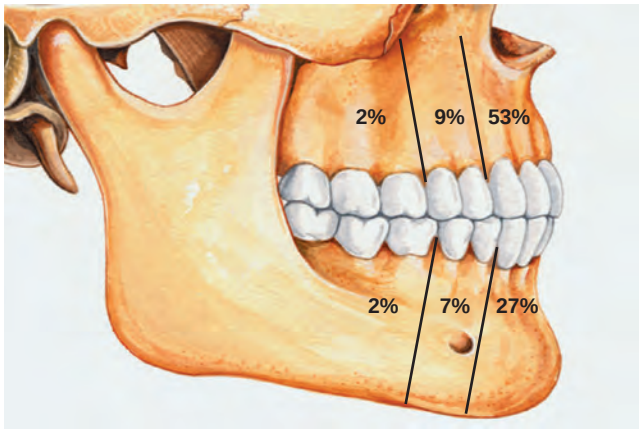
small amounts of glycogen, but mucin stains are negative. In some cases, islands more typical of ameloblastoma are interspersed among the other tumor elements.

Hyalinizing clear cell carcinoma resembles clear cell odontogenic carcinoma, and although the salivary gland tumor develops in the soft tissues, for those lesions that have significant bone destruction, it may be difficult to identify the site of origin. Clear cell odontogenic carcinoma also may be difficult to distinguish from intraosseous mucoepidermoid carcinoma with a prominent clear cell component, although the negative mucin stains are consistent with the former. Amyloid stains would confirm the diagnosis of clear cell variant of the calcifying epithelial odontogenic tumor, because amyloid would not be present in clear cell odontogenic tumor. A metastatic clear cell neoplasm, such as a renal cell carcinoma, clear cell breast carcinoma, or clear cell melanoma, may also need to be ruled out before the diagnosis of clear cell odontogenic carcinoma can be established. If the diagnosis is unresolved using routine studies, molecular analysis can be employed to identify the characteristic translocation of the *EWSR1* gene and the fusion products that have been described in clear cell odontogenic carcinoma.

• **Fig. 15.87 Clear Cell Odontogenic Carcinoma.** Hyperchromatic epithelial nests including clusters of cells with abundant clear cytoplasm.

• **Fig. 15.88 Clear Cell Odontogenic Carcinoma.** Tumor island demonstrating cells with a clear cytoplasm. Note the peripheral columnar differentiation.

Treatment and Prognosis



Clear cell odontogenic carcinomas largely demonstrate an aggressive clinical course, with invasion of contiguous structures and a significant tendency to recur, particularly if the initial treatment is enucleation or curettage. Most patients require fairly radical surgery that may include hemimandibulectomy or hemimaxillectomy. Metastatic involvement of regional lymph nodes has been documented in about 9% of these patients, and pulmonary metastases have been identified in approximately 15%.

◆ ADENOMATOID ODONTOGENIC TUMOR

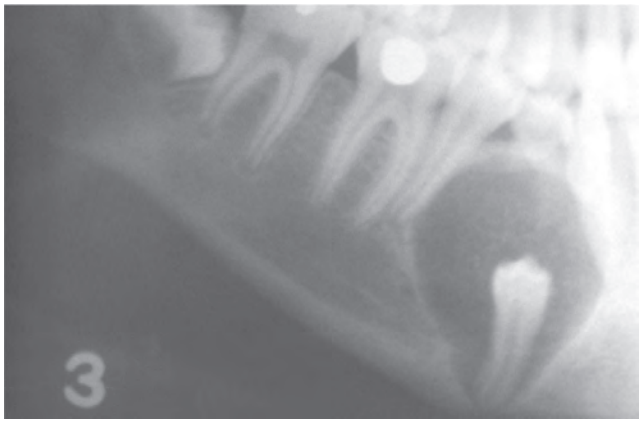
The **adenomatoid odontogenic tumor** represents 2%–7% of all odontogenic tumors, and more than 1,500 examples have been reported in the literature. Although this lesion was formerly considered to be a variant of the ameloblastoma and was designated as "adenoameloblastoma," its clinical features and biologic behavior indicate that it is a separate entity. Postulated histogenetic sources of the tumor cells have included enamel organ epithelium, reduced enamel epithelium, and rests of Malassez; however, some investigators have suggested that the lesion arises from remnants of dental lamina associated with the gubernacular cord. The lack of recurrence following enucleation, combined with the immunohistochemical profile of this lesion, have led some to the hypothesis that the adenomatoid odontogenic tumor is perhaps better thought of as a hamartoma, rather than a neoplasm.

Clinical and Radiographic Features

Adenomatoid odontogenic tumors are largely limited to younger patients, and two-thirds of all cases are diagnosed when patients are 10–19 years of age. This tumor is definitely uncommon in a patient older than age 30. It has a striking tendency to occur in the anterior portions of the jaws and is found twice as often in the maxilla as in the mandible (Fig. 15.89). Females are affected about twice as often as males.

• **Fig. 15.89 Adenomatoid Odontogenic Tumor.** Relative distribution of adenomatoid odontogenic tumor in the jaws.

dentlearn.ir

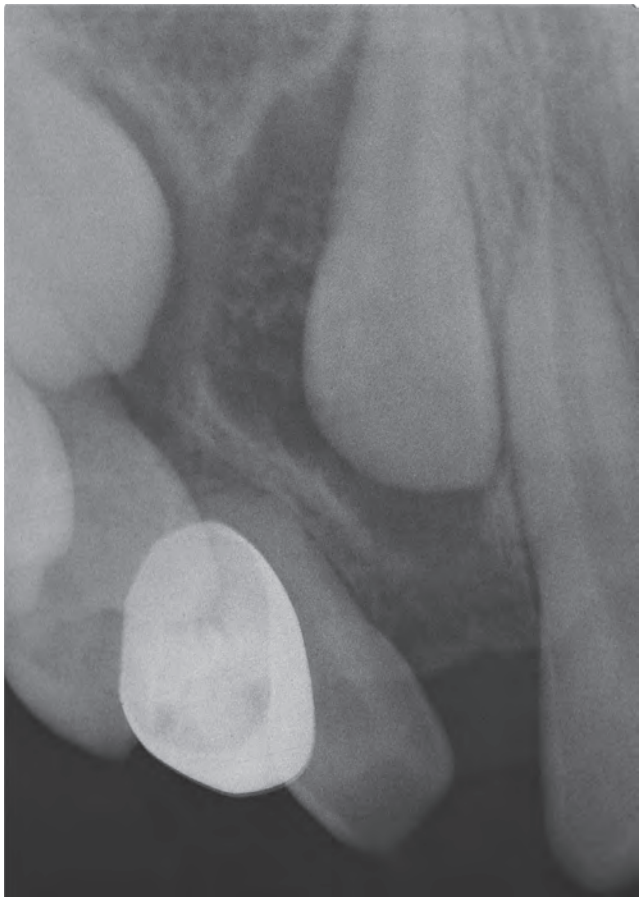


Most adenomatoid odontogenic tumors are relatively small. They seldom exceed 3 cm in greatest diameter, although a few large lesions have been reported. Peripheral (extraosseous) forms of the tumor are also encountered but are rare. These usually appear as small, sessile masses on the facial gingiva of the maxilla. Clinically, these lesions cannot be differentiated from the common gingival fibrous lesions.

Adenomatoid odontogenic tumors are frequently asymptomatic and are discovered during the course of a routine radiographic examination or when films are made to determine why a tooth has not erupted. Larger lesions cause a painless expansion of the bone.

In about 75% of cases, the tumor appears as a circumscribed, unilocular radiolucency that involves the crown of an unerupted tooth, most often a canine. This follicular type of adenomatoid odontogenic tumor may be impossible to differentiate radiographically from the more common dentigerous cyst. The radiolucency associated with the follicular type of adenomatoid odontogenic tumor sometimes extends apically along the root past the cementoenamel junction. This feature may help to distinguish an adenomatoid odontogenic tumor from a dentigerous cyst (Fig. 15.90). Rare examples of multiple adenomatoid odontogenic tumors associated with impacted teeth have been described in nevus sebaceus syndrome (Schimmelpenning syndrome).

The adenomatoid odontogenic tumor also may present as a well-delineated unilocular radiolucency that is not related to an unerupted tooth, but rather is located between the roots of erupted teeth (extrafollicular type) (Fig. 15.91), although this is less common than the follicular type.



The lesion may appear completely radiolucent; often, however, it contains fine (snowflake) calcifications (Fig. 15.92). This feature may be helpful in differentiating the adenomatoid odontogenic tumor from a dentigerous cyst.

• **Fig. 15.90 Adenomatoid Odontogenic Tumor.** Radiolucent lesion involving an unerupted mandibular first premolar. In contrast to the usual dentigerous cyst, the radiolucency extends almost to the apex of the tooth. (Courtesy of Dr. Tony Traynham.)

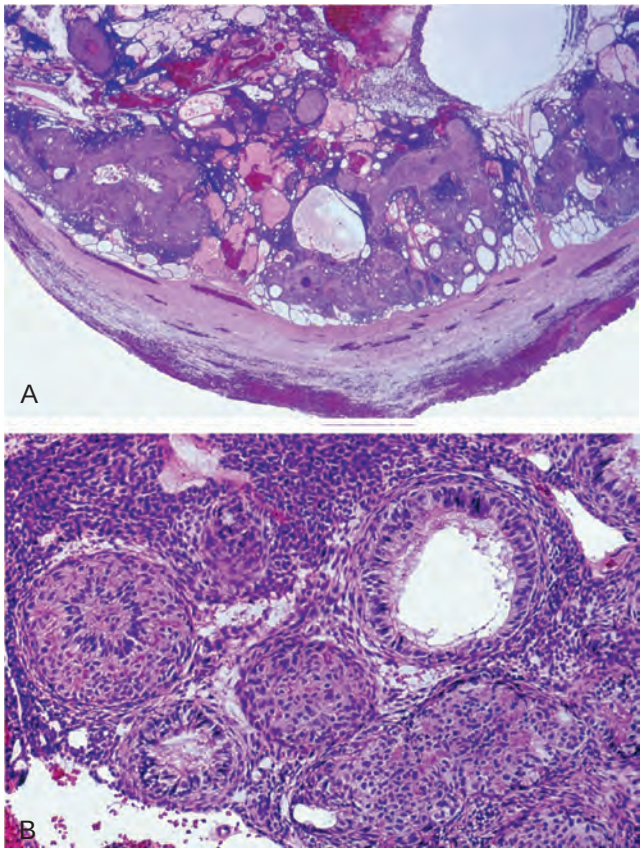
dentlearn.ir

• **Fig. 15.93 Adenomatoid Odontogenic Tumor.** A well-circumscribed cystlike mass can be seen enveloping the crown of a maxillary cuspid. Note the intraluminal vegetations, which represent nodular tumor growth.



Histopathologic Features

The adenomatoid odontogenic tumor is a well-defined lesion that is usually surrounded by a thick, fibrous capsule. When the lesion is bisected, the central portion of the tumor may be essentially solid or may show varying degrees of cystic change (Fig. 15.93).

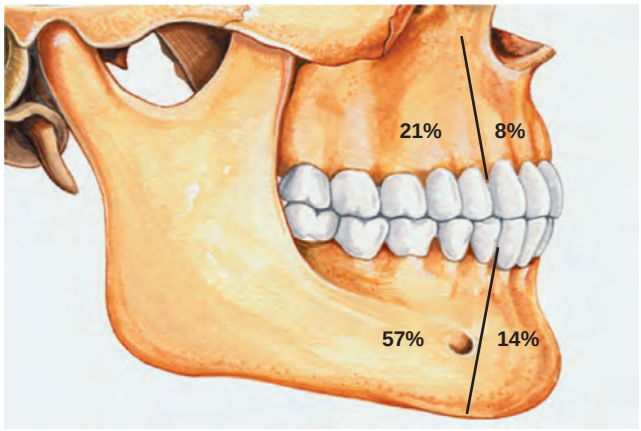
Microscopically, the tumor is composed of spindle-shaped epithelial cells that form sheets, strands, or whorled masses of cells in a scant fibrous stroma. The epithelial cells may form rosettelike structures about a central space, which may be empty or contain small amounts of eosinophilic material. This material may stain for amyloid.

The tubular or ductlike structures, which are the characteristic feature of the adenomatoid odontogenic tumor, may be prominent, scanty, or even absent in a given lesion. These consist of a central space surrounded by a layer of columnar or cuboidal epithelial cells. The nuclei of these cells tend to be polarized away from the central space. The mechanism of formation of these tubular structures is not entirely clear but is likely the result of the secretory activity of the tumor cells, which appear to be preameloblasts. In any event, these structures are not true ducts, and no glandular elements are present in the tumor (Fig. 15.94).

Small foci of calcification may also be scattered throughout the tumor. These have been interpreted as abortive enamel formation. Some adenomatoid odontogenic tumors contain larger areas of matrix material or calcification. This material has been interpreted as dentinoid or cementum. Some lesions also have another pattern, particularly at the periphery of the tumor adjacent to the capsule. This consists of narrow, often anastomosing cords of epithelium in an eosinophilic, loosely arranged matrix.

• **Fig. 15.94 Adenomatoid Odontogenic Tumor. A,** Low-power view demonstrating a thick capsule surrounding the tumor. **B,** Higher magnification showing the ductlike epithelial structures. The nuclei of the columnar cells are polarized away from the central spaces.

The histopathologic features of this lesion are distinctive and should not be confused with any other odontogenic tumor. Interestingly, some adenomatoid odontogenic tumors have been described with focal areas that resemble calcifying epithelial odontogenic tumor, odontoma, or calcifying odontogenic cyst. These lesions appear to behave as a routine adenomatoid odontogenic tumor, however. The chief problem relates to mistaking this tumor for an ameloblastoma by a pathologist who is not familiar with this lesion. This error can lead to unnecessary radical surgery.

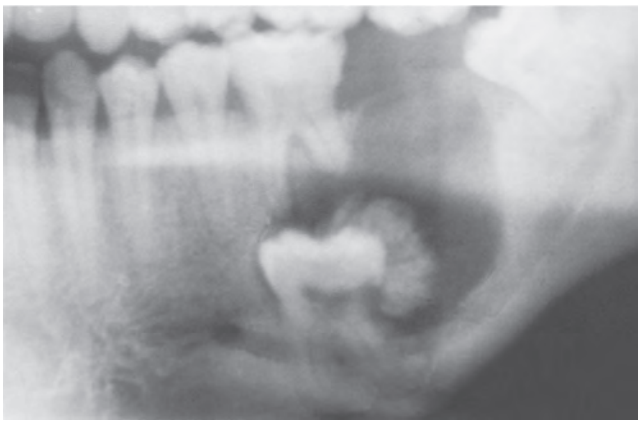


Treatment and Prognosis

The adenomatoid odontogenic tumor is completely benign; because of its capsule, it enucleates easily from the bone. Aggressive behavior has not been documented, and recurrence after enucleation seldom, if ever, occurs.

◆ CALCIFYING EPITHELIAL ODONTOGENIC TUMOR (PINDBORG TUMOR)

The **calcifying epithelial odontogenic tumor,** also widely known as the **Pindborg tumor,** is an uncommon lesion that accounts for less than 1% of all odontogenic tumors.



dentlearn.ir

• **Fig. 15.95 Calcifying Epithelial Odontogenic Tumor.** Relative distribution of calcifying epithelial odontogenic tumor in the jaws.

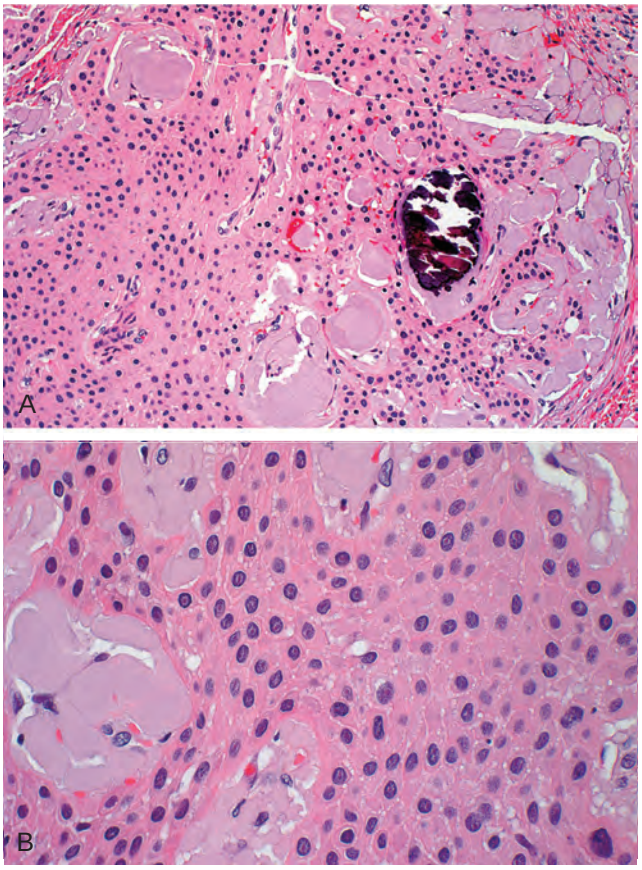
• **Fig. 15.96 Calcifying Epithelial Odontogenic Tumor.** Honeycombed multilocular radiolucency containing fine calcifications.

• **Fig. 15.97 Calcifying Epithelial Odontogenic Tumor.** Prominent calcification around the crown of an impacted second molar that is involved in the tumor. (Courtesy of Dr. Harold Peacock.)

Approximately 360 cases have been reported to date. Although the tumor is clearly of odontogenic origin, its histogenesis is uncertain. The tumor cells bear a close morphologic resemblance to the cells of the stratum intermedium of the enamel organ; however, some investigators have recently suggested that the tumor arises from dental lamina remnants based on its anatomic distribution in the jaws. Mutations of the *PTCH1* gene have been identified in one small series of this neoplasm. This gene is characteristically associated with nevoid basal cell carcinoma syndrome (see page 694), but the calcifying epithelial odontogenic tumor is not a component of that condition.

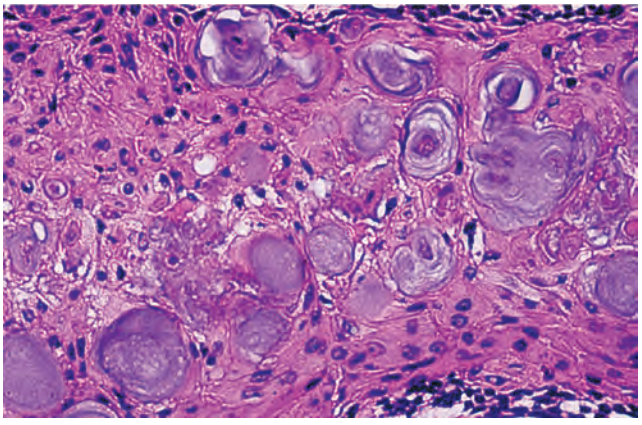
Clinical and Radiographic Features

Although the calcifying epithelial odontogenic tumor has been found in patients across a wide age range and in many parts of the jaw, it is most often encountered in patients between 30 and 50 years of age. There is no sex predilection. About two-thirds of all reported cases have been found in the mandible, most often in the posterior areas (Fig. 15.95). A painless, slow-growing swelling is the most common presenting sign. Rare examples of multiple, synchronous calcifying epithelial odontogenic tumors also have been reported.



Radiographically, the tumor exhibits either a unilocular or a multilocular radiolucent defect (Fig. 15.96), with the unilocular pattern encountered more commonly in the maxilla. The margins of the lytic defect are often scalloped and usually relatively well defined. However, approximately 20% of cases have an ill-defined periphery, and an additional 20% exhibit a corticated border. The tumor is frequently associated with an impacted tooth, most often a mandibular molar. The lesion may be entirely radiolucent, but calcified structures of varying size and density are commonly seen. Although some authors have suggested that these are often most prominent around the crown of the impacted tooth (Fig. 15.97), a review of the literature identified this feature in only 12% of published cases with adequate radiographic documentation. Similarly, the description of a "driven-snow" pattern of the calcifications appears to be much less common than previously believed.

A few cases of peripheral (extraosseous) calcifying epithelial odontogenic tumor have been reported. These appear as nonspecific, sessile gingival masses, most often on the anterior gingiva. Some of these have been associated with cupped-out erosion of the underlying bone.



Histopathologic Features

The calcifying epithelial odontogenic tumor has discrete islands, strands, or sheets of polyhedral epithelial cells in a fibrous stroma (Fig. 15.98). The cellular outlines of the epithelial cells are distinct, and intercellular bridges may be noted. The nuclei show considerable variation, and giant nuclei may be seen. Some tumors show considerable nuclear pleomorphism, but this feature is not considered to indicate malignancy. Large areas of amorphous, eosinophilic, hyalinized (amyloid-like) extracellular material are also often present. The tumor islands frequently enclose masses of this hyaline material, resulting in a cribriform appearance. Calcifications, which are a distinctive feature of the tumor,

dentlearn.ir

develop within the amyloid-like material and form concentric rings *(Liesegang ring calcifications)* (Fig. 15.99). These tend to fuse and form large, complex masses.

Several microscopic variations may be encountered. Some tumors consist of large sheets of epithelial cells with minimal

• **Fig. 15.100 Calcifying Epithelial Odontogenic Tumor.** With Congo red staining, the pools of amyloid exhibit an apple-green birefringence when viewed with polarized light.

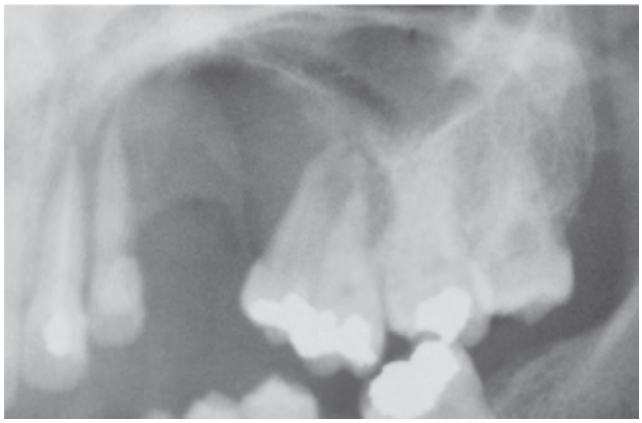
production of amyloid-like material and calcifications. Others show large diffuse masses of amyloid-like material that contain only small nests or islands of epithelium. A clear cell variant has been described, in which clear cells constitute a significant portion of the epithelial component, and this tumor also has been reported to have a cystic growth pattern. A microcystic pattern has also been described in some Pindborg tumors.

The amyloid-like material in the Pindborg tumor has been extensively investigated by histochemical, immunohistochemical, and biochemical methods, as well as by electron microscopy. The material generally stains as amyloid (i.e., positive staining results with Congo red). After Congo red staining, the amyloid will exhibit apple-green birefringence when viewed with polarized light (Fig. 15.100). Investigators have identified this material as a unique protein that is produced by this tumor, as well as by the normal odontogenic apparatus and other odontogenic neoplasms. Both the protein structure and the DNA sequence of the responsible gene have been described, and this material has been designated as odontogenic ameloblast-associated protein (ODAM).

Treatment and Prognosis

Although it was originally believed that the calcifying epithelial odontogenic tumor had about the same biologic behavior as the ameloblastoma, accumulating experience indicates that it tends to be less aggressive. Conservative local resection to include a narrow rim of surrounding bone appears to be the treatment of choice, although lesions in the posterior maxilla should probably be treated more aggressively. A recurrence rate of about 15% has been reported; tumors treated by curettage have the highest frequency of recurrence. The overall prognosis appears good, although rare examples of malignant or borderline malignant calcifying epithelial odontogenic tumor have been reported, with documented metastasis to regional lymph nodes and lung.

dentlearn.ir



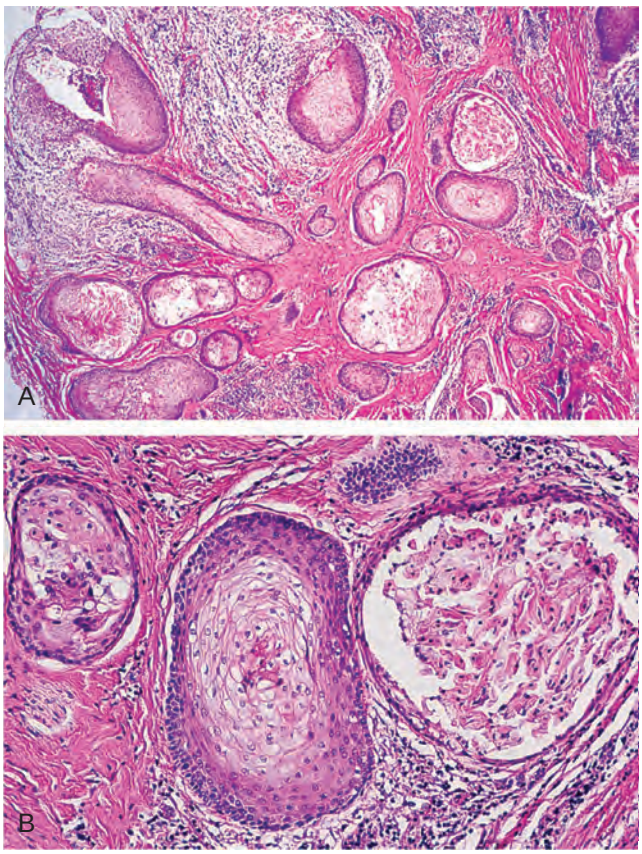
◆ SQUAMOUS ODONTOGENIC TUMOR

Squamous odontogenic tumor is a rare benign odontogenic neoplasm that was first described in 1975 and is now recognized as a distinct entity. Approximately 110 examples have been reported to date, although a recent review of the literature suggested that some of these may have been misdiagnosed, based on accompanying photomicrographs, or had no microscopic documentation. Thus, a more accurate figure is likely closer to 50 cases. Most of these have been located within bone, although a few peripheral examples have been described. Before 1975, this lesion was probably believed to represent an atypical acanthomatous ameloblastoma or even a squamous cell carcinoma. The squamous odontogenic tumor may arise from neoplastic transformation of dental lamina rests or perhaps the epithelial rests of Malassez. In some cases, the tumor appears to originate within the periodontal ligament that is associated with the lateral root surface of an erupted tooth.

Clinical and Radiographic Features

Squamous odontogenic tumors have been found in patients whose ages ranged from 9 to 67 years (average age, 34). They are randomly distributed throughout the alveolar processes of the maxilla and mandible, with no site of predilection. A few patients have had multiple squamous odontogenic tumors that involved several quadrants of the mouth; one family with three affected siblings who each had multiple lesions has been reported. There is no apparent sex predilection. A painless or mildly painful gingival swelling, often associated with mobility of the associated teeth, is the most common complaint. About 10% of reported patients have had no symptoms, and their lesions were detected during a radiographic examination.

The radiographic findings are not specific or diagnostic and consist of a triangular radiolucent defect lateral to the root or roots of the teeth (Fig. 15.101). In some instances, this suggests vertical periodontal bone loss. The radiolucent area may be somewhat ill defined or may show a well-defined, corticated margin. Most examples are relatively small lesions that seldom exceed 1.5 cm in greatest diameter.



• **Fig. 15.101 Squamous Odontogenic Tumor.** Lucent defect extending along the roots of the lateral incisor and first premolar teeth. (Courtesy of Dr. Ed McGaha.)

Histopathologic Features

The microscopic findings of squamous odontogenic tumor are distinctive and consist of varying-shaped islands of bland-appearing squamous epithelium in a mature fibrous connective tissue stroma. The peripheral cells of the epithelial islands do not show the characteristic polarization seen in ameloblastomas (Fig. 15.102). Vacuolization and individual cell keratinization within the epithelial islands are common features. Small microcysts are sometimes observed within the epithelial islands. Laminated calcified bodies and globular eosinophilic structures, which do not stain for amyloid, are present within the epithelium in some cases. The former probably represents dystrophic calcifications; the nature of the latter is unknown.

Islands of epithelium that closely resemble those of the squamous odontogenic tumor have been observed within the fibrous walls of dentigerous and radicular cysts. These have been designated as *squamous odontogenic tumorlike proliferations* in odontogenic cysts. These islands do not appear to have any significance relative to the behavior of the cyst,

• **Fig. 15.102 Squamous Odontogenic Tumor. A,** Low-power photomicrograph showing islands of bland-appearing squamous epithelium in a fibrous stroma. **B,** Higher-power photomicrograph showing bland appearance of the epithelium with microcyst formation.

dentlearn.ir

and evaluation of the clinical, radiographic, and histopathologic features should permit differentiation from a squamous odontogenic tumor.

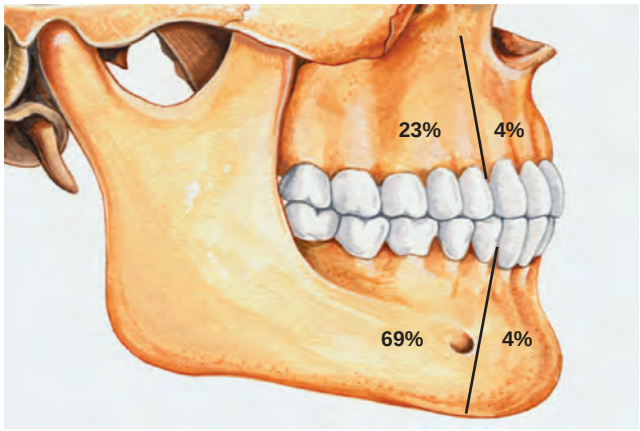
In published reports, some squamous odontogenic tumors have been misdiagnosed initially as ameloblastomas, resulting in unnecessary radical surgery.

Treatment and Prognosis

Conservative local excision or curettage appears to be effective for patients with squamous odontogenic tumors, and most reported cases have not recurred after local excision. A few instances of recurrence have been reported, but these have responded well to further local excision. The overall recurrence rate following conservative treatment is estimated to be approximately 19%. Maxillary squamous odontogenic tumors may be somewhat more aggressive than mandibular lesions, with a greater tendency to invade adjacent structures. This may be because of the porous, spongy nature of the maxillary bone. The multicentric lesions have typically exhibited a less aggressive, almost hamartomatous behavior when compared with solitary lesions. A well-documented example of apparent malignant transformation of squamous odontogenic tumor has been reported.

MIXED ODONTOGENIC TUMORS

The group of mixed odontogenic tumors, composed of proliferating odontogenic epithelium in a cellular ectomesenchyme resembling the dental papilla, poses problems in classification. Some of these lesions show varying degrees of inductive effect by the epithelium on the mesenchyme, leading to the formation of varying amounts of enamel and dentin. Some of these lesions (the common odontomas) are clearly nonneoplastic developmental anomalies; others appear to be true neoplasms. The nature of others is uncertain.



In some instances, the histopathologic findings alone cannot distinguish between the neoplastic lesions and the developmental anomalies. Clinical and radiographic features often are of considerable assistance in making this distinction.

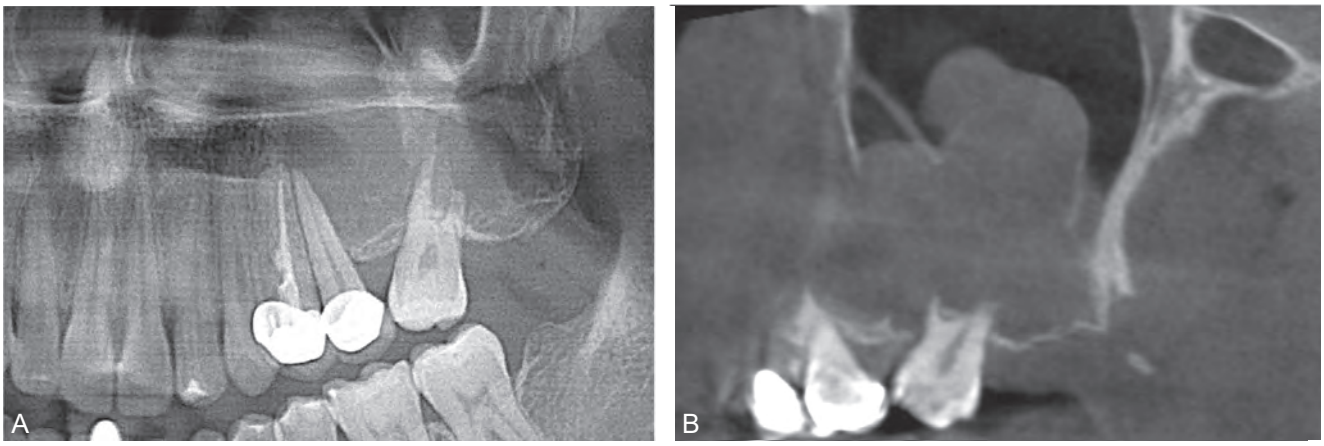
◆ AMELOBLASTIC FIBROMA

The **ameloblastic fibroma** is considered to be a true mixed tumor in which the epithelial and mesenchymal tissues are both neoplastic. It is an uncommon tumor, but the data regarding its frequency are difficult to evaluate because (particularly in earlier reports) some lesions that were diagnosed as ameloblastic fibroma may actually have represented the early developing stage of an odontoma.

Clinical and Radiographic Features

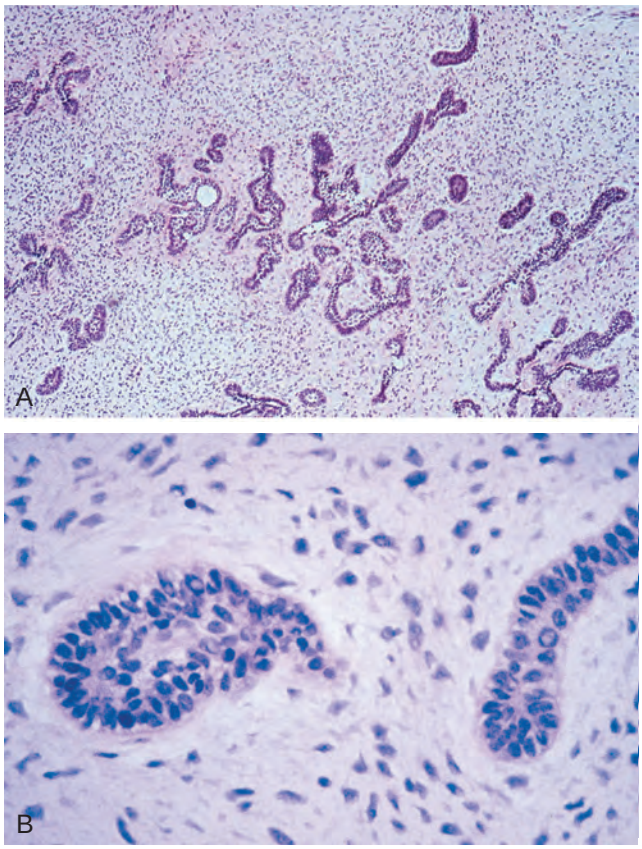
Ameloblastic fibromas tend to occur in younger patients; most lesions are diagnosed in the first two decades of life, with an average age of 15 years. This lesion, however, is occasionally encountered in middle-aged patients. The tumor is slightly more common in males than in females. Small ameloblastic fibromas are asymptomatic; larger tumors are associated with swelling of the jaws. The posterior mandible is the most common site; about 70% of all cases are located in this area (Fig. 15.103). Convincing examples of this tumor arising within the gingival soft tissue have been described, but this appears to represent a rare phenomenon.

• **Fig. 15.103 Ameloblastic Fibroma.** Relative distribution of ameloblastic fibroma in the jaws.



Radiographically, either a unilocular or multilocular radiolucent lesion is seen, with the smaller lesions tending to be unilocular. The radiographic margins tend to be well defined, and they may be corticated. An unerupted tooth is associated with the lesion in about 75% of cases. The ameloblastic fibroma may grow to a large size, and cases that involve a considerable portion of the body and ascending ramus of the mandible or the posterior maxilla have been reported (Fig. 15.104).

Histopathologic Features



The ameloblastic fibroma appears as a solid, soft tissue mass with a smooth outer surface. A definite capsule may or may not be present. Microscopically, the tumor is composed of a cell-rich mesenchymal tissue resembling the primitive dental papilla admixed with proliferating odontogenic epithelium. The latter may have one of two patterns, both of which are usually present in any given case. The most common epithelial pattern consists of long, narrow cords of odontogenic epithelium, often in an anastomosing arrangement. These cords are usually only two cells in thickness and are composed of cuboidal or columnar cells (Fig. 15.105). In the other pattern, the epithelial cells form small, discrete islands that resemble the follicular stage of the developing enamel organ. These show peripheral columnar cells, which surround a mass of loosely arranged epithelial cells that resemble stellate reticulum. In contrast to the follicular type of ameloblastoma, these follicular islands in the ameloblastic fibroma seldom demonstrate microcyst formation.

The mesenchymal portion of the ameloblastic fibroma consists of plump stellate and ovoid cells in a loose matrix, which closely resembles the developing dental papilla.

dentlearn.ir

• **Fig. 15.104 Ameloblastic Fibroma. A,** Panoramic radiograph showing a destructive radiolucent lesion of the left posterior maxilla. **B,** Cone-beam computed tomography (CBCT) image demonstrating extension of the tumor into the maxillary sinus. (Courtesy of Dr. Michael Menis.)

• **Fig. 15.105 Ameloblastic Fibroma. A,** Long, narrow cords of odontogenic epithelium supported by richly cellular, primitive connective tissue. **B,** Basophilic epithelial islands with peripheral nuclear palisading.

Collagen formation is generally inconspicuous. Juxtaepithelial hyalinization of the mesenchymal portion of the tumor is sometimes seen, and occasionally diffuse areas of hyalinized acellular lesional tissue are evident.

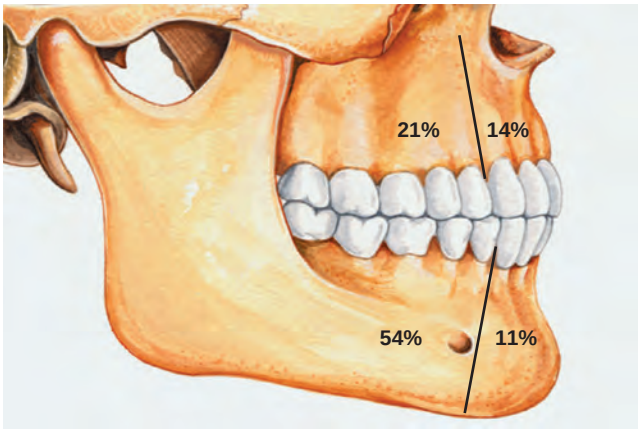
A few examples of ameloblastic fibroma occurring in conjunction with calcifying odontogenic cyst also have been reported.

Treatment and Prognosis

The proper management of ameloblastic fibroma has been an ongoing topic of debate. Although initially it was believed that the ameloblastic fibroma was an innocuous lesion that seldom recurred after simple local excision or curettage, subsequent reports seemed to indicate a substantial risk of recurrence after conservative therapy. The highest recurrence rate (43.5%) was recorded in a series of cases from the Armed Forces Institute of Pathology, and it could be argued that this was a biased sample of larger lesions that were inherently more difficult to manage. In analysis of cases reported in the literature, approximately 19% of ameloblastic fibromas were reported to recur after enucleation or marginal resection and an adequate follow-up period. Based on these data, recent recommendations have emphasized conservative initial therapy for ameloblastic fibroma, followed by long-term monitoring. More aggressive surgical excision should probably be reserved for recurrent lesions. Approximately 26% of the cases of the rare ameloblastic fibrosarcoma develop in the setting of a recurrent ameloblastic fibroma.

◆ AMELOBLASTIC FIBRO-ODONTOMA

The **ameloblastic fibro-odontoma** is defined as a tumor with the general features of an ameloblastic fibroma but that also contains enamel and dentin. Some investigators believe that the ameloblastic fibro-odontoma is only a stage in the development of an odontoma and do not consider it to be a separate entity. Certainly the histopathologic features of a developing odontoma may overlap somewhat with ameloblastic fibro-odontoma. There are well-documented examples, however, of this tumor exhibiting progressive growth and causing considerable deformity and bone destruction. Such lesions appear to be true neoplasms. However, distinguishing between a developing odontoma and an ameloblastic fibro-odontoma may be difficult based on histopathologic grounds alone, and it is quite likely that some examples of developing odontoma have been reported in the literature

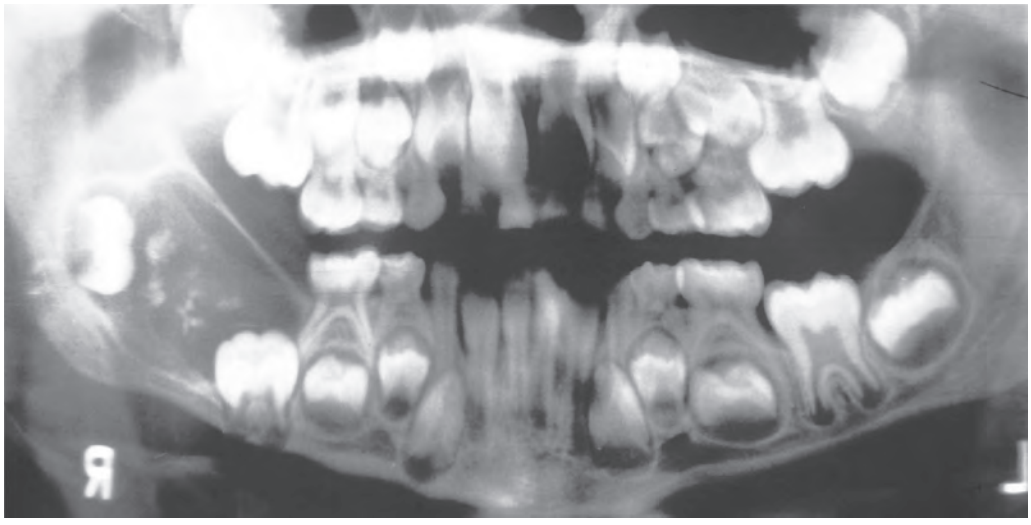


dentlearn.ir

as ameloblastic fibro-odontoma. A recent publication that analyzed reported cases of odontoma and ameloblastic fibro-odontoma found that lesions that were 2.1 cm or greater in size and developed in patients younger than 13.5 years of age were more likely to have features consistent with a neoplasm. The latest World Health Organization has eliminated the ameloblastic fibro-odontoma from its classification of odontogenic tumors, an action with which the authors of this textbook disagree, for reasons noted above. Whether molecular genetic studies that might be performed at some time in the future will resolve this dilemma remains to be seen.

Clinical and Radiographic Features

The ameloblastic fibro-odontoma is usually seen in children with an average age of 10 years. It is rarely encountered in adults. Like the **ameloblastic fibroma,** ameloblastic fibro-odontomas occur more frequently in the posterior regions of the jaws, and the majority involves the mandible (Fig. 15.106). Males are affected somewhat more often than females, with a 3:2 ratio noted in the literature. The lesion is commonly asymptomatic and is discovered when radiographs are taken to determine the reason for failure of a tooth to erupt. Large examples may be associated with a painless swelling of the affected bone.



Radiographically, the tumor shows a well-circumscribed unilocular or, infrequently, multilocular radiolucent defect that contains a variable amount of calcified material with the radiodensity of tooth structure. The calcified material within the lesion may appear as multiple, small radiopacities or as a solid conglomerate mass (Fig. 15.107). In most instances, an unerupted tooth is present at the margin of the lesion, or the crown of the unerupted tooth may be included within the defect. Approximately 5% of ameloblastic fibro-odontomas contain only a minimal amount of calcifying enamel and dentin matrix and appear primarily as radiolucent lesions (Fig. 15.108). These cannot be

• **Fig. 15.106 Ameloblastic Fibro-Odontoma.** Relative distribution of ameloblastic fibro-odontoma in the jaws.

dentlearn.ir

differentiated from the wide variety of unilocular radiolucencies that may involve the jaws. At the other extreme, some ameloblastic fibro-odontomas appear as largely calcified masses with only a narrow rim of radiolucency about the periphery of the lesion, which would be a pattern that certainly suggests a maturing odontoma.

Histopathologic Features

The soft tissue component of the ameloblastic fibro-odontoma is microscopically identical to the **ameloblastic fibroma** and has narrow cords and small islands of odontogenic epithelium in a loose primitive-appearing connective tissue that resembles the dental papilla. The calcifying element consists of foci of enamel and dentin matrix formation in close relationship to the epithelial structures (Fig. 15.109). The more calcified lesions show mature dental structures in the form of rudimentary small teeth or conglomerate masses of enamel and dentin. Some researchers have designated a similar tumor in which the calcifying component consists only of dentin matrix and dentinoid material as **ameloblastic fibro-dentinoma.** It is questionable whether this lesion represents a separate entity, and it is probably best considered as only a variant of the ameloblastic fibro-odontoma.

• **Fig. 15.109 Ameloblastic Fibro-Odontoma. A,** The soft tissue component of the tumor is indistinguishable from an ameloblastic fibroma. **B,** Formation of disorganized tooth structure can be seen.

Treatment and Prognosis

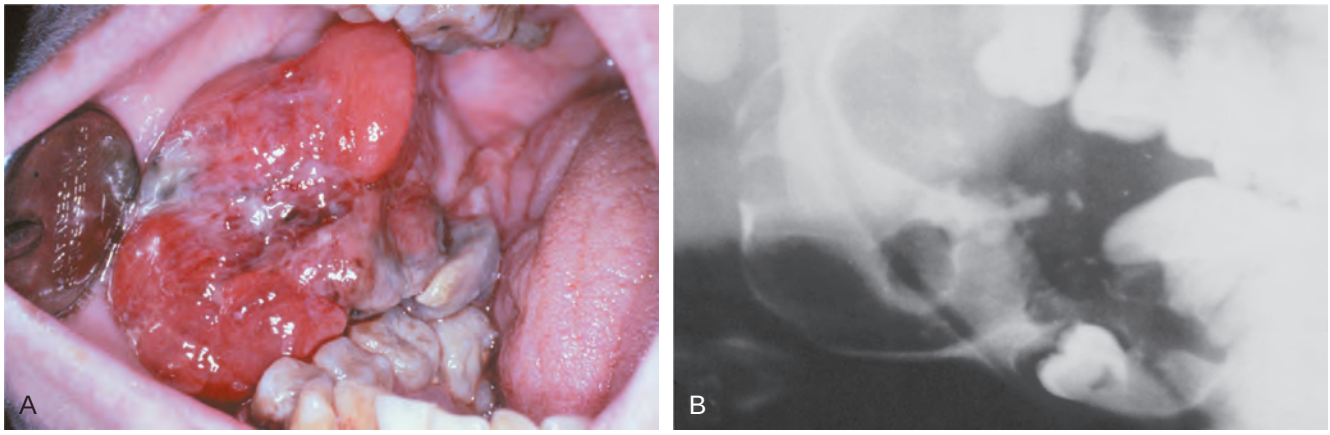
A patient with an ameloblastic fibro-odontoma is generally treated by conservative curettage, and the lesion usually separates easily from its bony bed. The tumor is well circumscribed and does not invade the surrounding bone.

The prognosis is excellent, and the recurrence rate after conservative removal is estimated to be about 7%. Development of an ameloblastic fibrosarcoma after curettage of an ameloblastic fibro-odontoma has been reported, but this is exceedingly rare.

◆ AMELOBLASTIC FIBROSARCOMA (AMELOBLASTIC SARCOMA)

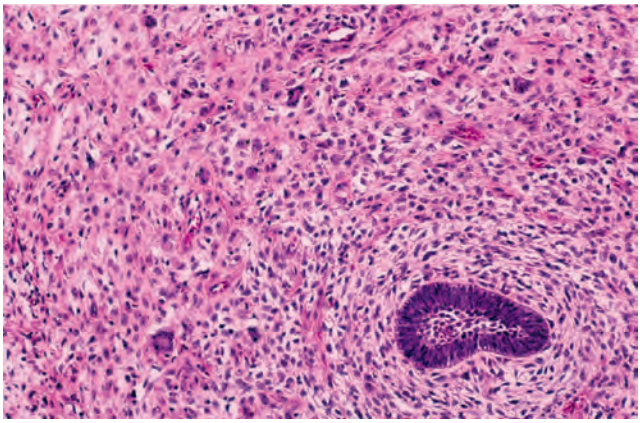
The rare **ameloblastic fibrosarcoma** is considered to be the malignant counterpart of the ameloblastic fibroma, and approximately 110 cases have been documented in the literature. Interestingly, in most cases, only the mesenchymal portion of the lesion shows features of malignancy; the epithelial component remains rather bland. These tumors may apparently arise *de novo;* however, in approximately one-quarter of known cases, the malignant lesion represents a recurrence of a tumor previously diagnosed as an ameloblastic fibroma or an ameloblastic fibro-odontoma. Recent molecular analysis of a small series of this tumor has identified mutations of *BRAF*, and less commonly, *NRAS*. Pharmacologic blocking agents for these genetic pathways are currently available, and evaluation of their efficacy in clinical treatment trials may determine their therapeutic benefit in the future.

Clinical and Radiographic Features



Ameloblastic fibrosarcomas occur slightly more often in males as in females, based on reported cases. The lesion tends to occur in younger patients (mean reported age, approximately 30 years). Although either the maxilla or the mandible may be involved, about 80% of cases have occurred in the mandible. Pain and swelling associated with rapid clinical growth are the common complaints.

Radiographically, the ameloblastic fibrosarcoma may show an ill-defined destructive radiolucent presentation, suggestive of a malignant process (Fig. 15.110).



Histopathologic Features

Ameloblastic fibrosarcomas contain an epithelial component similar to that seen in the ameloblastic fibroma, although it is frequently less prominent. The epithelial component appears histopathologically benign and does not demonstrate any cytologic atypia. The mesenchymal portion of the tumor,

dentlearn.ir

• **Fig. 15.111 Ameloblastic Fibrosarcoma.** The cellular mesenchymal tissue shows hyperchromatism and atypical cells. A small island of ameloblastic epithelium is present.

however, is highly cellular and shows hyperchromatic and often bizarre pleomorphic cells (Fig. 15.111). Mitoses are usually prominent. In some cases with multiple recurrences, the epithelial component becomes progressively less conspicuous so that the tumor eventually shows only a poorly differentiated fibrosarcoma.

In a few instances, dysplastic dentin or small amounts of enamel may be formed. Some have called such lesions **ameloblastic dentinosarcomas** or **ameloblastic fibro-odontosarcomas.** This additional subclassification, however, appears unnecessary. Another rare event that actually may be overrepresented in the literature is concurrent malignant transformation of both the epithelial and mesenchymal elements of an ameloblastic fibroma, resulting in an **ameloblastic** (or **odontogenic**) **carcinosarcoma.**

Treatment and Prognosis

Once the diagnosis of ameloblastic fibrosarcoma has been confirmed, radical surgical excision appears to be the treatment of choice. Curettage or local excision is usually followed by rapid local recurrence. The tumor is locally aggressive and infiltrates adjacent bone and soft tissues.

The long-term prognosis is difficult to ascertain because of the few reported cases with adequate follow-up, with the best estimates suggesting that 20% of these patients will succumb to their tumor. Most deaths have resulted from uncontrolled local disease, and metastatic tumor has been documented in only four of 54 evaluable cases.

◆ ODONTOAMELOBLASTOMA

The **odontoameloblastoma** is an extremely rare odontogenic tumor that contains an ameloblastomatous component and odontoma-like elements. Fewer than 20 cases have been reported with sufficient documentation to support this diagnosis, and odontoameloblastoma as an entity was formally eliminated from the World Health Organization Classification of Head and Neck Tumours as of 2017. This tumor was formerly called *ameloblastic odontoma* and was confused with the more common (though still relatively rare) lesion currently designated as **ameloblastic fibro-odontoma.** Because the clinical behavior of these two tumors is quite different, they should be distinguished from one another. This neoplasm is also frequently confused with an odontoma that is in its early stages of development. Some investigators believe that this lesion represents simply an ameloblastoma that has developed in conjunction with an odontoma, with the two lesions being otherwise unrelated.

Clinical and Radiographic Features

Because of the rarity of odontoameloblastomas, little reliable information is available. The lesion appears to occur more often in younger patients, and either jaw can be affected. Pain, delayed eruption of teeth, and expansion of the affected bone may be noted.

Radiographically, the tumor shows a radiolucent, destructive process that contains calcified structures. These have the radiodensity of tooth structure and may resemble miniature

dentlearn.ir

teeth or occur as larger masses of calcified material similar to a complex odontoma.

Histopathologic Features

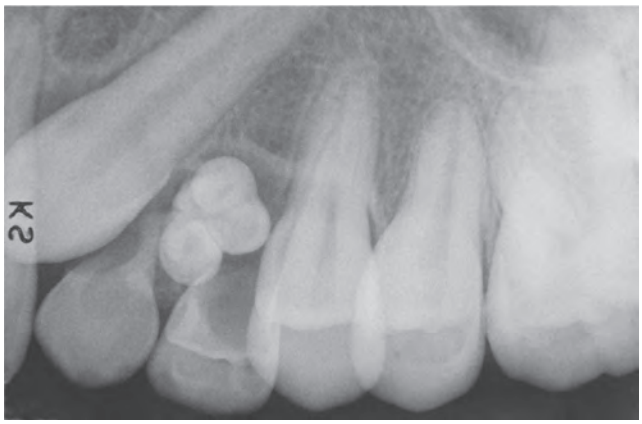
The histopathologic features of the odontoameloblastoma are complex. The proliferating epithelial portion of the tumor has features of an **ameloblastoma,** most often of the plexiform or follicular pattern. The ameloblastic component is intermingled with immature or more mature dental tissue in the form of developing rudimentary teeth, which is similar to the appearance of a **compound odontoma,** or conglomerate masses of enamel, dentin, and cementum, as seen in a **complex odontoma.**

Treatment and Prognosis

Multiple recurrences of odontoameloblastomas have been reported after local curettage, and it appears that this tumor has the same biologic potential as the ameloblastoma. It is probably wise to treat a patient with this lesion in the same manner as one with an ameloblastoma. However, there are no valid data on the long-term prognosis.

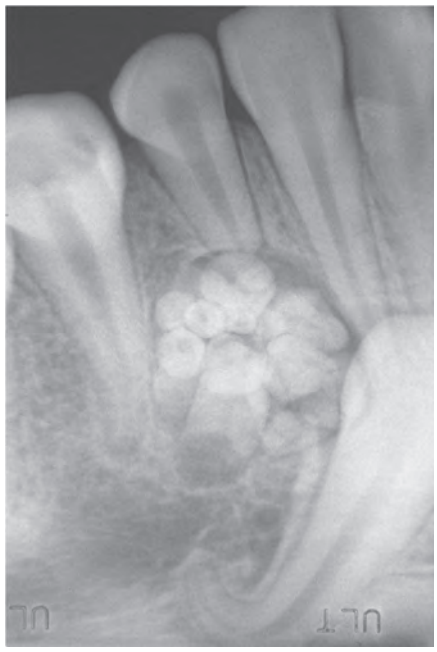
◆ ODONTOMA

Odontomas are the most common types of odontogenic tumors. Their prevalence exceeds that of all other odontogenic tumors combined. Odontomas are considered to be developmental anomalies **(hamartomas),** rather than true neoplasms. When fully developed, odontomas consist chiefly of enamel and dentin, with variable amounts of pulp and cementum. In their earlier developmental stages, varying amounts of proliferating odontogenic epithelium and mesenchyme are present.



Odontomas are further subdivided into compound and complex types. The **compound odontoma** is composed of multiple, small toothlike structures. The **complex odontoma** consists of a conglomerate mass of enamel and dentin, which bears no anatomic resemblance to a tooth. In most series, compound odontomas are more frequently diagnosed than complex, and it is possible that some compound odontomas are not submitted for microscopic examination because the clinician is comfortable with the clinical and radiographic diagnosis. Occasionally, an odontoma may show both compound and complex features.

Clinical and Radiographic Features



Most odontomas are detected during the first two decades of life, and the mean age at the time of diagnosis is 14 years. The majority of these lesions are completely asymptomatic, being discovered on a routine radiographic examination or when films are taken to determine the reason for failure of a tooth to erupt. Odontomas are typically relatively small and seldom exceed the size of a tooth in the area where they are located. However, large odontomas up to 6 cm or more in diameter are occasionally seen. These large odontomas can cause expansion of the jaw.

Odontomas occur somewhat more frequently in the maxilla than in the mandible. Although compound and complex odontomas may be found in any site, the compound type is more often seen in the anterior maxilla; complex odontomas occur more often in the molar regions of either jaw. Occasionally, an odontoma will develop completely within the gingival soft tissues.

Radiographically, the **compound odontoma** appears as a collection of toothlike structures of varying size and shape surrounded by a narrow radiolucent zone (Figs. 15.112 and 15.113). The **complex odontoma** appears as a calcified mass with the radiodensity of tooth structure, which is also surrounded by a narrow radiolucent rim. An unerupted

dentlearn.ir

• **Fig. 15.114 Complex Odontoma.** A large radiopaque mass is overlying the crown of the mandibular right second molar, which has been displaced to the inferior border of the mandible.

• **Fig. 15.115 Compound Odontoma.** Surgical specimen consisting of more than 20 malformed toothlike structures.

• **Fig. 15.116 Complex Odontoma.** This decalcified section shows a disorganized mass of dentin intermixed with small pools of enamel matrix.

tooth is frequently associated with the odontoma, and the odontoma prevents eruption of the tooth (Fig. 15.114). Some small odontomas are present between the roots of erupted teeth and are not associated with disturbance in eruption. The radiographic findings are usually diagnostic, and the compound odontoma is seldom confused with any other lesion. A developing odontoma may show little evidence of calcification and appear as a circumscribed radiolucent lesion. A complex odontoma, however, may be radiographically confused with an osteoma or some other highly calcified bone lesion.

Histopathologic Features

The compound odontoma consists of multiple structures resembling small, single-rooted teeth, contained in a loose fibrous matrix (Fig. 15.115). The mature enamel caps of the toothlike structures are lost during decalcification for preparation of the microscopic section, but varying amounts of enamel matrix are often present. Pulp tissue may be seen in the coronal and root portions of the toothlike structures. In patients with developing odontomas, structures that resemble tooth germs are present.

Complex odontomas consist largely of mature tubular dentin. This dentin encloses clefts or hollow circular structures that contained the mature enamel that was removed during decalcification. The spaces may contain small amounts of enamel matrix or immature enamel (Fig. 15.116). Small islands of eosinophilic-staining epithelial ghost cells are present in about 20% of complex odontomas. These may represent remnants of odontogenic epithelium that have undergone keratinization and cell death from the local anoxia. A thin layer of cementum is often present about the periphery of the mass. Occasionally, a dentigerous cyst may arise from the epithelial lining of the fibrous capsule of a complex odontoma.

Treatment and Prognosis

Odontomas are treated by simple local excision, and the prognosis is excellent.

dentlearn.ir

◆ PRIMORDIAL ODONTOGENIC TUMOR

The primordial odontogenic tumor is the most recent addition to the spectrum of odontogenic neoplasms, being first identified as a distinct entity in 2014. Previously these rare lesions were categorized as an unusual example of ameloblastic fibroma, myxoma, or central odontogenic fibroma. As more cases were documented over the years, it became apparent that this tumor was unique and deserved to be recognized in its own right.

Clinical and Radiographic Features

The primordial odontogenic tumor typically affects patients in the first or second decade of life, presenting as a firm, painless swelling of the posterior mandible, or less commonly, maxilla. Radiographically, the lesion appears as an expansile, unilocular or bilocular, well-demarcated radiolucency that is associated with the crown of a posterior tooth (Fig. 15.117), although sometimes the tooth appears to be completely contained within the lesion. The 3rd molars and primary molars are affected most frequently. Some of these tumors attain significant size, with the greatest dimension ranging from 1.5 to 9.0 cm.

Histopathologic Features

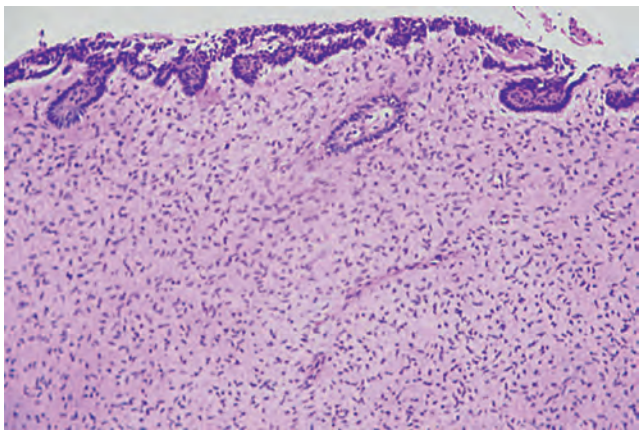
Microscopically the primordial odontogenic tumor is usually encapsulated, and the bulk of the lesion consists of sheets of myxoid to cellular ectomesenchymal tissue that often has a lobulated or undulating periphery. The edge of the tumor is lined by a thin layer of cuboidal to columnar epithelium that resembles the inner enamel epithelium of a developing tooth (Fig. 15.118). Stellate reticulum-like differentiation adjacent to the columnar epithelium has been described in half of reported cases. In some instances, this epithelium may be somewhat more prominent, dipping between the ectomesenchymal lobules of the tumor. Occasionally eosinophilic mineralized tissue that has been described as "enameloid" in appearance is identified in the lesion, as well as basophilic calcifications that resemble enamel matrix.

Treatment and Prognosis

Enucleation or conservative excision, including the involved tooth, has been the preferred treatment, and this appears to be curative despite the relatively large size of some primordial odontogenic tumors. To date, of the 24 reported cases of this tumor, only one has recurred.

TUMORS OF ODONTOGENIC ECTOMESENCHYME

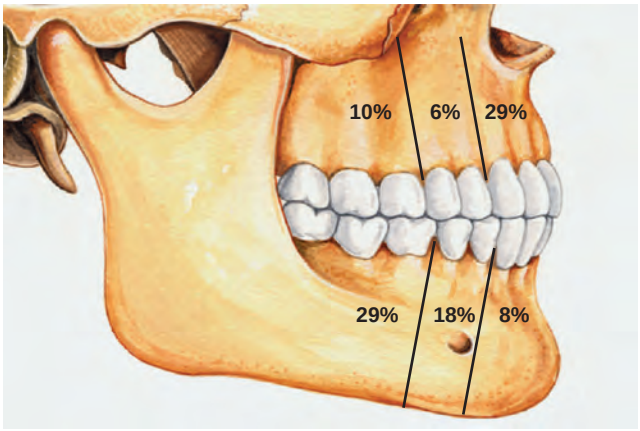
◆ CENTRAL ODONTOGENIC FIBROMA



The **central odontogenic fibroma** is an uncommon and somewhat controversial lesion. Approximately 235 examples have been reported. Formerly, some oral and maxillofacial pathologists designated solid fibrous masses that were almost always associated with the crown of an unerupted tooth as *odontogenic fibromas.* Most oral and maxillofacial pathologists today consider such lesions to represent only hyperplastic dental follicles, and these should not be considered to be neoplasms.

Clinical and Radiographic Features

Odontogenic fibromas have been reported in patients whose ages ranged from 3 to 77 years (mean age, 33 years). Of those cases reported in the literature, a 1.35:1.0 female-to-male ratio has been noted, indicating a strong female predilection. The maxilla and mandible are affected nearly equally, with most maxillary lesions located anterior to the first molar



• **Fig. 15.117 Primordial Odontogenic Tumor.** Panoramic radiograph depicting a large demarcated radiolucency involving the left posterior mandible and ramus. dentlearn.ir

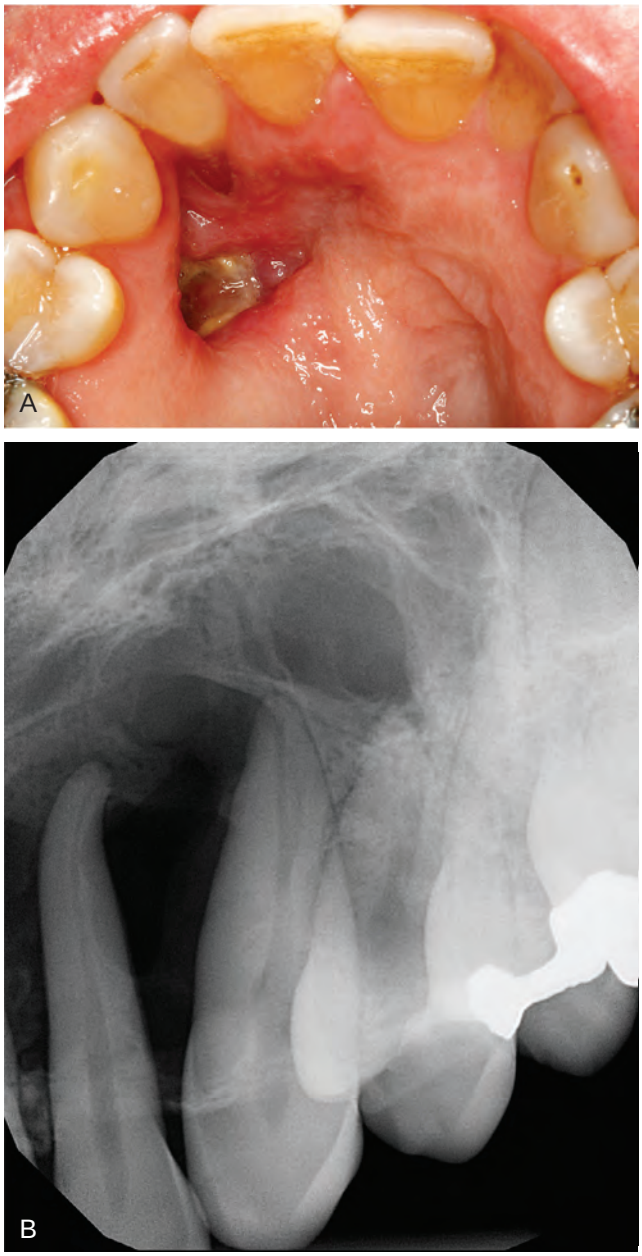
• **Fig. 15.119 Odontogenic Fibroma**. Relative distribution of odontogenic fibroma in the jaws.



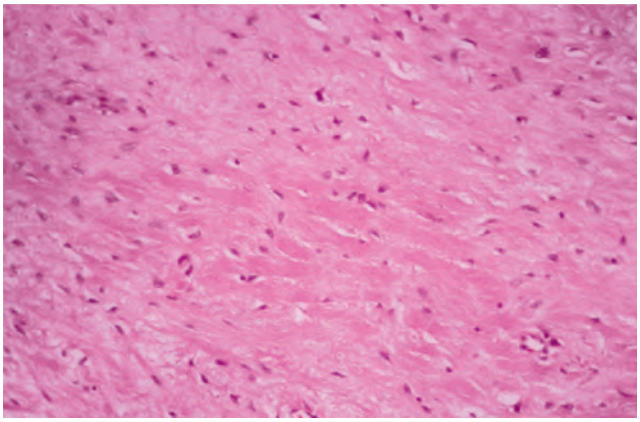
tooth (Fig. 15.119). In the mandible, however, about half of the tumors are located posterior to the first molar. A systematic review of odontogenic fibromas reported in the literature found that approximately 5% are associated with an unerupted tooth. Smaller odontogenic fibromas are usually completely asymptomatic; larger lesions may be associated with localized bony expansion or loosening of teeth. Interestingly, the palatal mucosa that overlies the tumor occasionally may exhibit a defect or groove.

Radiographically, smaller odontogenic fibromas tend to be well-defined, unilocular, radiolucent lesions often associated with the periradicular area of erupted teeth (Fig. 15.120). Larger lesions tend to be multilocular radiolucencies. Many lesions have a corticated border. Root resorption of associated teeth is common, and lesions located between the teeth often cause root divergence. Approximately 12% of central odontogenic fibromas will exhibit radiopaque flecks within the lesion.

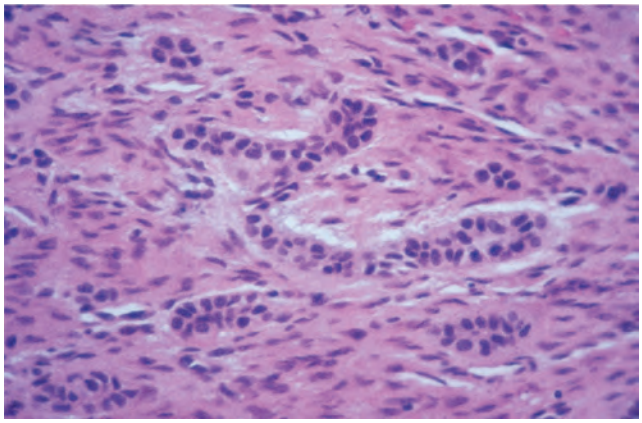
Histopathologic Features

Lesions reported as central odontogenic fibroma have shown considerable histopathologic diversity; in the past, this led some authors to describe two separate types, although this concept has been questioned. The simple type of odontogenic fibroma is rare, being composed of stellate fibroblasts, often arranged in a whorled pattern with fine collagen fibrils and considerable ground substance (Fig. 15.121). Small foci of odontogenic epithelial rests may be present. Spindle cell collagenous lesions that do not have epithelial rests may represent other entities, such as desmoplastic fibroma, myofibroma, or neurofibroma. Occasional foci of dystrophic calcification may be seen.

Epithelium-rich odontogenic fibromas (sometimes called WHO odontogenic fibromas) are more common and have a more complex pattern, which often consists of a fairly cellular fibrous connective tissue with collagen fibers arranged in interlacing bundles. Odontogenic epithelium in the form of long strands or isolated nests is present throughout the

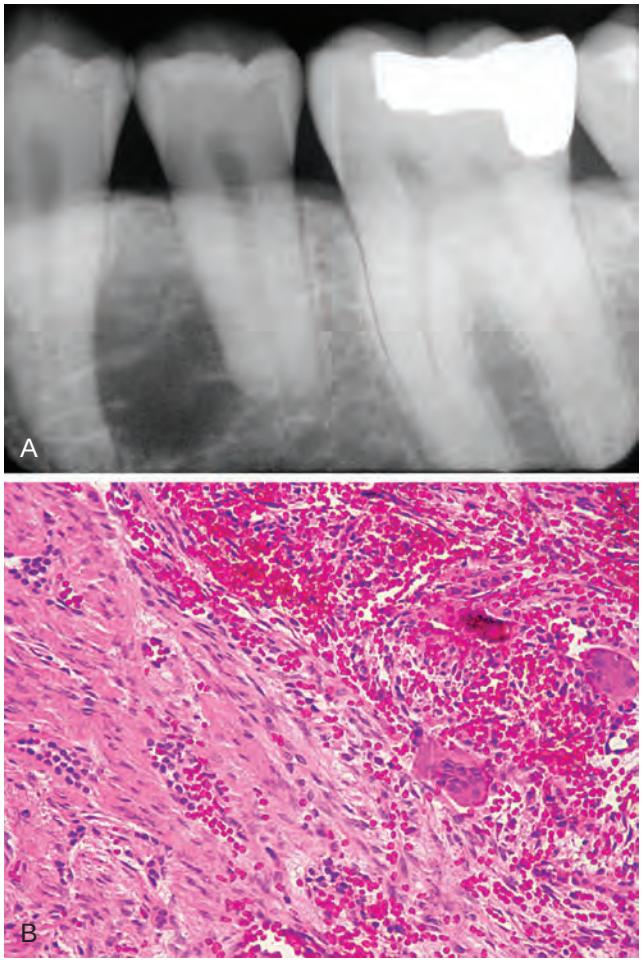


• **Fig. 15.120 Odontogenic Fibroma. A**, Clinical image showing a groove or defect in the palatal mucosa, a feature that has been described with maxillary lesions. **B,** Radiograph of this patient, depicting a multilocular radiolucency of the anterior maxilla. (Courtesy of Dr. Greg Adams.)



lesion and may be a prominent component (Fig. 15.122). The fibrous component may vary from myxoid to densely hyalinized.

Calcifications composed of cementum-like material or dentinoid are present in some cases. Focal deposits of odontogenic ameloblast-associated protein (ODAM), which represent a form of amyloid, have been described in a few central odontogenic fibromas, and Langerhans cells are often identified in these lesions as well. The possibility that some of these lesions may have been reported as non-calcifying Langerhans cell-rich calcifying epithelial odontogenic tumors cannot be



dentlearn.ir

• **Fig. 15.121 Odontogenic Fibroma.** Simple type of odontogenic fibroma showing scattered fibroblasts within a collagenous background. No epithelial rests were found on multiple sections from this tumor.

• **Fig. 15.122 Odontogenic Fibroma.** Epithelium-rich variant showing a cellular fibroblastic proliferation containing narrow cords of odontogenic epithelium.

• **Fig. 15.123 Odontogenic Fibroma with Associated Giant Cell Granuloma. A,** Unilocular radiolucency between the left mandibular bicuspids. **B,** Microscopic examination reveals two distinct patterns. On the left, one can see cords of odontogenic epithelium within a fibrous background, consistent with odontogenic fibroma. Typical features of central giant cell granuloma are present on the right side of the field.

excluded. Approximately 40 examples of central odontogenic fibroma associated with a **giant cell granuloma**–like component have been reported since 1992 (Fig. 15.123). It seems unlikely that this process represents a "collision" tumor with synchronous occurrence of an odontogenic fibroma and a giant cell granuloma. Several of these lesions have recurred, and the recurrences typically exhibit both components. Whether the odontogenic fibroma somehow induced a giant cell response in these patients, a giant cell granuloma triggered formation of an odontogenic fibroma, or whether this is a distinct biphasic lesion remains to be clarified.

Treatment and Prognosis

Odontogenic fibromas are usually treated by enucleation and vigorous curettage. Although the tumor does not have a definite capsule, it appears to have a limited growth potential, particularly in the anterior regions of the jaws. A few recurrences have been documented, but the prognosis is very good.

◆ PERIPHERAL ODONTOGENIC FIBROMA

The relatively uncommon **peripheral odontogenic fibroma** is considered to represent the soft tissue counterpart of the **central (intraosseous) odontogenic fibroma.** In the past, some authors have designated clinically and histopathologically similar lesions as **odontogenic epithelial hamartoma** or as **peripheral fibroameloblastic dentinoma.** It is likely that all of these terms refer to the same lesion, and peripheral odontogenic fibroma seems to be the most appropriate designation. A few series of this lesion have been reported in the past three decades, bringing the total number of cases in the literature to over 420.

Clinical and Radiographic Features

The peripheral odontogenic fibroma appears as a firm, slow-growing, and usually sessile gingival mass covered by normal-appearing mucosa (Fig. 15.124). Rarely, multifocal or diffuse

dentlearn.ir

lesions have been described. Clinically, the peripheral odontogenic fibroma cannot be distinguished from the much more common fibrous gingival lesions (see Chapter 12). The lesion is most often encountered on the facial gingiva of the mandible. Most lesions are between 0.5 and 1.5 cm in diameter, and they infrequently cause displacement of the teeth. Peripheral odontogenic fibromas have been recorded in patients across a wide age range, with most identified from the second to the fourth decades of life.

Radiographic studies demonstrate a soft tissue mass, which in some cases has shown areas of calcification. The lesion typically does not involve the underlying bone, although occasionally a "cupped out" appearance has been noted. Rarely resorption caused by the tumor, affecting either the root or crown of the adjacent tooth, can be seen radiographically.

Histopathologic Features

The peripheral odontogenic fibroma shows similar histopathologic features to the central odontogenic fibroma (WHO type). The tumor consists of interwoven fascicles of cellular fibrous connective tissue, which may be interspersed with areas of less cellular, myxoid connective tissue. A granular cell change has been rarely identified in the connective tissue component, and giant cell granuloma–like areas have been described in a few lesions. Islands or strands of odontogenic epithelium are scattered throughout the connective tissue. These may be prominent or scarce. The epithelial cells may show vacuolization. Dysplastic dentin, amorphous ovoid cementum-like calcifications, and trabeculae of osteoid may also be present.

Treatment and Prognosis

The peripheral odontogenic fibroma is treated by local surgical excision, and the prognosis is good. Recurrence of this lesion has been documented, however, so the patient and clinician should be aware of this possibility.

• **Fig. 15.124 Peripheral Odontogenic Fibroma.** This sessile gingival mass cannot be clinically distinguished from the common peripheral ossifying fibroma. (Courtesy of Dr. Jerry Stovall.)

◆ GRANULAR CELL ODONTOGENIC TUMOR (GRANULAR CELL ODONTOGENIC FIBROMA)

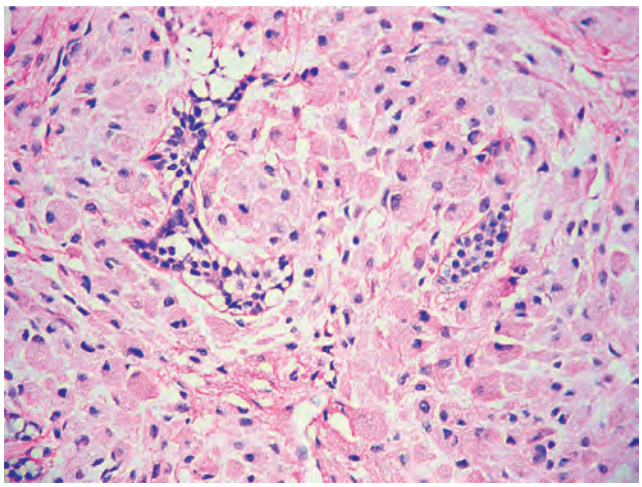
The rare **granular cell odontogenic tumor** was initially reported as "granular cell ameloblastic fibroma." Subsequently, it was designated as **granular cell odontogenic fibroma,** although the authors prefer the noncommittal term **granular cell odontogenic tumor**. Approximately 40 cases of this unusual neoplasm have been reported.

Clinical and Radiographic Features

Patients with granular cell odontogenic tumors have all been adults at the time of diagnosis, with more than half being older than 40 years of age. More than 70% of the cases have developed in women. The tumor occurs primarily in the mandible and most often in the premolar and molar region. Some lesions are completely asymptomatic; others present as a painless, localized expansion of the affected area. A few cases of granular cell odontogenic tumor have been described in the gingival soft tissues as well.

Radiographically, the lesion appears as a well-demarcated radiolucency, which may be unilocular or multilocular and occasionally shows small calcifications (Fig. 15.125).

Histopathologic Features



The granular cell odontogenic tumor is composed of large eosinophilic granular cells, which closely resemble the granular cells seen in the soft tissue granular cell tumor (see page 544) or the granular cells seen in the granular cell variant of the ameloblastoma (see page 711). Narrow cords or small islands of odontogenic epithelium are scattered among the granular cells (Fig. 15.126). Small cementum-like or dystrophic calcifications associated with the granular cells have been seen in some lesions.

The nature of the granular cells is controversial. Ultrastructural studies reveal the features of mesenchymal cells, and bodies consistent with lysosomal structures have been

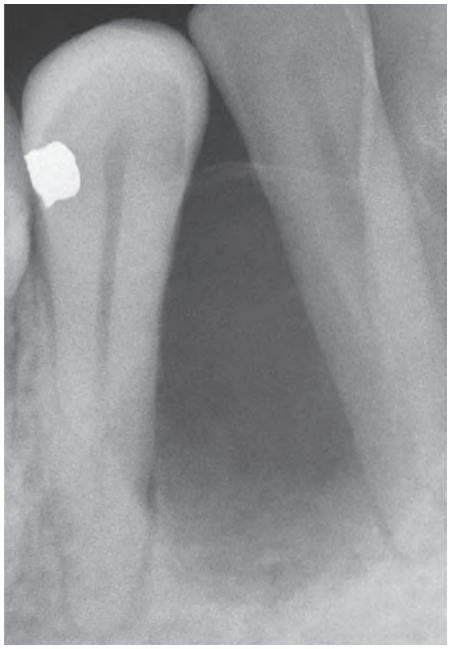
dentlearn.ir

• **Fig. 15.126 Granular Cell Odontogenic Tumor.** Sheet of large granular mesenchymal cells with small nests of odontogenic epithelium.

• **Fig. 15.127 Odontogenic Myxoma.** Relative distribution of odontogenic myxoma in the jaws.

identified within the lesional cell cytoplasm. Immunohistochemically, the granular cells in the granular cell odontogenic tumor do not react with antibodies directed against S-100 protein, in contrast to the positive S-100 reactivity of the granular cell tumor.

Treatment and Prognosis



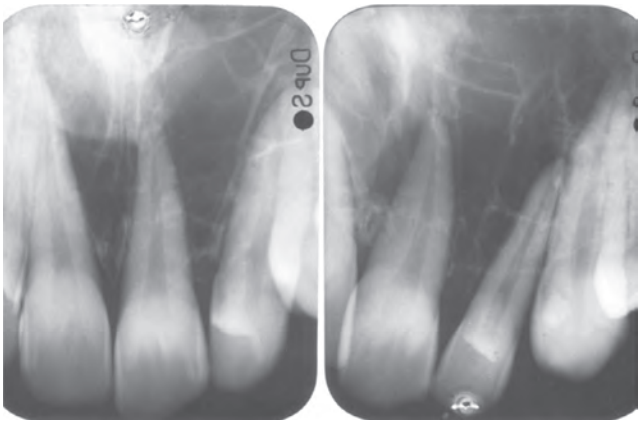
The granular cell odontogenic fibroma appears to be completely benign in the overwhelming majority of instances and responds well to curettage. Only one recurrence has been documented, and a solitary example of a malignant central granular cell odontogenic fibroma has been reported.

◆ ODONTOGENIC MYXOMA

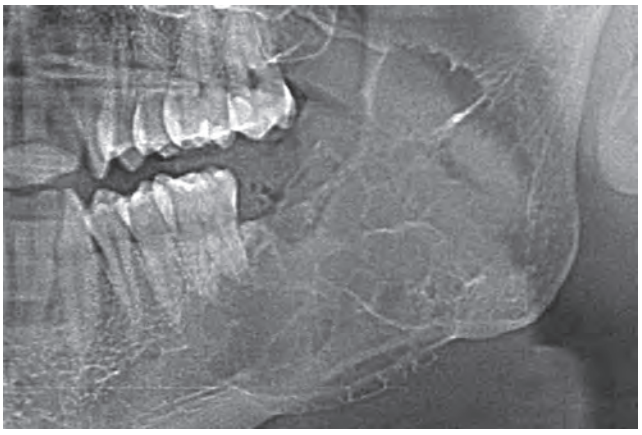
Myxomas of the jaws are believed to arise from odontogenic ectomesenchyme. They bear a close microscopic resemblance to the mesenchymal portion of a developing tooth. Formerly, some investigators made a distinction between **odontogenic myxomas** (derived from odontogenic mesenchyme) and **osteogenic myxomas** (presumably derived from primitive bone tissue). However, most authorities in orthopedic pathologic practice do not accept that myxomas occur in the extragnathic skeleton, and all myxomas of the jaws are currently considered to be of odontogenic origin.

Clinical and Radiographic Features

Myxomas are predominantly found in young adults but may occur across a wide age group. The average age for patients with myxomas is 25–30 years. Recent systematic reviews of the literature suggest a slight female sex predilection. The tumor may be found in almost any area of the jaws, and the mandible is involved more commonly than the maxilla (Fig. 15.127). Smaller lesions may be asymptomatic and are discovered only during a radiographic examination. Larger lesions are often associated with a painless expansion



• **Fig. 15.128 Odontogenic Myxoma.** Unilocular radiolucency between the right mandibular lateral incisor and cuspid.

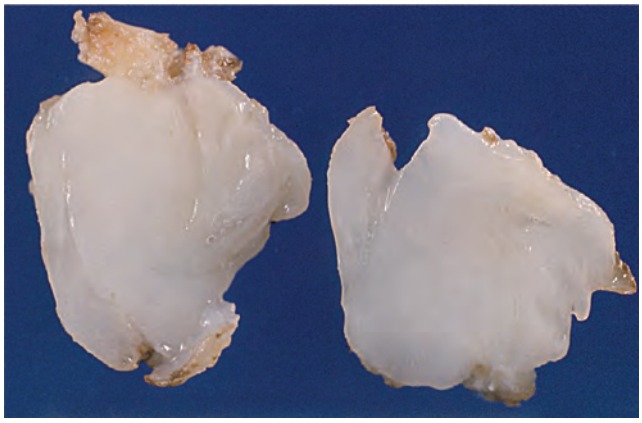


of the involved bone. In some instances, clinical growth of the tumor may be rapid; this is probably related to the accumulation of myxoid ground substance in the tumor.

Radiographically, the myxoma appears as a unilocular or multilocular radiolucency that may displace or cause resorption of teeth in the area of the tumor (Fig. 15.128). The margins of the radiolucency are often irregular or scalloped. The radiolucent defect may contain thin, wispy trabeculae of residual bone, which are often arranged at right angles to one another (Fig. 15.129). Large myxomas of the mandible may show a "soap bubble" radiolucent pattern, which is indistinguishable from that seen in ameloblastomas (Fig. 15.130). In addition, a few large odontogenic myxomas have been reported as having a "sun-burst" or "sun-ray"

dentlearn.ir

• **Fig. 15.129 Odontogenic Myxoma.** Radiolucent lesion of anterior maxilla showing fine residual bone trabeculae arranged at right angles to one another ("stepladder" pattern).



• **Fig. 15.130 Odontogenic Myxoma.** Multilocular expansile radiolucency of the posterior mandible. (Courtesy of Dr. Robert Pulliam.)

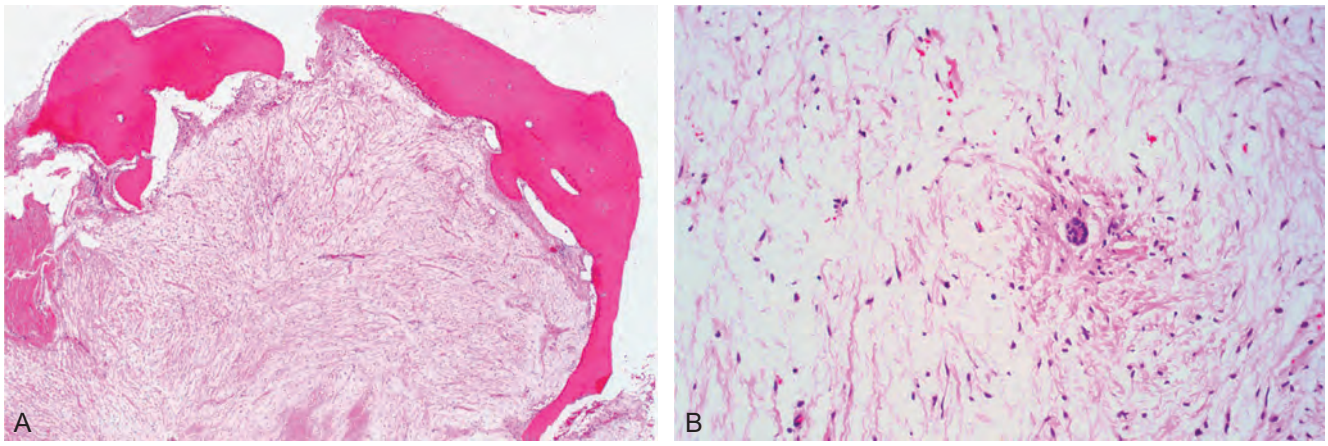
radiographic appearance that mimics osteosarcoma radiographically.

Histopathologic Features

At the time of surgery or gross examination of the specimen, the gelatinous, loose structure of the myxoma is obvious (Fig. 15.131). Microscopically, the tumor is composed of haphazardly arranged stellate, spindle-shaped, and round cells in an abundant, loose myxoid stroma that contains only a few collagen fibrils (Fig. 15.132). Histochemical study shows that the ground substance is composed of glycosaminoglycans, chiefly hyaluronic acid and chondroitin sulfate. Immunohistochemically, the myxoma cells show diffuse immunoreactivity with antibodies directed against vimentin, with some cases having focal reactivity for muscle-specific actin. Small islands of inactive-appearing odontogenic epithelial rests may be scattered throughout the myxoid ground substance. These epithelial rests are not required for the diagnosis and are not obvious in most cases. In some patients, the tumor may have a greater

• **Fig. 15.131 Odontogenic Myxoma.** Gross specimen of case shown in Fig. 15.128, demonstrating a white gelatinous mass.

tendency to form collagen fibers; such lesions are sometimes designated as **fibromyxomas** or **myxofibromas.** There is no evidence that the more collagenized variants deserve separate consideration, although some investigators have suggested that these may represent part of a spectrum that includes the central odontogenic fibroma at the other endpoint. Myxomas may rarely exhibit cementum-like calcifications.



A myxoma may be microscopically confused with other myxoid jaw neoplasms, such as the rare chondromyxoid fibroma (see page 661) or the myxoid neurofibroma (see page 534). Chondromyxoid fibroma should have areas of cartilaginous differentiation, whereas myxoid neurofibromas tend to have areas in which lesional cells are arranged in vague fascicles, as well as scattered cells that are positive for antibodies directed against S-100 protein. Myxoid change in an enlarged dental follicle or the dental papilla of a developing tooth may be microscopically similar to a myxoma. Evaluation of the clinical and radiographic features, however, prevents overdiagnosis of these lesions as myxomas.

Another tumor that should be considered in the histopathologic differential diagnosis is the sinonasal myxoma, a lesion that has been recognized only in the past two decades. This lesion typically develops in the first 2 years of life, presenting as a swelling of the maxilla. A unilocular or multilocular radiolucency is seen with imaging studies. Microscopically, the tumor appears very similar to odontogenic myxoma; however, a few sinonasal myxomas have been reported to show positivity for antibodies directed against β-catenin immunohistochemically, unlike odontogenic myxoma. It should also be noted that odontogenic myxomas are exceedingly rare in the first decade of life.

Treatment and Prognosis

Small myxomas are generally treated by curettage, but careful periodic reevaluation is necessary for at least 5 years. For larger lesions, more extensive resection may be required

dentlearn.ir

• **Fig. 15.132 Odontogenic Myxoma. A,** A loose, myxomatous tumor can be seen filling the marrow space between the bony trabeculae. **B,** Higher-power view showing loosely arranged spindle cells and fine collagen fibrils. A small odontogenic epithelial rest is seen in the center of the image.

because myxomas are not encapsulated and tend to infiltrate the surrounding bone. Complete removal of a large tumor by curettage is often difficult to accomplish, and lesions of the posterior maxilla, in particular, should be treated more aggressively in most instances. Recurrence rates from various studies average approximately 25%. In spite of local recurrences, the overall prognosis is good, and metastases do not occur.

In rare cases the myxoma microscopically shows marked cellularity and cellular atypism. Some have designated these lesions as *myxosarcomas* or *malignant odontogenic myxoma.* They appear to have a more aggressive local course than do the usual myxomas. Death because of involvement of vital structures by the tumor has been described, but distant metastases have not been reported.

◆ CEMENTOBLASTOMA ("TRUE CEMENTOMA")

Many oral and maxillofacial pathologists consider the **cementoblastoma** to represent an odontogenic tumor. However, other pathologists have pointed out that the histopathologic features of cementoblastomas of the jaws are identical to those of a bone tumor, osteoblastoma, seen both in the jaws and extragnathic skeleton. Cementoblastomas are discussed in Chapter 14 (see page 659).

16 Dermatologic Diseases

◆ ECTODERMAL DYSPLASIA

Ectodermal dysplasia represents a group of inherited conditions in which two or more ectodermally derived anatomic structures fail to develop. Thus depending on the type of ectodermal dysplasia, hypoplasia or aplasia of tissues (e.g., skin, hair, nails, teeth, and sweat glands) may be seen. The various types of this disorder may be inherited in any one of several genetic patterns, including autosomal dominant, autosomal recessive, and X-linked patterns. Even though by some accounts almost 200 different subtypes of ectodermal dysplasia can be defined, these disorders are considered to be relatively rare, with an estimated frequency of seven cases occurring in every 10,000 births. For fewer than 50% of these conditions, the specific genetic mutations and their chromosomal locations have been identified. Systematically classifying these conditions can be challenging because of their wide-ranging clinical features; however, some investigators have suggested that a classification scheme based on the molecular genetic alteration associated with each type might be appropriate. Thus groups of ectodermal dysplasia syndromes could be categorized as being caused by mutations in genes encoding cell-cell signals, genes encoding adhesion molecules, or genes regulating transcription.

Clinical Features

Perhaps the best known of the ectodermal dysplasia syndromes is **hypohidrotic ectodermal dysplasia**. In most instances, this disorder seems to show an X-linked inheritance pattern, with the gene mapping to Xq12-q13.1; therefore, a male predominance is usually seen. However, a few families have been identified that show autosomal recessive or autosomal dominant patterns of inheritance.

Affected individuals typically display heat intolerance because of a reduced number of eccrine sweat glands. Sometimes the diagnosis is made during infancy because the baby appears to have a fever of undetermined origin; however, the infant simply cannot regulate body temperature appropriately because of the decreased number of sweat glands. Uncommonly, death results from the markedly elevated body temperature, although this generally happens only when the condition is not identified. Sometimes, as a diagnostic aid, a special impression can be made of the patient's fingertips and then examined microscopically to count the density of the sweat glands. Such findings should be interpreted in conjunction with appropriate age-matched controls.

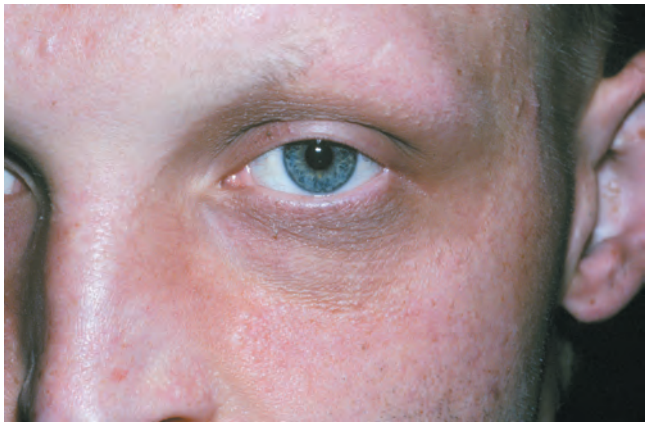
Other signs of this disorder include fine, sparse hair, including a reduced density of eyebrow and eyelash hair (Fig. 16.1). The periocular skin may show a fine wrinkling with hyperpigmentation (Fig. 16.2), and midface hypoplasia is frequently observed, often resulting in protuberant lips. Because the salivary glands are ectodermally derived, these glands may be hypoplastic or absent, and patients may exhibit varying degrees of xerostomia. The nails may also appear dystrophic and brittle.

The teeth are usually markedly reduced in number **(oligodontia** or **hypodontia),** and their crown shapes are characteristically abnormal (Fig. 16.3). The incisor crowns usually appear tapered, conical, or pointed, and the molar crowns are reduced in diameter. Complete lack of tooth development **(anodontia)** has also been reported, but this appears to be uncommon.

Female patients may show partial expression of the abnormal gene; that is, their teeth may be reduced in number or may have mild structural changes. This incomplete presentation can be explained by the **Lyon hypothesis,** with half of the female patient's X chromosomes expressing the normal gene, and the other half expressing the defective gene.

Histopathologic Features

Histopathologic examination of the skin from a patient with hypohidrotic ectodermal dysplasia shows a decreased number of sweat glands and hair follicles. The adnexal structures that are present are hypoplastic and malformed.



Treatment and Prognosis

Management of hypohidrotic ectodermal dysplasia warrants genetic counseling for the parents and the patient. The dental problems are best managed by a team of dental specialists, including prosthodontists, orthodontists, and oral and maxillofacial surgeons. Treatment options include prosthetic replacement of the dentition with complete dentures, overdentures, or fixed appliances, depending on the number and location of the remaining teeth. With careful site selection, endosseous dental implants may be considered for facilitating prosthetic management of patients older than 6 years of age. Orthognathic surgery may be necessary to correct skeletal

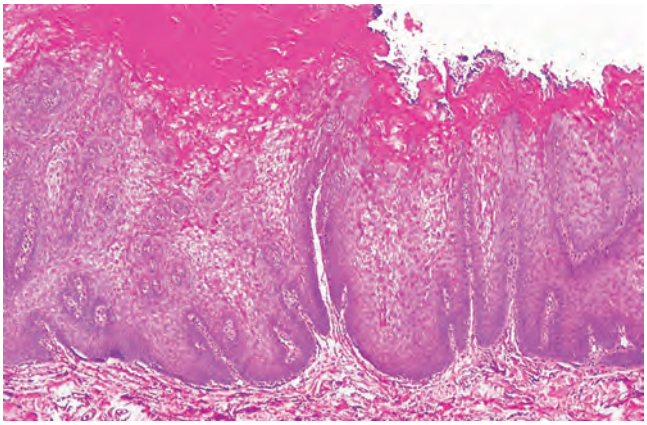
discrepancies of the jaws, and orthodontic movement of the existing teeth may benefit the placement and function of fixed or removable prostheses.

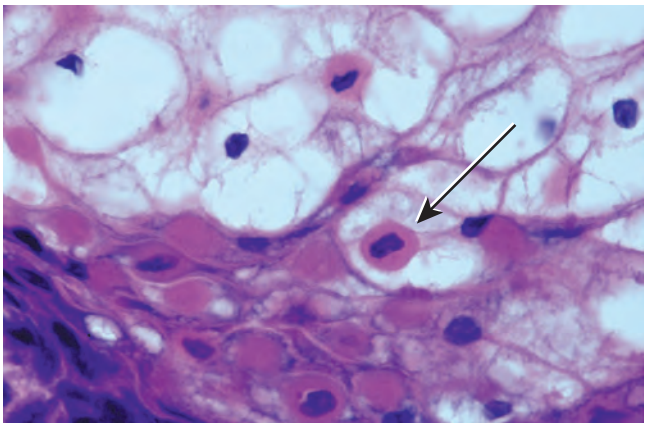
◆ WHITE SPONGE NEVUS (CANNON DISEASE)

White sponge nevus is a relatively rare genodermatosis (a genetically determined skin disorder) that is inherited as an autosomal dominant trait displaying a high degree of penetrance and variable expressivity. This condition is due to a defect in the normal keratinization of the oral mucosa. In the 30-member family of keratin filaments, the pair of keratins known as *keratin 4* and *keratin 13* is specifically expressed in the spinous cell layer of mucosal epithelium. Mutations in either of these keratin genes have been shown to be responsible for the clinical manifestations of white sponge nevus.

• **Fig. 16.3 Ectodermal Dysplasia.** Oligodontia and conical crown forms are typical oral manifestations. (Courtesy of Dr. Charles Hook and Dr. Bob Gellin.)



• **Fig. 16.4 White Sponge Nevus.** Diffuse, thickened white plaques of the buccal mucosa.

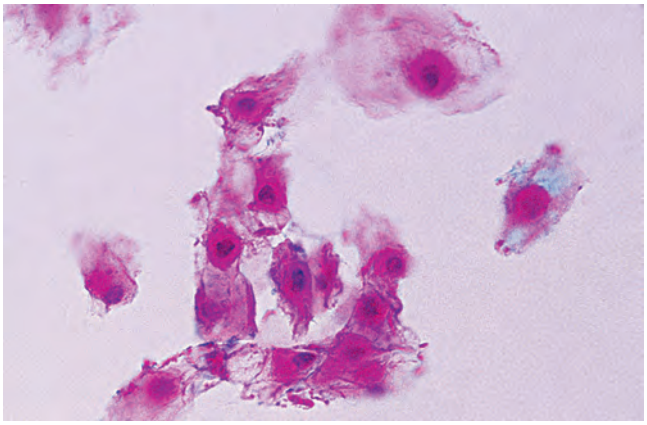


Clinical Features

The lesions of white sponge nevus usually appear at birth or in early childhood, but sometimes the condition develops during adolescence. Symmetrical, thickened, white, corrugated or velvety, diffuse plaques affect the buccal mucosa bilaterally in most instances (Fig. 16.4). Other common intraoral sites of involvement include the ventral tongue, labial mucosa, soft palate, alveolar mucosa, and floor of the mouth, although the extent of involvement can vary from patient to patient. Extraoral mucosal sites, such as the nasal, esophageal, laryngeal, and anogenital mucosa, appear to be less commonly affected. Patients are usually asymptomatic.

dentlearn.ir

• **Fig. 16.5 White Sponge Nevus.** This low-power photomicrograph shows prominent hyperparakeratosis, marked thickening (acanthosis), and vacuolation of the spinous cell layer.



• **Fig. 16.6 White Sponge Nevus.** This high-power photomicrograph shows vacuolation of the cytoplasm of the cells of the spinous layer, with no evidence of epithelial atypia. Perinuclear condensation of keratin tonofilaments can also be observed in some cells.

Histopathologic Features

The microscopic features of white sponge nevus are characteristic but not necessarily pathognomonic. Prominent hyperparakeratosis and marked acanthosis with clearing of the cytoplasm of the cells in the spinous layer are common features (Figs. 16.5 and 16.6); however, similar microscopic findings may be associated with leukoedema and hereditary benign intraepithelial dyskeratosis (HBID). In some instances, an eosinophilic condensation is noted in the perinuclear region of the cells in the superficial layers of the epithelium, a feature that is unique to white sponge nevus. Ultrastructurally, this condensed material can be identified as tangled masses of keratin tonofilaments.

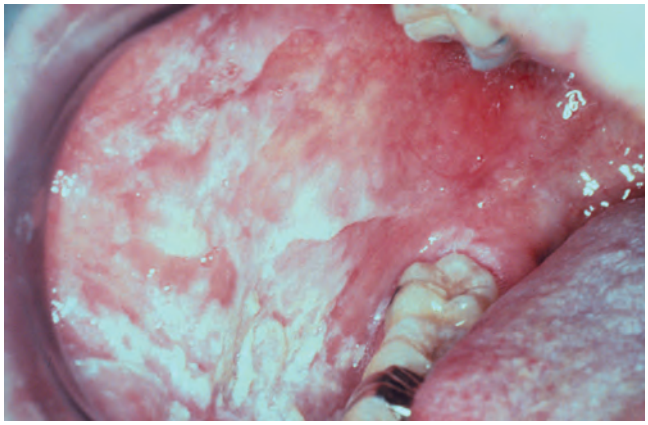
Exfoliative cytologic studies may provide more definitive diagnostic information. A cytologic preparation stained with the Papanicolaou method often shows the eosinophilic perinuclear condensation of the epithelial cell cytoplasm to a greater extent than does the histopathologic section (Fig. 16.7).

• **Fig. 16.7 White Sponge Nevus.** This high-power photomicrograph of a Papanicolaou-stained cytologic preparation shows the pathognomonic perinuclear condensation of keratin tonofilaments.

Treatment and Prognosis

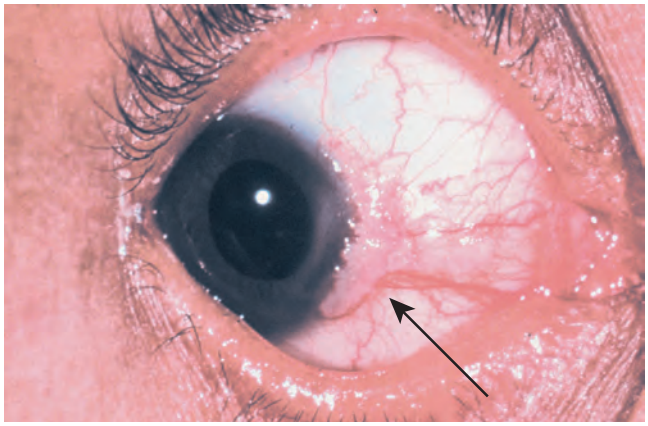
Because this is a benign condition, no treatment is necessary. The prognosis is good.

◆ HEREDITARY BENIGN INTRAEPITHELIAL DYSKERATOSIS (WITKOP-VON SALLMANN SYNDROME)



Hereditary benign intraepithelial dyskeratosis (HBID) is a rare autosomal dominant genodermatosis primarily affecting descendants of a triracial isolate (Native American, black, and white) of people who originally lived in North Carolina. Examples of HBID have sporadically been reported from other areas of the United States because of migration of affected individuals, and descriptions of affected patients with no apparent connection to North Carolina have also appeared in the literature.

Clinical Features



The lesions of HBID usually develop during childhood, in most instances affecting the oral and conjunctival mucosa. The oral lesions are similar to those of white sponge nevus, with both conditions showing thick, corrugated white plaques involving the buccal and labial mucosa (Fig. 16.8). Milder cases may exhibit the opalescent appearance of leukoedema. Other oral mucosal sites, such as the floor of the mouth and lateral tongue, may also be affected. These oral lesions may exhibit a superimposed candidal infection as well.

The most interesting feature of HBID is the ocular lesions, which begin to develop very early in life. These appear as thick, opaque, gelatinous plaques affecting the bulbar conjunctiva adjacent to the cornea (Fig. 16.9) and sometimes involving the cornea itself. When the lesions are active, patients may experience tearing, photophobia, and itching of the eyes. In many patients, the plaques are most prominent in the spring and tend to regress during the summer or

dentlearn.ir

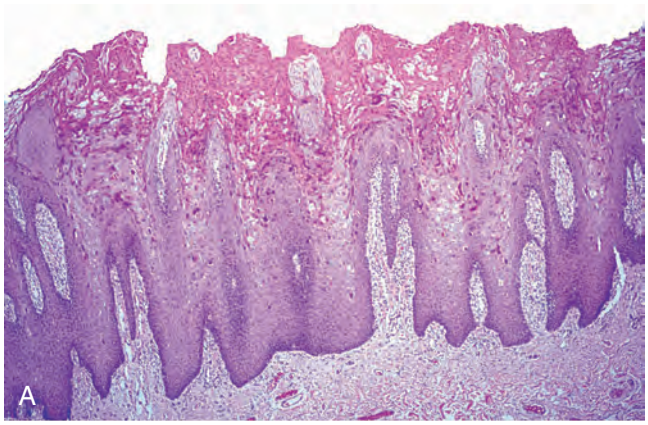
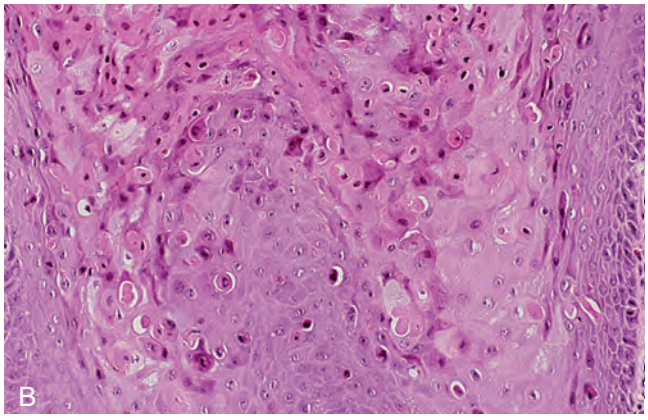
• **Fig. 16.9 Hereditary Benign Intraepithelial Dyskeratosis (HBID).** Ocular lesions appear as gelatinous plaques *(arrow)* of the bulbar conjunctivae. (Courtesy of Dr. Carl Witkop.)



autumn. Sometimes blindness may result from the induction of vascularity of the cornea secondary to the shedding process.



Histopathologic Features

The histopathologic features of HBID include prominent parakeratin production in addition to marked acanthosis. A peculiar dyskeratotic process, similar to that of Darier disease, is scattered throughout the upper spinous layer of the surface oral epithelium (Fig. 16.10). With this dyskeratotic process, an epithelial cell appears to be surrounded or engulfed by an adjacent epithelial cell, resulting in the so-called *cell-within-a-cell* phenomenon.

Treatment and Prognosis

Because HBID is a benign condition, no treatment is generally required or indicated for the oral lesions. If superimposed candidiasis develops, then an antifungal medication can be used. Patients with symptomatic ocular lesions should be referred to an ophthalmologist. Typically, the plaques that obscure vision must be surgically excised. This procedure, however, is recognized as a temporary measure because the lesions often recur.

• **Fig. 16.10 Hereditary Benign Intraepithelial Dyskeratosis (HBID). A,** Medium-power photomicrograph exhibiting hyperparakeratosis, acanthosis, and dyskeratosis. **B,** Higher magnification showing dyskeratotic cells.

◆ PACHYONYCHIA CONGENITA (JADASSOHN-LEWANDOWSKY TYPE; JACKSON-LAWLER TYPE)

Pachyonychia congenita is a group of rare genodermatoses that are usually inherited as an autosomal dominant trait, although a *de novo* mutation is seen in approximately 45% of affected patients. Mutations of genes that encode for keratin 6a, 6b, 6c, 16, or 17 are responsible for this condition, with different phenotypic expressions depending on the particular mutation. The nails, especially the toenails, are dramatically affected in most patients. Oral lesions are seen most frequently in patients who have mutation of the keratin 6a (*KRT6A*) gene, but can be found in a reduced percentage of the other keratin mutations. Throughout the world, approximately 5000–10,000 people are thought to have this condition. Historically, pachyonychia congenita has been divided into the Jadassohn-Lewandowsky type

dentlearn.ir

• **Fig. 16.11 Pachyonychia Congenita.** The nails often have a tubular configuration due to keratin accumulation beneath the nailbed.

(pachyonychia congenita, type 1) and the Jackson-Lawler type (pachyonychia congenita, type 2). It may be more appropriate, however, to categorize this group of disorders based on the specific keratin mutation that affects a particular patient.

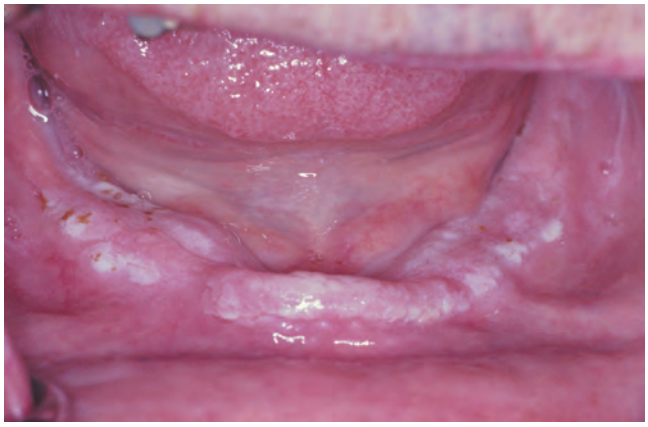
Clinical Features

Virtually all patients with pachyonychia congenita exhibit characteristic nail changes, either at birth or in the early neonatal period. The free margins of the nails are lifted up because of an accumulation of keratinaceous material in the nail beds. This results in a pinched, tubular configuration (Fig. 16.11). Ultimately, nail loss may occur.

Other skin changes that may occur include marked hyperkeratosis of the palmar and plantar surfaces, producing thick, callous-like lesions (Fig. 16.12). Hyperhidrosis of the palms and soles is also commonly present. The rest of the skin shows punctate papules, representing an abnormal accumulation of keratin in the hair follicles. One disabling feature of the syndrome is severe pain with walking, which is believed to be due to the formation of blisters beneath the thick calluses on the soles of the feet, although recent studies have suggested that neuropathic pain may be a contributing factor. Fissuring of the thickened plantar calluses can also occur and cause pain upon walking.

The oral lesions seen in pachyonychia congenita consist of thickened white plaques that involve the lateral margins and dorsal surface of the tongue. Other oral mucosal regions that are frequently exposed to mild trauma, such as the palate, buccal mucosa, and alveolar mucosa, may also be affected (Fig. 16.13). Neonatal teeth are seen in a majority of patients with mutations of the keratin 17 gene, but only one-third of these individuals have oral white lesions. The increased incidence in dental caries that is identified in these patients may be related to the impact that abnormal keratin proteins have on enamel structure. Hoarseness and dyspnea have been described in some patients as a result of laryngeal mucosal involvement.

• **Fig. 16.12 Pachyonychia Congenita.** The soles of the feet of affected patients typically show marked callus-like thickenings.



Histopathologic Features

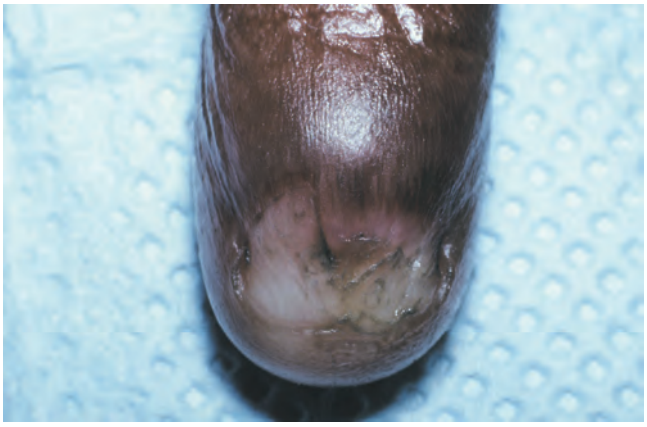
Microscopic examination of lesional oral mucosa shows marked hyperparakeratosis and acanthosis with perinuclear clearing of the epithelial cells.

Treatment and Prognosis

Because the oral lesions of pachyonychia congenita show no apparent tendency for malignant transformation, no treatment is required. The nails are often lost or may need to be surgically removed because of the deformity. In addition, the keratin accumulation on the palms and soles can be quite uncomfortable and distressing to many of the affected individuals. Most patients have to pay continuous attention to

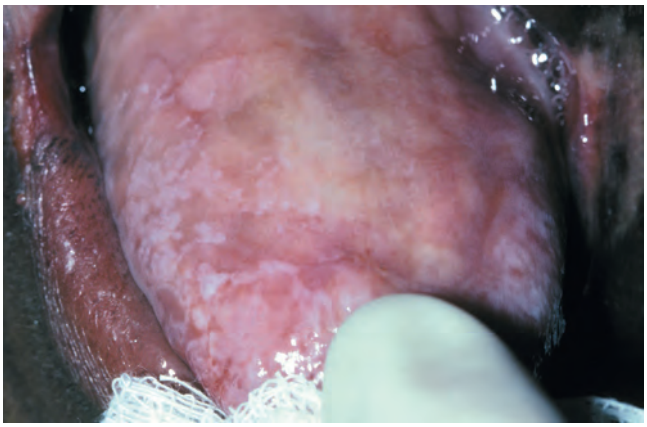
dentlearn.ir

• **Fig. 16.13 Pachyonychia Congenita.** Although tongue lesions are more common in patients with pachyonychia congenita, other oral mucosal sites exposed to minor trauma, such as the alveolar mucosa, may develop thickened white patches. (Courtesy of Dr. John Lenox.)



removal of the excess keratin, and issues related to quality of life often arise. If laryngeal involvement results in dyspnea, laser debulking may improve airway function. Oral retinoids may be of some benefit for select patients, but the dosage has to be carefully monitored in order to minimize medication side effects. Patients should receive genetic counseling, as an aid in family planning. Chorionic villus sampling can be used to identify the various keratin mutations associated with these disorders, thereby allowing prenatal diagnosis.

◆ DYSKERATOSIS CONGENITA (COLE-ENGMAN SYNDROME; ZINSSER-COLE-ENGMAN SYNDROME)



Dyskeratosis congenita is a rare genodermatosis that is usually inherited as an X-linked recessive trait, resulting in a striking male predilection. Autosomal dominant and autosomal recessive forms, although less common, have been reported. Mutations in the *DKC1* gene initially were determined to cause the X-linked form of dyskeratosis congenita. The mutated gene appears to disrupt the normal maintenance of telomerase, an enzyme that is critical in determining normal cellular longevity. Subsequently, mutations of 14 other genes responsible for telomere maintenance have been identified for the other inheritance patterns of dyskeratosis congenital, and the condition is now considered part of a spectrum of telomere biology disorders. The clinician should be aware of the condition because the oral lesions may undergo malignant transformation, and patients are susceptible to aplastic anemia.

Clinical Features

Dyskeratosis congenita usually becomes evident during the first 10 years of life. A reticular pattern of skin hyperpigmentation develops, affecting the face, neck, and upper chest. In addition, abnormal, dysplastic changes of the nails are evident at this time (Fig. 16.14).

• **Fig. 16.14 Dyskeratosis Congenita.** Dysplastic nail changes.

• **Fig. 16.15 Dyskeratosis Congenita.** Atrophy and hyperkeratosis of the dorsal tongue mucosa are visible.

Intraorally, the tongue and buccal mucosa develop bullae; these are followed by erosions and, eventually, leukoplakic lesions (Fig. 16.15). The leukoplakic lesions are considered to be premalignant, and approximately one-third of them become malignant in a 10- to 30-year period. The actual rate of transformation may be higher, but this may not be appreciated because of the shortened life span of these patients. Rapidly progressive periodontal disease has been reported sporadically.

Thrombocytopenia is usually the first hematologic problem that develops, typically during the second decade of life, followed by anemia. Ultimately, aplastic anemia develops in approximately 80% of these patients (see page 586). Mild to moderate intellectual disability may also be present. Generally, the autosomal recessive and X-linked recessive forms show a more severe pattern of disease expression.

Histopathologic Features

Biopsy specimens of the early oral mucosal lesions show hyperorthokeratosis with epithelial atrophy. As the lesions progress, epithelial dysplasia develops until frank squamous cell carcinoma evolves.

dentlearn.ir

Treatment and Prognosis

The discomfort of the oral lesions is managed symptomatically, and careful periodic oral mucosal examinations are performed to check for evidence of malignant transformation. Routine medical evaluation is warranted to monitor the patient for the development of aplastic anemia. Certain anabolic steroids have been shown to increase telomerase activity, and treatment with these drugs may result in temporary improvement in the hematologic status. Bone marrow failure ultimately ensues, however. Selected patients may be considered for allogeneic hematopoietic stem cell transplantation once the aplastic anemia is identified.

As a result of these potentially life-threatening complications, the prognosis is guarded. The average life span for the more severely affected patients is 32 years of age. The parents and the patient should receive genetic counseling.

◆ XERODERMA PIGMENTOSUM

Xeroderma pigmentosum is a rare genodermatosis in which numerous cutaneous malignancies develop at a very early age. The prevalence of the condition in the United States is estimated to be 1 in 250,000–500,000. The condition is inherited as an autosomal recessive trait and is caused by one of several defects in the excision repair and/or postreplication repair mechanism of DNA. As a result of the inability of the epithelial cells to repair ultraviolet (UV) light-induced damage, mutations in the epithelial cells occur, leading to the development of nonmelanoma skin cancer at a rate 10,000 times what would normally be expected in people younger than 20 years of age.

Clinical Features

During the first few years of life, patients affected by xeroderma pigmentosum show a markedly increased tendency to sunburn. Skin changes, such as atrophy, freckled pigmentation, and patchy depigmentation, soon follow (Fig. 16.16). In early childhood, **actinic keratoses** begin developing, a process that normally does not take place before 40 years of age. These lesions quickly progress to **squamous cell carcinoma,** with **basal cell carcinoma** also appearing; consequently, in most patients a nonmelanoma skin cancer develops during the first decade of life. Melanoma develops in about 5% of patients with xeroderma pigmentosum, but it evolves at a slightly later time. As a consequence of sun exposure, the head and neck region is the site most frequently affected by these cutaneous malignancies. Neurologic degenerative changes occur in 20% to 30% of affected patients and include subnormal intelligence, ataxia, sensorineural deafness, and impaired eyesight. The precise cause for the neurologic problems is currently unclear.

Oral manifestations, which often occur before 20 years of age, include development of **squamous cell carcinoma** of the lower lip and the tip of the tongue. This latter site is most unusual for oral cancer, and its involvement is again undoubtedly related to the increased sun exposure, however minimal, which this area receives in contrast to the rest of the oral mucosa.

• **Fig. 16.16 Xeroderma Pigmentosum.** The atrophic changes and pigmentation disturbances shown are characteristic of xeroderma pigmentosum.

The diagnosis of xeroderma pigmentosum is usually made when the patient is evaluated for the cutaneous lesions, because it is highly unusual for a very young person to have skin cancer. Because xeroderma pigmentosum is an autosomal recessive trait, a family history of the disorder is not likely to be present, but the possibility of a consanguineous relationship of the affected child's parents should be investigated.

Histopathologic Features

The histopathologic features of xeroderma pigmentosum are relatively nonspecific, in that the cutaneous premalignant lesions and malignancies that occur are microscopically indistinguishable from those observed in unaffected patients.

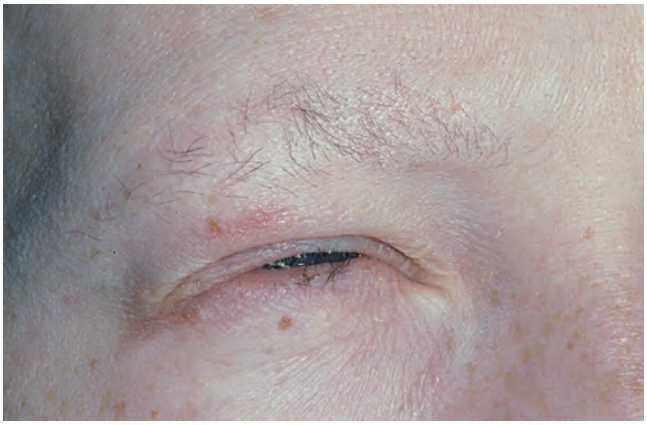
Treatment and Prognosis

Treatment of xeroderma pigmentosum is challenging because in most instances significant sun damage has already occurred by the time of diagnosis. Patients are advised to avoid sunlight and unfiltered fluorescent light and to wear appropriate protective clothing and sunscreens if they cannot avoid sun exposure. Because sunlight exposure is reduced, these patients often require vitamin D supplementation. Before receiving dental treatment, a calibrated UV light

dentlearn.ir

meter should be used to evaluate the amount of UV light being emitted from various sources in the dental office, such as the examination light, the radiograph view box, computer screens in the area, fiber-optic lights, or lights that are used for curing composite restorations. Some authors have suggested that any reading greater than 0 nm/cm^2 would be unacceptable. A dermatologist should evaluate the patient every 3 months to monitor the development of cutaneous lesions.

Topical chemotherapeutic agents (e.g., 5-fluorouracil or imiquimod) may be used to treat actinic keratoses. Nonmelanoma skin cancers should be excised conservatively, preferably with microscopically controlled excision (Mohs surgery) to preserve as much normal tissue as possible. Patients should also receive genetic counseling, because a high number of consanguineous marriages have been reported in some series.



The prognosis is still poor. Most patients die 30 years earlier than the normal population, either directly from cutaneous malignancy or from complications associated with the treatment of the cancer. The outlook is much better if patients adhere to a strict program of life-long UV light avoidance, but this can be difficult to achieve.

◆ HEREDITARY MUCOEPITHELIAL DYSPLASIA

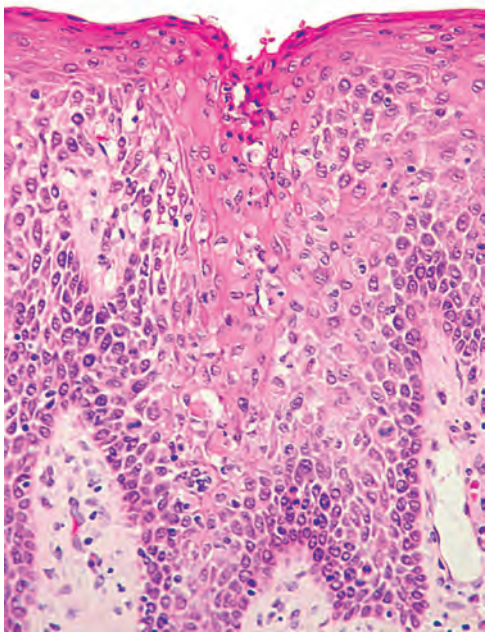
Hereditary mucoepithelial dysplasia is a rare disorder that may occur sporadically or may be inherited as an autosomal dominant trait; however, the precise genetic alteration is currently unknown. Approximately 60 cases have been reported, although affected patients may not be recognized due to the rarity of condition. For reasons that are not entirely understood, the mucosal epithelial cells do not develop in a normal fashion, and for this reason the designation of *dysplasia* has been given. However, in this situation, no increased risk of malignant transformation is seen. When a cervical exfoliative cytologic preparation (Pap smear) is done, the epithelial cells that are harvested may be interpreted as appearing cytologically unusual or atypical; in the past, some female patients have been advised to undergo hysterectomy because of this misinterpretation. Consequently, accurate identification of this disorder is extremely important for these patients.

Clinical Features

Hereditary mucoepithelial dysplasia is characterized by both cutaneous and mucosal abnormalities. Patients typically have sparse, coarse hair with nonscarring alopecia. Eyelashes and eyebrows are generally affected (Fig. 16.17). Severe photophobia develops at an early age, and most of these patients will have evidence of cataracts beginning in childhood or early adult life. Corneal vascularization, keratitis secondary to corneal erosions, cataracts, and nystagmus are also commonly described. As would be expected, vision is usually markedly impaired for these patients. Other skin manifestations include a prominent perineal rash that appears during infancy, as well as a widespread rough, dry texture because of follicular keratosis.

• **Fig. 16.17 Hereditary Mucoepithelial Dysplasia.** Sparse hair is noted on the eyebrows and eyelashes.

• **Fig. 16.18 Hereditary Mucoepithelial Dysplasia.** Marked erythema of the anterior hard palate.



Pulmonary complications related to mucoepithelial dysplasia can range in severity, presumably because of the degree of gene expression. In one family, cavitary bullae were reported to form within the lung parenchyma, and these led to recurrent bouts of pneumonia, often resulting in life-threatening complications.

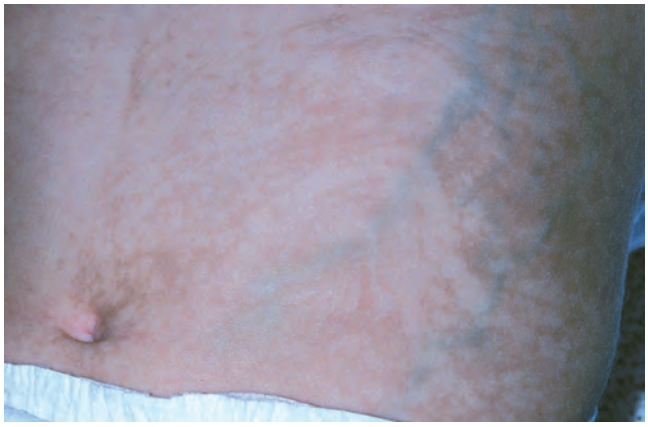
The oral manifestations of hereditary mucoepithelial dysplasia are usually quite striking, appearing as demarcated fiery-red erythema of the hard palate (Fig. 16.18), with generally less involvement of the attached gingivae and tongue mucosa. These mucosal alterations are typically asymptomatic, despite their remarkable clinical appearance. The nasal, conjunctival, vaginal, cervical, urethral, and bladder mucosa may have the same unusual erythematous features.

Histopathologic Features

Biopsies of the mucosal lesions of hereditary mucoepithelial dysplasia show epithelium with minimal keratinization and a disorganized maturation pattern. The squamous epithelial

dentlearn.ir

• **Fig. 16.19 Hereditary Mucoepithelial Dysplasia.** Disorganized epithelium exhibiting scattered intracytoplasmic vacuoles.



cells may have a relatively high nuclear/cytoplasmic ratio, but significant nuclear or cellular pleomorphism is not observed. Cytoplasmic vacuoles have been described and may appear as grayish inclusions (Fig. 16.19). These vacuoles also may be observed in exfoliative cytology samples. Ultrastructurally, the lesional cells have been described as having reduced numbers of desmosomes and internalized gap junctions.

Treatment and Prognosis

Given the genetic nature of this disease, supportive care and genetic counseling are typically offered. Affected patients should be monitored for development of pulmonary disease.

◆ INCONTINENTIA PIGMENTI (BLOCH-SULZBERGER SYNDROME)

Incontinentia pigmenti is a relatively rare inherited disorder, with approximately 800 cases reported worldwide. It typically evolves in several stages, primarily affecting the skin, eyes, and central nervous system (CNS), as well as oral structures. There is a marked female predilection, with a 37:1 female-to-male ratio reported. The condition is inherited as an X-linked dominant trait, with the single unpaired gene on the X chromosome being lethal for most males. The mutated gene responsible for producing the phenotypic features of incontinentia pigmenti maps to the Xq28 locus, where the *IKBKG* gene (*inhibitor of kappa B kinase gamma*, formerly known as *NEMO*) is found. This gene is active in early embryogenesis, and acts to protect the developing tissues of the embryo from apoptosis. Mutation of this gene in females has less of an impact, due to the presence of two X chromosomes. If this mutated gene is present in a male embryo, that embryo will not remain viable. Of the few males who survive, a small percentage have Klinefelter syndrome (XXY karyotype), whereas the rest usually show mosaicism for the *IKBKG* gene, suggesting a postzygotic mutation.

• **Fig. 16.20 Incontinentia Pigmenti.** Swirling pattern of pigmentation on the abdomen of an infant.

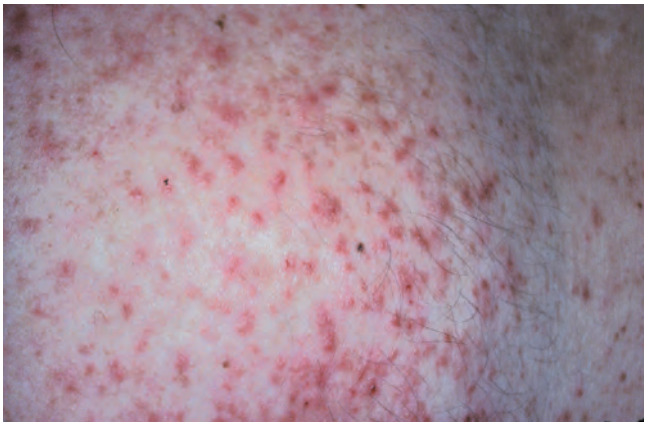
Clinical Features

The clinical manifestations of incontinentia pigmenti usually begin in the first few weeks of infancy. There are four classic stages associated with the cutaneous lesions:

1. Vesicular stage: Vesiculobullous lesions appear on the skin of the trunk and limbs. Spontaneous resolution usually occurs within 4 months.
2. Verrucous stage: Verrucous cutaneous plaques develop, affecting the limbs. These clear by 6 months of age, evolving into the third stage.
3. Hyperpigmentation stage: Macular, brown skin lesions appear, characterized by a strange swirling pattern (Fig. 16.20), although these tend to fade around the time of puberty.
4. Atrophy and depigmentation stage: Atrophy and depigmentation of the skin ultimately occur. Considerable overlap among these stages can occur at times, however.

CNS abnormalities occur in approximately 30% of affected patients. The most common problems are intellectual disability, seizure disorders, and motor difficulties. Ocular problems (e.g., strabismus, nystagmus, cataracts, retinal vascular abnormalities, and optic nerve atrophy) may also be identified in nearly 35% of these patients.

The oral manifestations of incontinentia pigmenti, noted in 70%–95% of the cases, include **oligodontia (hypodontia),** delayed eruption, high-arched palate, and hypoplasia or malformed crowns of the teeth (Fig. 16.21). The teeth are often small and cone shaped; both the primary and permanent dentitions are affected.



Histopathologic Features

The microscopic findings in incontinentia pigmenti vary, depending on when a biopsy of the skin lesions is performed.

dentlearn.ir

• **Fig. 16.21 Incontinentia Pigmenti.** Hypodontia and conical teeth.

• **Fig. 16.22 Darier Disease.** Erythematous cutaneous papules on the chest.

In the initial vesicular stage, intraepithelial clefts filled with eosinophils are observed. During the verrucous stage, hyperkeratosis, acanthosis, and papillomatosis are noted. The hyperpigmentation stage shows numerous melanin-containing macrophages (melanin incontinence) in the subepithelial connective tissue, the feature from which the disorder derives its name.

Treatment and Prognosis

Treatment of incontinentia pigmenti is directed toward the various abnormalities. Dental management includes appropriate prosthodontic and restorative care, although this is sometimes difficult if CNS problems are severe. Prenatal genetic testing can be performed, but currently this is not widely available.

◆ DARIER DISEASE (KERATOSIS FOLLICULARIS; DYSKERATOSIS FOLLICULARIS; DARIER-WHITE DISEASE)

Darier disease is an uncommon genodermatosis with rather striking skin involvement and relatively subtle oral mucosal lesions. The condition is generally inherited as an autosomal dominant trait, having a high degree of penetrance and variable expressivity, although as much as 40-50% of cases may represent new mutations. A lack of cohesion among the surface epithelial cells characterizes this disease, and mutation of a gene (identified as *ATP2A2*) that encodes an intracellular calcium pump (SERCA2—sarco/endoplasmic reticulum Ca^{2+}-ATPase isoform 2) has been identified as the cause for abnormal desmosomal organization in the affected epithelial cells. Estimates of the prevalence of Darier disease in Northern European populations range from 1 in 36,000–1 in 100,000.

Clinical Features

Patients with Darier disease have numerous erythematous, often pruritic, papules on the skin of the trunk and the scalp that develop during the first or second decade of life

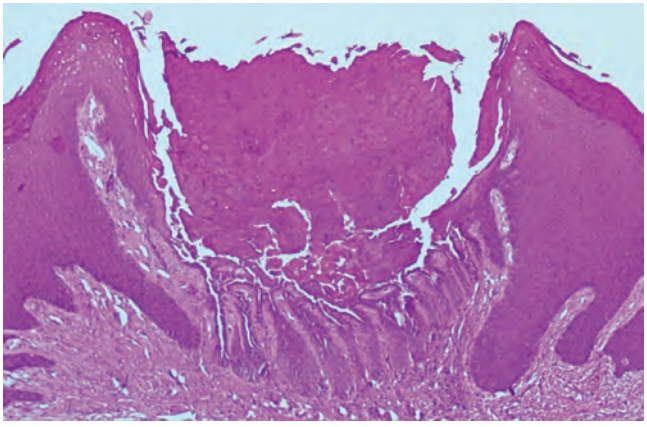
• **Fig. 16.23 Darier Disease.** The oral mucosa may show multiple white papules. (Courtesy of Dr. George Blozis.)

(Fig. 16.22). An accumulation of keratin, producing a rough texture, may be seen in association with the lesions, and a foul odor may be present as a result of bacterial degradation of the keratin. The process generally becomes worse during the summer months, either because of sensitivity of some patients to UV light or because increased heat results in sweating, which induces more epithelial clefting. The palms and soles often exhibit pits and keratoses. The nails show longitudinal lines, ridges, or painful splits.

The oral lesions are typically asymptomatic and are discovered on routine examination. The frequency of occurrence of oral lesions ranges from 15% to 50%. They consist of multiple, normal-colored or white, flat-topped papules that, if numerous enough to be confluent, result in a cobblestone mucosal appearance (Fig. 16.23). These lesions affect the hard palate and alveolar mucosa primarily, although the buccal mucosa or tongue may be occasionally involved. If the palatal lesions are prominent, then the condition may resemble inflammatory papillary hyperplasia or nicotine stomatitis. Some patients with this condition also experience recurrent obstructive parotid swelling secondary to duct abnormalities.

dentlearn.ir

Histopathologic Features



Microscopic examination of the cutaneous or mucosal lesions shows a dyskeratotic process characterized by a central keratin plug that overlies epithelium exhibiting a suprabasilar cleft (Fig. 16.24). This intraepithelial clefting phenomenon, also known as **acantholysis,** is not unique to Darier disease and may be seen in conditions, such as pemphigus vulgaris (see page 769). In addition, the epithelial rete ridges associated with the lesions appear narrow, elongated, and "test tube"–shaped. Closer inspection of the epithelium reveals varying numbers of two types of dyskeratotic cells, called ***corps ronds*** (round bodies) or **grains** (because they resemble cereal grains).

Treatment and Prognosis

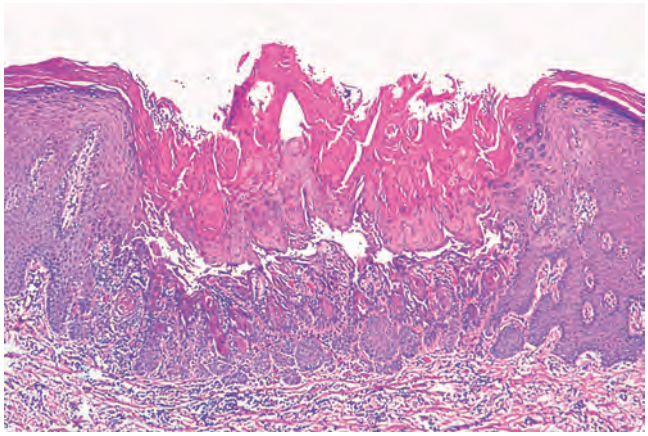
Treatment of Darier disease depends on the severity of involvement. Photosensitive patients should use a sunscreen, and all patients should minimize unnecessary exposure to hot environments. For relatively mild cases, keratolytic agents or emollients may be the only treatment required. For more severely affected patients, systemic retinoids are often beneficial, but the side effects of such medications are often quite bothersome to the patient and can be significant; therefore, the physician should carefully monitor their use. Although the condition is not premalignant or otherwise life threatening, genetic counseling is appropriate.

◆ WARTY DYSKERATOMA (ISOLATED DARIER DISEASE; ISOLATED DYSKERATOSIS FOLLICULARIS; FOCAL ACANTHOLYTIC DYSKERATOSIS; FOLLICULAR DYSKERATOMA)

The **warty dyskeratoma** is a distinctly uncommon solitary lesion that can occur on skin or oral mucosa. It is histopathologically identical to Darier disease. For this reason the lesion has been termed **isolated Darier disease.** The lesion is not otherwise related to Darier disease, however, and its cause remains unknown.

• **Fig. 16.24 Darier Disease.** Low-power photomicrograph showing a thick keratin plug, intraepithelial clefting, and elongated rete ridges.

Clinical Features



The cutaneous warty dyskeratoma typically appears as a solitary, asymptomatic, umbilicated papule on the skin of the head or neck of an older adult, although multiple cutaneous lesions have been reported. The intraoral lesion also develops in patients older than age 40, and a slight male predilection has been identified. The intraoral warty dyskeratoma appears as a pink or white, umbilicated papule located on the keratinized mucosa, especially the hard palate and the alveolar ridge (Fig. 16.25). A warty or roughened surface is noted in some lesions. Most warty dyskeratomas are smaller than 0.5 cm in diameter.

Histopathologic Features

Histopathologically, the warty dyskeratoma appears very similar to **keratosis follicularis.** Both conditions display dyskeratosis, basilar hyperplasia, and a suprabasilar cleft (Fig. 16.26). The warty dyskeratoma is a solitary lesion, however, and the formation of *corps ronds* and grains is not a prominent feature.

• **Fig. 16.25 Warty Dyskeratoma.** Umbilicated papule on the hard palate. (Courtesy of Dr. Greg Adams.)

• **Fig. 16.26 Warty Dyskeratoma.** Well-circumscribed invagination filled with a thick parakeratin plug. There is hyperplasia of the basilar cells with a suprabasilar cleft.

dentlearn.ir

Treatment and Prognosis

Treatment of the warty dyskeratoma consists of conservative excision. The prognosis is excellent; these lesions have not been reported to recur, and they have no apparent malignant potential. Careful histopathologic evaluation of the tissue should be performed, because some epithelial dysplasias may show a marked lack of cellular cohesiveness, resulting in a similar acantholytic appearance microscopically.

◆ PEUTZ-JEGHERS SYNDROME

Peutz-Jeghers syndrome is a relatively rare but well-recognized condition, having a prevalence of approximately 1 in 50,000–200,000 births. It is characterized by freckle-like lesions of the hands, perioral skin, and oral mucosa, in conjunction with intestinal polyposis and predisposition for affected patients to develop cancer. The syndrome is generally inherited as an autosomal dominant trait, although as many as 35% of cases represent new mutations. Mutation of the tumor suppressor gene, *STK11* (also known as *LKB1*) is responsible for most cases of Peutz-Jeghers syndrome. This gene, which encodes for a serine/threonine kinase, is located on chromosome 19p13.3.

Clinical Features

The skin lesions of Peutz-Jeghers syndrome usually develop early in childhood and involve the periorificial areas (e.g., mouth, nose, anus, and genital region). The skin of the extremities is affected in about 50% of patients (Fig. 16.27). The lesions resemble freckles, but they do not wax and wane with sun exposure, as do true freckles.

The intestinal polyps, generally considered to be hamartomatous growths, are scattered throughout the mucus-producing areas of the gastrointestinal tract. The jejunum and ileum are most commonly affected. Patients often have problems with intestinal obstruction because of intussusception ("telescoping" of a proximal segment of the bowel into a distal portion), a problem that usually becomes evident during the third decade of life. Most of these episodes are self-correcting, but surgical intervention is sometimes necessary to prevent ischemic necrosis of the bowel, with subsequent peritonitis. Gastrointestinal adenocarcinoma develops in a significant percentage of affected patients, although the polyps themselves do not appear to be premalignant. In one large series of cases, 9% of the patients had developed gastrointestinal malignancy by 40 years of age and 33% by 60 years of age. This compares to 0.1% and 1.0%, respectively, in the general population. Other tumors affecting the pancreas, male and female genital tract, breast, and ovary may also develop. In women, the risk of developing breast cancer approaches 50% by 60 years of age. The increased frequency of malignancy in these patients overall is estimated to be approximately 10–18 times greater than normal.

The oral lesions essentially represent an extension of the perioral freckling. These 1- to 4-mm brown to blue-gray macules primarily affect the vermilion zone, the labial and buccal mucosa, and the tongue; they are seen in more than 90% of these patients (Fig. 16.28). The number of lesions and the extent of involvement can vary markedly from patient to patient. Some degree of fading of the pigmented lesions may be noted during adolescence.

Histopathologic Features

The gastrointestinal polyps of Peutz-Jeghers syndrome histopathologically represent benign overgrowths of intestinal glandular epithelium supported by a core of smooth muscle. Epithelial atypia is not usually a prominent feature, unlike the polyps of Gardner syndrome (see page 656).

Microscopic evaluation of the pigmented cutaneous lesions shows slight acanthosis of the epithelium with elongation of the rete ridges. No apparent increase in melanocyte number is detected by electron microscopy, but the dendritic processes of the melanocytes are elongated. Furthermore, the melanin pigment appears to be retained in the melanocytes rather than being transferred to adjacent keratinocytes.

• **Fig. 16.27 Peutz-Jeghers Syndrome.** Cutaneous lesions appear as brown, macular, freckle-like areas, often concentrated around the mouth or on the hands. (Courtesy of Dr. Ahmed Uthman.)

• **Fig. 16.28 Peutz-Jeghers Syndrome.** Oral manifestations include multiple, dark, freckle-like lesions of the lips. (Courtesy of Dr. Ahmed Uthman.)

dentlearn.ir

Treatment and Prognosis

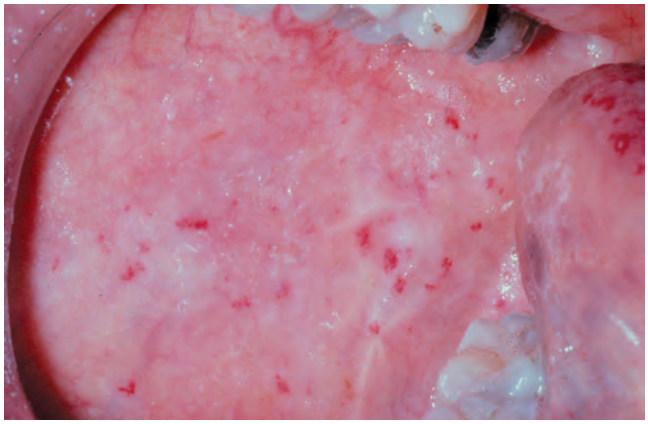
Patients with Peutz-Jeghers syndrome should be monitored for development of intussusception or tumor formation. Genetic counseling is also appropriate; moreover, prenatal or preimplantation genetic testing may now be available at some tertiary care centers.

◆ HEREDITARY HEMORRHAGIC TELANGIECTASIA (OSLER-WEBER-RENDU SYNDROME)

Hereditary hemorrhagic telangiectasia (HHT) is an uncommon mucocutaneous disorder that is inherited as an autosomal dominant trait, and epidemiologic studies suggest a prevalence that ranges from 1 in 5000 to 18,000 people, depending on the geographic region. Mutation of either one of two different genes at two separate loci is responsible for the condition. HHT1 is caused by a mutation of the *endoglin (ENG)* gene on chromosome 9, whereas mutation of *activin receptor-like kinase-1 (ALK1; ACVRL1)*, a gene located on chromosome 12, produces HHT2. The proteins produced by these genes may play a role in blood vessel wall integrity. With both types of HHT, numerous vascular hamartomas develop, affecting the skin and mucosa; however, other vascular problems, such as arteriovenous fistulas, may also be seen. Patients affected with HHT1 tend to have more pulmonary and cerebral involvement, whereas those with HHT2 generally have a later onset of their telangiectasias and a greater degree of hepatic involvement. A much less common mutation, involving the *MADH4* gene, has also been identified, and these patients exhibit an overlap syndrome characterized by HHT and juvenile polyposis. The polyps involve both the upper and lower gastrointestinal tract, and these patients have an increased risk for developing colorectal carcinoma at an early age. The clinician should be familiar with HHT because the oral lesions are often the most dramatic and most easily identified component of this syndrome.

Clinical Features

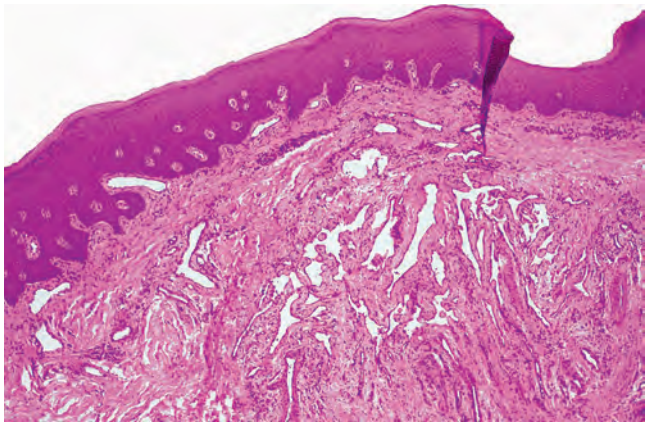
Patients with HHT are often diagnosed initially because of frequent episodes of epistaxis. On further examination, the nasal and oropharyngeal mucosae exhibit numerous scattered red papules, 1–2 mm in size, which blanch when diascopy is used. This blanching indicates that the red color is due to blood contained within blood vessels (in this case, small collections of dilated capillaries **[telangiectasias]** that are close to the surface of the mucosa). These telangiectatic vessels are most frequently found on the vermilion zone of the lips, tongue, and buccal mucosa, although any oral mucosal site may be affected (Figs. 16.29 and 16.30). With aging, the telangiectasias tend to become more numerous and slightly larger.



In many patients, telangiectasias are seen on the hands and feet. The lesions are often distributed throughout the gastrointestinal mucosa, the genitourinary mucosa, and the conjunctival mucosa. The gastrointestinal telangiectasias have a tendency to rupture, which may cause significant blood loss. Chronic iron-deficiency anemia is often a problem for such individuals. Significantly, arteriovenous fistulas may develop in the lungs (15%–45% of HHT patients), liver (30%), or brain (10%–20%). The pulmonary arteriovenous malformations seem to predispose these patients to the development of brain abscesses due to right-to-left shunting of bacteria that might be introduced into the bloodstream. In at least one instance, periodontal vascular malformations were felt to be the cause of septic pulmonary emboli that resolved only after several teeth with periodontal abscesses were extracted.

A diagnosis of HHT can be made if a patient has three of the following four criteria:

1. Recurrent spontaneous epistaxis
2. Telangiectasias of the mucosa and skin
3. Arteriovenous malformation involving the lungs, liver, or CNS
4. Family history of HHT



• **Fig. 16.29 Hereditary Hemorrhagic Telangiectasia (HHT).** The tongue of this patient shows multiple red papules, which represent superficial collections of dilated capillary spaces.

• **Fig. 16.30 Hereditary Hemorrhagic Telangiectasia (HHT).** Red macules similar to the tongue lesions are observed on the buccal mucosa.

dentlearn.ir

• **Fig. 16.31 Hereditary Hemorrhagic Telangiectasia (HHT).** This low-power photomicrograph shows multiple dilated vascular spaces located immediately subjacent to the epithelium.

In some instances, CREST syndrome (**C**alcinosis cutis, **R**aynaud phenomenon, **E**sophageal dysfunction, **S**clerodactyly, and **T**elangiectasia) (see page 805) must be considered in the differential diagnosis. In these cases, serologic studies for anticentromere autoantibodies often help to distinguish between the two conditions because these antibodies typically would be present only in CREST syndrome.

Histopathologic Features

If one of the telangiectasias is submitted for biopsy, the microscopic features essentially show a superficially located collection of thin-walled vascular spaces that contain erythrocytes (Fig. 16.31).

Treatment and Prognosis

For mild cases of HHT, no treatment may be required. Moderate cases may be managed by selective cryosurgery or electrocautery of the most bothersome of the telangiectatic vessels. Laser ablation of the telangiectatic lesions has also been used, although this approach appears to be most successful for patients with mild to moderate disease. More severely affected patients, particularly those troubled by repeated episodes of epistaxis, may require a surgical procedure of the nasal septum (septal dermoplasty). The involved nasal mucosa is removed and replaced by a skin graft; however, some long-term follow-up studies suggest that the grafts eventually become revascularized, resulting in recurrence of the problem. Nasal closure is another surgical technique that has been performed for patients with severe epistaxis in whom other methods have failed.

Combined progesterone and estrogen therapy may benefit some patients, but because of the potentially serious side effects, this should be limited to the most severely affected individuals. Bevacizumab, an antibody directed against vascular endothelial growth factor, has shown some promise in controlling epistaxis, but this is a costly medication. Iron replacement therapy is indicated for the iron-deficient patient, and occasionally blood transfusions may be necessary to compensate for blood loss.

From a dental standpoint, the use of prophylactic antibiotics is indicated before dental procedures that might cause bacteremia in patients with HHT and a history of either a treated or untreated pulmonary arteriovenous malformation. For patients with a history of HHT, such antibiotics are advocated until a pulmonary arteriovenous malformation is ruled out because of the 1% prevalence of brain abscesses in affected individuals. Researchers believe that antibiotic coverage, similar to that for endocarditis prophylaxis, may prevent this serious complication. Patients with a history of HHT should be screened for arteriovenous malformations, which can be eliminated by embolization or other vasodestructive techniques using interventional radiologic methods. The decision to treat such a lesion often depends on the anatomic site and the severity of the malformation. For patients who have been treated for a pulmonary arteriovenous malformation, monitoring for recurrence of the condition and for development of additional arteriovenous malformations in other pulmonary sites is recommended.

The prognosis is generally good, although studies indicate a reduced lifespan, which can range from 7 to 14 years shorter than average. Patients with milder disease expression may have a more modest decrease in longevity. A 1%–2% mortality rate is reported from complications related to blood loss. For patients with brain abscesses, the mortality rate can range up to 40%, even with early diagnosis and appropriate therapy.

◆ EHLERS-DANLOS SYNDROMES

The **Ehlers-Danlos syndromes,** a group of inherited connective tissue disorders, are relatively heterogeneous. At least thirteen types have been described over the years, and these are typically distinguished based on clinical and molecular features. The affected patient exhibits problems that are usually attributed to the production of abnormal collagen, the protein that is the main structural component of the connective tissue. Because the production of collagen necessitates many biochemical steps that are controlled by several genes, the potential exists for any one of these genes to mutate, producing selective defects in collagen synthesis. The various forms of abnormal collagen result in many overlapping clinical features for each of the types of the Ehlers-Danlos syndrome (Table 16.1). This discussion concentrates on the three most common and significant forms of this group of conditions.

Typical clinical findings include hypermobility of the joints, easy bruisability, and marked elasticity of the skin. In the past, some affected individuals worked in circus sideshows as the "rubber" man and the "contortionist" as a result of their pronounced joint mobility and ability to stretch the skin.

Clinical Features

The pattern of inheritance and the clinical manifestations vary with the type of Ehlers-Danlos syndrome being examined. About 80% of patients have the **classical type** in either

dentlearn.ir

TABLE 16.1 Ehlers-Danlos Syndromes

Common Types	Clinical Features	Inheritance	Defect
Classical (severe)	Hyperextensible skin, easy bruising, hypermobile joints, papyraceous scarring of skin	AD	Collagen type V mutations
Classical (mild)	Less severe classical manifestations	AD	Collagen type V mutations
Hypermobility	Soft skin, no scarring, marked joint hyperextensibility	AD	Not known
Vascular	Severe bruising; risk for arterial, bowel, and uterine rupture	AD	Collagen type III mutations
Rare Types	**Clinical Features**	**Inheritance**	**Defect**
Kyphoscoliotic EDS	Ocular globe fragility, hyperextensible skin, hypermobile joints, scoliosis	AR	Lysyl hydroxylase point mutations
Arthrochalasia EDS	Congenital hip dislocation, joint hypermobility, normal scarring, mandibular hypoplasia	AD	Collagen type I mutations
Dermatosparaxis EDS	Severe skin fragility, sagging skin	AR	Procollagen peptidase deficiency
Classical-like	Hyperextensible skin, easy and severe bruising, hypermobile joints, no abnormal scarring of skin	AR	Tenascin X glycoprotein deficiency
Periodontal EDS	Considerable range of features related to skin and joints; early onset of periodontitis	AR	Mutations in C1R and C1S
Brittle cornea syndrome	Thin cornea (microcornea); predisposition to corneal rupture; early onset keratoconus and keratoglobus; joint hypermobility	AR	Mutations of *ZNF469* and *PRDM5*
Musculo-contractural EDS	Kyphoscoliosis; adducted thumbs, congenital talipes, arachnodactyly; joint hypermobility, hyperextensible, fragile skin; poor wound healing	AR	Mutations of CHST14 and DSE genes, with CHST14 more severe
Myopathic	Muscle hypotonia; proximal joint contractures; hypermobile distal joints	AD or AR	Mutation of *COL12A1* causing Type XII collagen abnormalities
Spondylo-dysplastic	Short stature; muscle hypotonia; bowing of limbs; skin hyperextensibility	AR	Mutation of *B4GALT7, B3GALT6,* and *SLC39A13*

AD, Autosomal dominant; *AR,* autosomal recessive; *XLR,* X-linked recessive.

the **mild** or **severe** form. Classical Ehlers-Danlos syndrome is inherited as an autosomal dominant trait, and mutations of genes responsible for type V collagen (*COL5A1* or *COL5A2*) have been identified in these patients. Hyperelasticity of the skin (Fig. 16.32) and cutaneous fragility can be observed as a result. An unusual healing response that often occurs with relatively minor injury to the skin is termed **papyraceous scarring** because it resembles crumpled cigarette paper (Fig. 16.33).

Patients with the **hypermobility type** of Ehlers-Danlos syndrome exhibit remarkable joint hypermobility but no evidence of unusual scarring. Chronic musculo-skeletal pain is often present to a greater degree than is seen with other types of Ehlers-Danlos syndrome.

The **vascular type** of Ehlers-Danlos used to be known as the **ecchymotic** type because of the extensive bruising that occurs with everyday trauma. Defects in type III collagen have been identified in this disorder. This form is inherited in an autosomal dominant pattern, and a young patient may be mistaken for a victim of child abuse. The life expectancy of these patients is often greatly reduced because of the tendency for aortic aneurysm formation and rupture.

Periodontal Ehlers-Danlos syndrome is a rare variant that has dental manifestations as a hallmark feature, with patients showing marked periodontal disease activity at a relatively early age, as well as reduced or no attached gingiva. Although these patients may have overlapping features with either the classical or vascular forms of the disease, genetic analysis of this form of Ehlers-Danlos syndrome has found specific mutations of two genes, *C1R* and *C1S*.

The oral manifestations of Ehlers-Danlos syndrome include the ability of 50% of these patients to touch the tip of their nose with their tongue **(Gorlin sign)** (Fig. 16.34), a feat that can be achieved by less than 10% of the general population. Some authors have noted easy bruising and bleeding during minor manipulations of the

dentlearn.ir

• **Fig. 16.32 Ehlers-Danlos Syndrome.** The hyperelasticity of the skin is evident in this patient affected by the mild form of classical Ehlers-Danlos syndrome.

• **Fig. 16.33 Ehlers-Danlos Syndrome.** Scarring that resembles crumpled cigarette paper (papyraceous scarring) is associated with minimal trauma in patients with Ehlers-Danlos syndromes. These lesions involve the skin of the knee.

• **Fig. 16.34 Ehlers-Danlos Syndrome.** Patient demonstrating the Gorlin sign by touching the tip of the nose with their tongue.

oral mucosa; others state that oral mucosal friability is present. A tendency for recurrent subluxation of the temporomandibular joint (TMJ) and the development of other TMJ disorders has also been reported.

Most patients with Ehlers-Danlos syndrome have relatively normal teeth, although high cusps and deep developmental fissures in the posterior teeth have been described. A variety of dental abnormalities have been described, however, including malformed, stunted tooth roots, large pulp stones, and hypoplastic enamel. Although most of these findings have not been consistently correlated with any particular type of the syndrome, pulp stones seem to occur more commonly in patients affected by classical Ehlers-Danlos syndrome.

Treatment and Prognosis

The prognosis for the patient with Ehlers-Danlos syndrome depends on the type. Some forms, such as the vascular type, can be very serious, with sudden death occurring from rupture of the aorta secondary to the weakened, abnormal collagen that constitutes the vessel wall. The mild classical type is generally compatible with a normal life span, although affected women may have problems with placental tearing and hemorrhage during gestation. Pain management for patients with Ehlers-Danlos syndrome often requires physical therapy and pharmacologic treatment.

Accurate diagnosis is important because it affects the prognosis heavily. Similarly, because the various types of this syndrome show a variety of inheritance patterns, an accurate diagnosis is required so that appropriate genetic counseling can be provided.

◆ TUBEROUS SCLEROSIS (EPILOIA; BOURNEVILLE-PRINGLE SYNDROME)

Tuberous sclerosis is an uncommon syndrome that is classically characterized by intellectual disability, seizure disorders, and angiofibromas of the skin. The condition is often inherited as an autosomal dominant trait, but

dentlearn.ir

two-thirds of the cases are sporadic and appear to represent new mutations. These mutations involve either one of two tumor suppressor genes: *TSC1* (found on chromosome 9) or, more commonly, *TSC2* (found on chromosome 16). Both of these gene products are components of the same intracellular biochemical pathway known as mechanistic (formerly "mammalian") Target of Rapamycin (mTOR) that is one of the regulators of cell growth. The multiple hamartomatous growths that are seen in this disorder are thought to arise from disruption of the normal regulatory function of these genes. Tuberous sclerosis has a wide range of clinical severity, although two-thirds of these patients have the *TSC2* mutation, and these patients have a more severe expression of the disease than those who have the *TSC1* mutation. Milder forms of tuberous sclerosis may be difficult to diagnose.

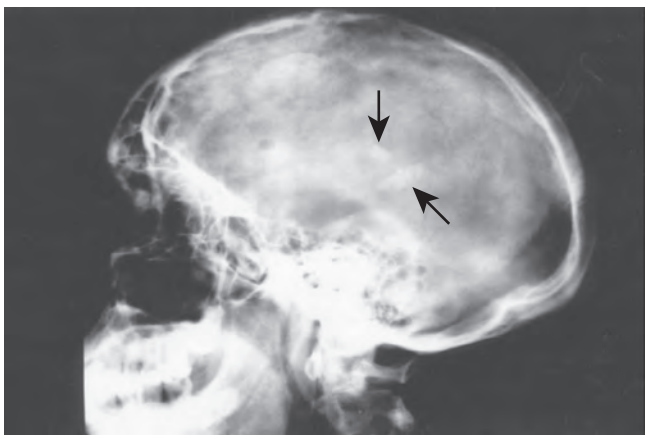
The prevalence is approximately 1 in 10,000 in the general population, although in some long-term care facilities tuberous sclerosis accounts for as high as 1% of the intellectually disabled patients. Nevertheless, average intelligence is present in over half of tuberous sclerosis patients.

Clinical Features

Several clinical features characterize tuberous sclerosis. The first of these, **facial angiofibromas,** used to be called *adenoma sebaceum.* Because these lesions are neither adenomas nor sebaceous, the use of that term should be discontinued. Facial angiofibromas appear as multiple, smooth-surfaced papules and occur primarily in the nasolabial fold area (Fig. 16.35). Similar lesions, called *ungual* or *periungual fibromas,* are seen around or under the margins of the nails (Fig. 16.36).

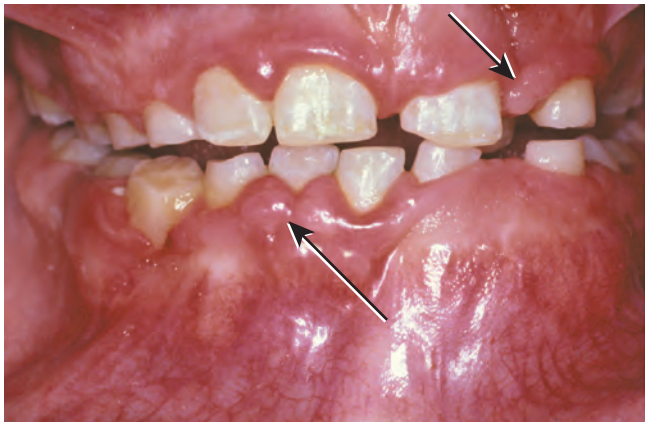
Two other characteristic skin lesions are connective tissue hamartomas called **shagreen patches** and ovoid areas of hypopigmentation called **ash-leaf spots.** Even though approximately 5% of the general population may have an ash-leaf spot, studies have reported that 90%–98% of children with tuberous sclerosis display these lesions. The shagreen patches, so named because of their resemblance to sharkskin-derived shagreen cloth, affect the skin of the trunk. The ash-leaf spots may appear on any cutaneous surface and may be best visualized using UV (Wood's lamp) illumination. "Confetti" spots also may be seen in tuberous sclerosis patients, appearing as 1–3 mm, pale macules that are symmetrically distributed on the trunk or extremities, somewhat resembling confetti that was tossed onto the skin.

CNS manifestations include seizure disorders in 80%–85% of affected patients and intellectual disability in approximately 30%. In addition, hamartomatous proliferations in the CNS develop into the potato-like growths ("tubers") seen at autopsy, from which the term *tuberous sclerosis* is derived (Fig. 16.37). The tuberous hamartomas can best be visualized using T2-weighted magnetic resonance imaging (MRI) and are present in 80%–95% of these patients. Also, approximately 10% of tuberous sclerosis patients will develop a type of benign brain tumor known as *subependymal giant cell astrocytoma.*



A relatively rare tumor of the heart muscle, called **cardiac rhabdomyoma,** is also typically associated with this syndrome. This lesion, which probably represents a hamartoma rather than a true neoplasm, occurs in approximately 30% to 50% of affected patients and is typically identified in early

• **Fig. 16.35 Tuberous Sclerosis.** Patients typically have multiple papular facial lesions that microscopically are angiofibromas.



• **Fig. 16.36 Tuberous Sclerosis.** Examination of the fingers often shows periungual fibromas.

• **Fig. 16.37 Tuberous Sclerosis.** Patchy calcifications *(arrows)* associated with intracranial hamartoma formation are seen on this lateral skull radiograph. (Courtesy of Dr. Reg Munden.)

dentlearn.ir

• **Fig. 16.38 Tuberous Sclerosis.** Patients often exhibit gingival hyperplasia, which may be secondary to phenytoin medications used to control seizures in some cases. Fibrous papules of the gingiva *(arrows)* may also be present.

childhood. Problems with myocardial function may develop as a result of this process, but many of these tumors undergo spontaneous regression.

Another hamartomatous type of growth related to this disorder is the **angiomyolipoma.** This is a benign neoplasm composed of vascular smooth muscle and adipose tissue and occurs primarily in the kidney, typically bilaterally. Even though the angiomyolipoma is benign, the tumors are often associated with large dilated blood vessels, and significant clinical problems can arise if these vessels rupture spontaneously.

Oral manifestations of tuberous sclerosis include developmental enamel pitting on the facial aspect of the anterior permanent dentition in 50% to 100% of patients. These pits are more readily appreciated after applying a dental plaque–disclosing solution to the teeth. Multiple fibrous papules affect 11% to 56% of patients. The fibrous papules are seen predominantly on the anterior gingival mucosa (Fig. 16.38), although the lips, buccal mucosa, palate, and tongue may be involved. Diffuse fibrous gingival enlargement is reported in affected patients—even those who are not taking phenytoin; however, most cases of gingival hyperplasia in these individuals are probably related to medication taken to control seizures. Some patients with tuberous sclerosis may also exhibit radiolucencies of the jaws that represent dense fibrous connective tissue proliferations (Fig. 16.39).

The diagnosis of tuberous sclerosis can be based on finding at least two of the following major features:

- Facial angiofibromas
- Ungual or periungual fibromas
- Hypomelanotic macules (three or more)
- Shagreen patch
- CNS hamartomas
- Subependymal nodules
- Subependymal giant cell astrocytoma
- Cardiac rhabdomyoma
- Renal angiomyolipoma
- Multiple retinal nodular hamartomas
- Lymphangioleiomyomatosis of the lung

• **Fig. 16.39 Tuberous Sclerosis.** Periapical radiograph exhibiting a well-defined radiolucency apical to the maxillary left lateral incisor. Biopsy revealed an intraosseous fibrous proliferation.

The presence of one major and two minor features may also confirm the diagnosis. The minor features include the following:

- Multiple, randomly distributed enamel pits
- Gingival fibromas
- Bone "cysts" (actually fibrous proliferations)
- "Confetti" skin lesions
- Multiple renal cysts
- Non-renal hamartomas

Histopathologic Features

Microscopic examination of the fibrous papules of the oral mucosa or the enlarged gingivae shows a nonspecific fibrous hyperplasia. Similarly, the radiolucent jaw lesions consist of dense fibrous connective tissue that resembles desmoplastic fibroma or the simple type of central odontogenic fibroma. The angiofibroma of the skin is a benign aggregation of delicate fibrous connective tissue characterized by plump, uniformly spaced fibroblasts with numerous interspersed thin-walled vascular channels.

Treatment and Prognosis

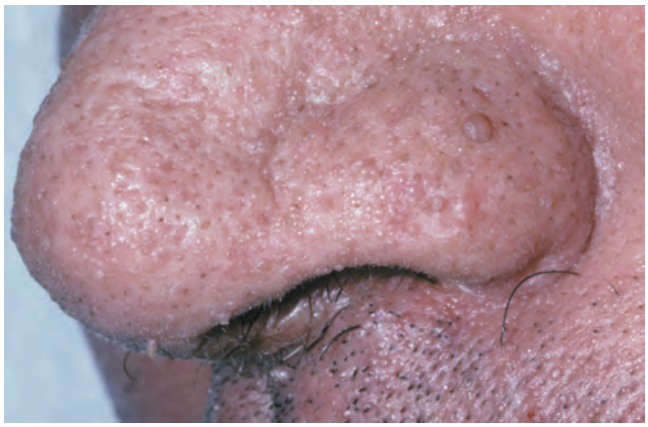
For patients with tuberous sclerosis, most of the treatment is directed toward the management of the seizure disorder with anticonvulsant agents. Periodic MRI of the head may be done to screen for intracranial lesions, whereas ultrasound evaluation is performed for evaluation of kidney involvement. Intellectually disabled patients may have problems with oral hygiene procedures, and poor oral hygiene contributes to phenytoin-induced gingival hyperplasia. Studies

dentlearn.ir

examining medications (such as, sirolimus and everolimus) that block the mTOR pathway that causes tuberous sclerosis have shown significant shrinkage of several tumor types associated with this disorder, including renal angiomyolipoma, facial angiofibroma, and subependymal giant cell astrocytoma. A decrease in tuberous sclerosis-related seizures has also been noted with this treatment. Patients affected by tuberous sclerosis have a slightly reduced life span compared with the general population, with death usually related to CNS or kidney disease.

Genetic counseling is also appropriate for affected patients, and careful clinical evaluation of the patient's parents is recommended in order to rule out overlooked mild expression of tuberous sclerosis affecting one of them. Genetic testing is available for both *TSC1* and *TSC2* mutations if prenatal or preimplantation family planning is desired.

◆ MULTIPLE HAMARTOMA SYNDROME (COWDEN SYNDROME; *PTEN* HAMARTOMA-TUMOR SYNDROME)



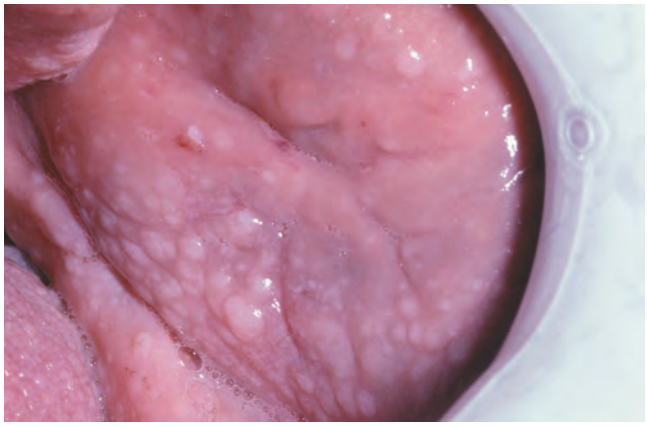
Multiple hamartoma syndrome is a rare condition that has important implications for the affected patient, because malignancies, in addition to the benign hamartomatous growths, develop in a high percentage of these individuals. Usually, the syndrome is inherited as an autosomal dominant trait showing a high degree of penetrance and a range of expressivity, although new mutations may account for as many as 45% of cases. The gene responsible for this disorder has been mapped to chromosome 10, and a mutation of the *phosphatase and tensin homolog deleted on chromosome 10 (PTEN)* gene has been implicated in its pathogenesis. The estimated prevalence of this condition is approximately 1 in 200,000, and more than 300 affected patients have been described in the literature. In recent years, overlapping clinical features of multiple hamartoma syndrome with **Lhermitte-Duclos disease, Bannayan-Riley-Ruvalcaba syndrome,** and **Proteus-like syndrome** have been noted, and all of these disorders have demonstrated mutations of the *PTEN* gene.

Clinical Features

Cutaneous manifestations are present in almost all patients with multiple hamartoma syndrome, usually developing during the second decade of life. The majority of the skin lesions appear as multiple, small (less than 1 mm) papules, primarily on the facial skin, especially around the mouth, nose, and ears (Fig. 16.40). Microscopically, most of these papules represent hair follicle hamartomas called **trichilemmomas.** Other commonly noted skin lesions are **acral keratosis,** a warty-appearing growth that develops on the dorsal surface of the hand, and **palmoplantar keratosis,** a prominent callus-like lesion on the palms or soles. Cutaneous **hemangiomas, sclerotic fibromas, neuromas, xanthomas,** and **lipomas** have also been described.

Other problems can appear in these patients as well. Thyroid disease usually presents as either a goiter or a thyroid adenoma, but papillary or follicular adenocarcinoma may develop. In one large series, thyroid malignancy was identified in 14% of patients with this condition. In women, fibrocystic disease of the breast is frequently observed. Unfortunately, breast cancer occurs with a relatively high frequency (25%–50%) in these patients. The mean age at diagnosis of breast malignancy is 40 years, which is much younger than usual. In the gastrointestinal tract, multiple benign hamartomatous polyps may be present. In addition, several types of benign and malignant tumors of the female genitourinary tract occur more often than in the normal population.

The oral lesions vary in severity from patient to patient and usually consist of multiple papules affecting the gingivae, dorsal tongue, and buccal mucosa (Figs. 16.41 and 16.42). These lesions have been reported in more than 80% of affected patients and generally produce no symptoms. Other possible oral findings include a high-arched palate, periodontitis, and extensive dental caries, although it is unclear whether the latter two conditions are significantly related to the syndrome.



• **Fig. 16.40 Multiple Hamartoma Syndrome.** These tiny cutaneous facial papules represent hair follicle hamartomas (trichilemmomas).

• **Fig. 16.41 Multiple Hamartoma Syndrome.** Multiple, irregular fibroepithelial papules involve the tongue *(center)* and alveolar ridge mucosa.

dentlearn.ir

• **Fig. 16.42 Multiple Hamartoma Syndrome.** Multiple papules on the left buccal mucosa.

Histopathologic Features

The histopathologic features of the oral lesions are rather nonspecific, essentially representing fibroepithelial hyperplasia. Other lesions associated with this syndrome have their own characteristic histopathologic findings, depending on the hamartomatous or neoplastic tissue origin.

Diagnosis

The diagnosis can be based on the finding of two of the following three pathognomonic signs:

1. Multiple facial trichilemmomas
2. Multiple oral papules
3. Acral keratoses

A variety of other major and minor diagnostic criteria, as well as a positive family history, are also helpful in confirming the diagnosis. Genetic testing for mutations of the *PTEN* gene are clinically available, but 20% of patients who otherwise have characteristic multiple hamartoma syndrome will not demonstrate a genetic abnormality; therefore, a negative test does not necessarily preclude the diagnosis of multiple hamartoma syndrome.

Treatment and Prognosis

Treatment of multiple hamartoma syndrome is controversial. Although most of the tumors that develop are benign, the prevalence of malignancy is higher than in the general population; therefore, annual physical examinations should be performed that focus specifically on anatomic sites of increased tumor prevalence, particularly breast, uterus, and thyroid. Because longitudinal studies have found that 85% of women with multiple hamartoma syndrome will develop breast cancer, some investigators have recommended bilateral prophylactic mastectomies as early as the third decade of life for female patients.

◆ EPIDERMOLYSIS BULLOSA

The term **epidermolysis bullosa** describes a heterogeneous group of inherited blistering mucocutaneous disorders. Each has a specific defect in the attachment mechanisms of the epithelial cells, either to each other or to the underlying connective tissue. Recent advances in the understanding of the clinical features, epidemiology, immunofluorescence mapping, and molecular genetic abnormalities of these conditions have led to the identification of more than 30 different forms. Depending on the defective mechanism of cellular cohesion, there are four broad categories:

1. Simplex
2. Junctional
3. Dystrophic
4. Kindler syndrome

Each category consists of several forms of the disorder. A variety of inheritance patterns may be seen, depending on the particular form. The degree of severity can range from relatively mild, annoying forms, such as the **simplex** types, through a spectrum that includes severe, fatal disease. For example, many cases of **junctional** epidermolysis bullosa result in death at birth because of the significant sloughing of the skin during passage through the birth canal. Specific mutations in the genes encoding keratin 5 and keratin 14 have been identified as being responsible for most of the **simplex** types, whereas mutations in the genetic codes of laminin-332, type XVII collagen, or α6β4 integrin have been documented for the **junctional** types. Most of the **dystrophic** types are caused by mutations in the genes responsible for type VII collagen production, with over 300 distinctly different mutations identified to date. **Kindler syndrome** is the most recently characterized pattern of this group of disorders, and mutations of the gene that encodes for a hemidesmosomal attachment protein, kindlin-1, are responsible for this rare condition.

A few representative examples of the types of epidermolysis bullosa are summarized in Table 16.2. Because oral lesions are most commonly observed in the dystrophic forms, this discussion centers on these forms. Dental abnormalities, such as anodontia, enamel hypoplasia, pitting of the enamel, neonatal teeth, severe periodontitis, and severe dental caries, have been variably associated with several of the different types of epidermolysis bullosa, although studies have suggested that the prevalence of dental abnormalities is significantly increased only with the **junctional** type. A disorder termed **epidermolysis bullosa acquisita** is mentioned because of the similarity of its name; however, this is an unrelated condition, having an autoimmune (rather than a genetic) origin (see page 778).

Clinical Features

Dominant Dystrophic Types

The **dystrophic** forms of epidermolysis bullosa that are inherited in an autosomal dominant fashion are not usually life threatening, although they may certainly be disfiguring and pose many problems. The initial lesions are vesicles or bullae, which are seen early in life and develop on areas exposed to low-grade, chronic trauma, such as the knuckles or knees (Fig. 16.43). The bullae rupture, resulting in erosions or ulcerations that ultimately heal with scarring. In the process, appendages such as fingernails may be lost.

The oral manifestations are typically mild, with some gingival erythema and tenderness. Gingival recession and

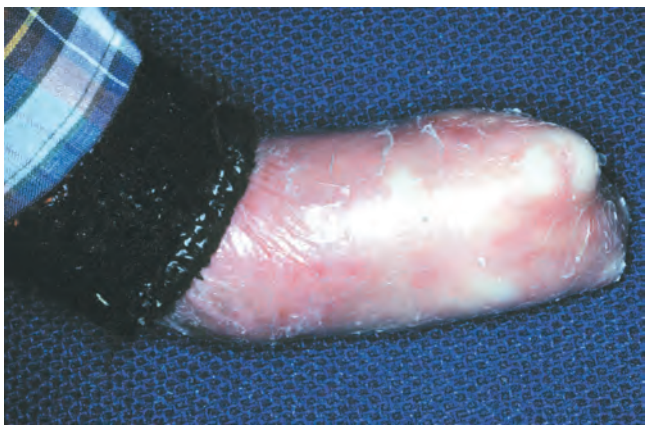
dentlearn.ir

TABLE 16.2 Examples of Epidermolysis Bullosa

Form	Inheritance	Clinical Features	Defect
EB simplex	AD	Blistering of the hands and feet; mucosal involvement uncommon; blisters heal without scarring; prognosis usually good	Keratin gene defects
Junctional EB, generalized gravis variant	AR	Severe blistering at birth; granulation tissue around the mouth; oral erosions common; pitted enamel hypoplasia; often fatal (previously called *EB letalis*)	Defects of hemidesmosomes
Dominant, dystrophic EB, Pasini type	AD	Generalized blistering, white papules	Defect in type VII collagen
Dominant, dystrophic EB, Cockayne-Touraine type	AD	Extremities primarily affected	Defect in type VII collagen
Recessive, dystrophic EB, generalized gravis type	AR	Severe mucosal involvement; mittenlike scarring; deformities of hands and feet; patients usually do not survive past early adulthood	Defect in type VII collagen
Recessive, dystrophic EB, inverse type	AR	Involvement of groin and axilla; severe oral and esophageal lesions	Defect in type VII collagen

EB, Epidermolysis bullosa; *AD*, autosomal dominant; *AR*, autosomal recessive.

• **Fig. 16.43 Epidermolysis Bullosa.** A young girl, affected by the dominant dystrophic form of epidermolysis bullosa, shows the characteristic hemorrhagic bullae, scarring, and erosion associated with minimal trauma to the hands.



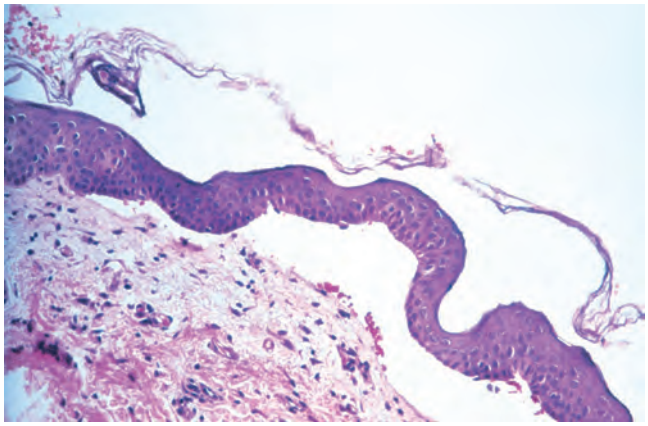
• **Fig. 16.44 Epidermolysis Bullosa.** A teenaged boy, affected by dominant dystrophic epidermolysis bullosa, shows a reduced depth of the labial vestibule caused by repeated mucosal tearing and healing with scarring.

reduction in the depth of the buccal vestibule may be observed (Fig. 16.44).

Recessive Dystrophic Types

Generalized recessive dystrophic epidermolysis bullosa represents one of the more debilitating forms of the disease. Vesicles and bullae form with even minor trauma. Secondary infections are often a problem because of the large surface areas that may be involved. If the patient manages to survive into the second decade, then hand function is often greatly diminished because of the repeated episodes of cutaneous breakdown and healing with scarring, resulting in fusion of the fingers into a mittenlike deformity (Fig. 16.45).

The oral problems are no less severe. Bulla and vesicle formation is induced by virtually any food having some degree of texture. Even with a soft diet, the repeated cycles of scarring often result in microstomia (Fig. 16.46) and



• **Fig. 16.45 Epidermolysis Bullosa.** A 19-year-old man, affected by recessive dystrophic epidermolysis bullosa, shows the typical mitten-like deformity of the hand caused by scarring of the tissue after damage associated with normal activity.

dentlearn.ir

• **Fig. 16.46 Epidermolysis Bullosa.** Same patient as depicted in Fig. 16.45. Microstomia has been caused by repeated trauma and healing with scarring. Note the severe dental caries activity associated with a soft cariogenic diet.

• **Fig. 16.47 Epidermolysis Bullosa.** Complete separation of the epithelium from the connective tissue is seen in this photomicrograph of a tissue section obtained from a patient affected by a junctional form of epidermolysis bullosa.

ankyloglossia. Similar mucosal injury and scarring may cause severe stricture of the esophagus. Because a soft diet is usually highly cariogenic, carious destruction of the dentition at an early age is common.

Histopathologic Features

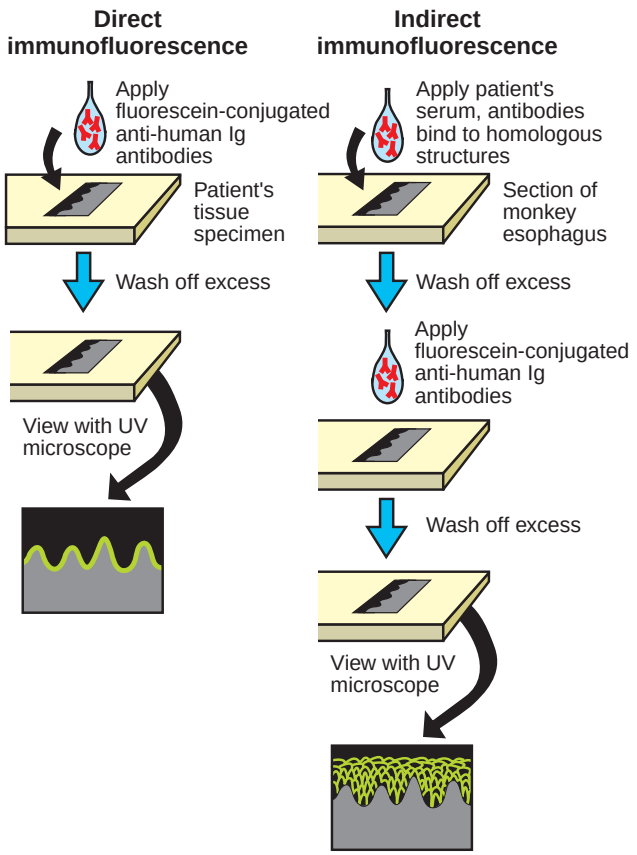
The histopathologic features of epidermolysis bullosa vary with the type being examined. The **simplex** form shows intraepithelial clefting by light microscopy. **Junctional, dystrophic,** and **Kindler** forms show subepithelial clefting (Fig. 16.47). Electron microscopic examination reveals clefting at the level of the lamina lucida of the basement membrane in the **junctional** forms and below the lamina densa of the basement membrane in the **dystrophic** forms. In contrast, the **Kindler** form shows clefting just below the basal cell layer, at its interface with the lamina lucida. Immunohistochemical evaluation of perilesional tissue is now typically used to identify specific defects to classify and subtype the condition further. Molecular genetic analysis may also be helpful for confirming the diagnosis in some instances.

Treatment and Prognosis

Treatment of epidermolysis bullosa varies with the type. For milder cases, no treatment other than local wound care may be needed. Sterile drainage of larger blisters and the use of topical antibiotics are often indicated in these situations. For the more severe cases, intensive management with oral antibiotics may be necessary if cellulitis develops; despite intensive medical care, some patients die as a result of infectious complications.

The "mitten" deformity of the hands, seen in recessive dystrophic epidermolysis bullosa, can be corrected with plastic surgery, but the problem usually recurs after a period of time, and surgical intervention is required every 2 years on average. With esophageal involvement, dysphagia may be a significant problem, resulting in malnutrition and weight loss. Placement of a gastrostomy tube may be necessary at times. Patients with the recessive dystrophic forms are also predisposed to development of **cutaneous squamous cell carcinoma.** This malignancy often develops in areas of chronic ulceration during the second through third decades of life and represents a significant cause of death for these patients. Infrequently, the lingual mucosa of affected patients has been reported to undergo malignant transformation as well.

Management of the oral manifestations also depends on the type of the disease. For patients who are susceptible to mucosal bulla formation, dental manipulation should be kept to a minimum. To achieve this, topical 1% neutral sodium fluoride solution should be administered daily to prevent dental caries. Occlusal sealants are also recommended. A soft diet that is as noncariogenic as possible, as well as atraumatic oral hygiene procedures, should be encouraged. Maintaining adequate nutrition for affected patients is critical to ensure optimal wound healing. Endosseous dental implants, followed by fixed dental prostheses, have been successfully placed in some patients with recessive dystrophic epidermolysis bullosa.



If dental restorative care is required, the lips should be lubricated to minimize trauma. Injections for local anesthesia can usually be accomplished by depositing the anesthetic slowly and deeply within the tissues. For extensive dental care, including extractions, endotracheal anesthesia may be performed without significant problems in most cases.

Unfortunately, because of the genetic nature of these diseases, no cure exists. Genetic counseling of affected families is indicated. Both prenatal diagnosis and preimplantation diagnosis are available as adjuncts to family planning.

IMMUNE-MEDIATED DISEASES AND THEIR EVALUATION

Several conditions discussed in this chapter are the result of inappropriate production of antibodies by the patient (autoantibodies). These autoantibodies are directed against various constituents of the molecular apparatus that hold epithelial cells together or that bind the surface epithelium to the underlying connective tissue. The ensuing damage

dentlearn.ir

• **Fig. 16.48 Immunofluorescence Techniques.** Comparison of the techniques for direct and indirect immunofluorescence. The left side depicts the direct immunofluorescent findings in mucous membrane pemphigoid, a disease that has autoantibodies directed toward the basement zone. The right side shows the indirect immunofluorescent findings for pemphigus vulgaris, a disease that has autoantibodies directed toward the intercellular areas between the spinous cells of the epithelium. *Ig,* Immunoglobulin; *UV,* ultraviolet.

produced by the interaction of these autoantibodies with the host tissue is seen clinically as a disease process, often termed an **immunobullous** disease. Because each disease is characterized by production of specific types of autoantibodies, identification of the antibodies and the tissues against which they are targeted is important diagnostically. The two techniques that are widely used to investigate the immunobullous diseases are (1) direct immunofluorescence and (2) indirect immunofluorescence studies. Following is a brief overview of how they work.

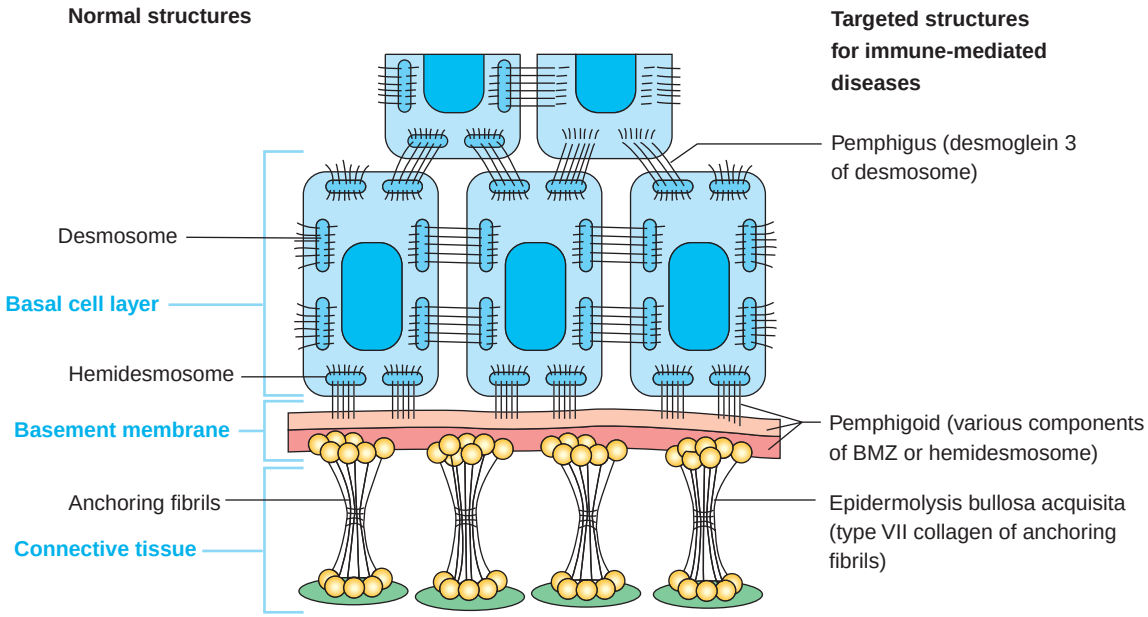
Direct immunofluorescence is used to detect autoantibodies that are bound to the patient's tissue. Before testing can take place, several procedures must occur. Inoculating human immunoglobulins into a goat creates antibodies directed against these human immunoglobulins. The antibodies raised in response to the human immunoglobulins are harvested from the animal and tagged with fluorescein, a dye that glows when viewed with UV light. As illustrated on the left side of Fig. 16.48, a frozen section of the patient's tissue is placed on a slide, and this is incubated with fluorescein-conjugated goat antihuman antibodies. These antibodies bind to the tissue at any site where human immunoglobulin is present. The excess antibody suspension is washed off, and the section is then viewed with a microscope having a UV light source.

With indirect immunofluorescence studies, the patient is being evaluated for presence of antibodies that are circulating in the blood. As shown on the right side of Fig. 16.48, a frozen section of tissue that is similar to human oral mucosa (e.g., Old World monkey esophagus) is placed on a slide and incubated with the patient's serum. If there are autoantibodies directed against epithelial attachment structures in the patient's serum, then they will attach to the homologous structures on the monkey esophagus. The excess serum is washed off, and fluorescein-conjugated goat antihuman antibody is incubated with the section. The excess is washed off, and the section is examined with UV light to detect the presence of autoantibodies that might have been in the serum.

Examples of the molecular sites of attack of the autoantibodies are seen diagrammatically in Fig. 16.49. Each site is distinctive for a particular disease; however, the complexities of the epithelial attachment mechanisms are still being elucidated, and more precise mapping may be possible in the future. A summary of the clinical, microscopic, and immunopathologic features of the more important immune-mediated mucocutaneous diseases is found in Table 16.3.

◆ PEMPHIGUS

The condition known as **pemphigus** represents four related diseases of an autoimmune origin:



1. Pemphigus vulgaris
2. Pemphigus vegetans
3. Pemphigus erythematosus
4. Pemphigus foliaceus

Only the first two of these affect the oral mucosa, and the discussion is limited to **pemphigus vulgaris. Pemphigus vegetans** is rare; most authorities now feel it represents simply a variant of pemphigus vulgaris.

Pemphigus vulgaris is the most common of these disorders *(vulgaris* is Latin for *common).* Even so, it is not seen very often. The estimated incidence is one to five cases per million people diagnosed each year in the general population. Nevertheless, pemphigus vulgaris is an important condition because, if untreated, it often results in the patient's death. Furthermore, the oral lesions are often the first sign of the disease, and they are the most difficult to resolve with therapy. This has prompted the description of the oral lesions as "the first to show, and the last to go."

The blistering that typifies this disease is due to an abnormal production, for unknown reasons, of autoantibodies that are directed against the epidermal cell surface glycoproteins, desmoglein 3 and desmoglein 1. These desmogleins are components of **desmosomes** (structures that bond epithelial cells to each other), and the autoantibodies attach to these desmosomal components, effectively inhibiting the molecular interaction that is responsible for adherence. As a result of this immunologic attack on the desmosomes, a split develops

dentlearn.ir

• **Fig. 16.49 Epithelial Attachment Apparatus.** Schematic diagram demonstrating targeted structures in several immune-mediated diseases. *BMZ,* Basement membrane zone.

within the epithelium, causing a blister to form. Desmoglein 3 is preferentially expressed in the parabasal region of the epidermis and oral epithelium, whereas desmoglein 1 is found primarily in the superficial portion of the epidermis, with minimal expression in oral epithelium. Patients who have developed autoantibodies directed against desmoglein 3, with or without desmoglein 1, will histopathologically show intraepithelial clefting just above the basal layer, and clinically oral mucosal blisters of pemphigus vulgaris will form. Patients who develop autoantibodies directed against only desmoglein 1 will histopathologically show superficial intraepithelial clefting of the epidermis, but oral mucosa will not be affected. Clinically, the fine scaly red lesions of pemphigus foliaceus or pemphigus erythematosus will be evident.

Occasionally, a pemphigus-like oral and cutaneous eruption may occur in patients taking certain medications (e.g., penicillamine, angiotensin-converting enzyme [ACE] inhibitors, nonsteroidal anti-inflammatory drugs [NSAIDs]) (see page 337) or in patients with malignancy, especially lymphoreticular malignancies (so-called **paraneoplastic pemphigus**) (see page 774). Similarly, a variety of other conditions may produce chronic vesiculoulcerative or erosive lesions of the oral mucosa, and these often need to be considered in the differential diagnosis (see Table 16.3). In addition, a rare genetic condition termed **chronic benign familial pemphigus** or **Hailey-Hailey disease** may have erosive cutaneous lesions, but oral involvement in that process appears to be uncommon.

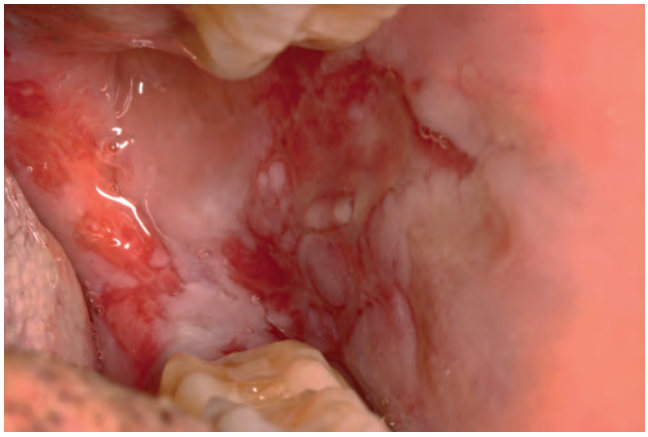
Clinical Features

The initial manifestations of pemphigus vulgaris often involve the oral mucosa, typically in adults. The average age at diagnosis is 50 years, although rare cases may be seen in childhood. A slight female predilection is observed in some reports, and the condition seems to be more common in persons of Mediterranean, South Asian, or Jewish heritage.

Patients usually complain of oral soreness, and examination shows superficial, ragged erosions and ulcerations distributed haphazardly on the oral mucosa (Figs. 16.50–16.53). Such lesions may affect virtually any oral mucosal location, although the palate, labial mucosa, buccal mucosa, ventral tongue, and gingivae are often involved. Patients rarely report vesicle or bulla formation intraorally, and such lesions can seldom be identified by the examining clinician, probably because of early rupture of the thin, friable roof of the blisters. More than 50% of the patients have oral mucosal lesions before the onset of cutaneous lesions, sometimes by as much as 1 year or more. Eventually, however, nearly all patients have intraoral involvement. The skin lesions appear as flaccid vesicles and bullae (Fig. 16.54) that rupture quickly, usually within hours to a few days, leaving an erythematous, denuded surface. Infrequently ocular involvement may be seen, usually appearing as bilateral conjunctivitis. Unlike mucous membrane pemphigoid, the ocular lesions of pemphigus typically do not cause scarring and symblepharon formation (see page 776).

Without proper treatment, the oral and cutaneous lesions tend to persist and progressively involve more surface area. A characteristic feature of pemphigus vulgaris is that a bulla can be induced on normal-appearing skin if firm lateral pressure is exerted. This is called a **positive Nikolsky sign.**

Histopathologic Features



Biopsy specimens of perilesional tissue show characteristic intraepithelial separation, which occurs just above the basal cell layer of the epithelium (Fig. 16.55). Sometimes the entire superficial layers of the epithelium are stripped away,

dentlearn.ir

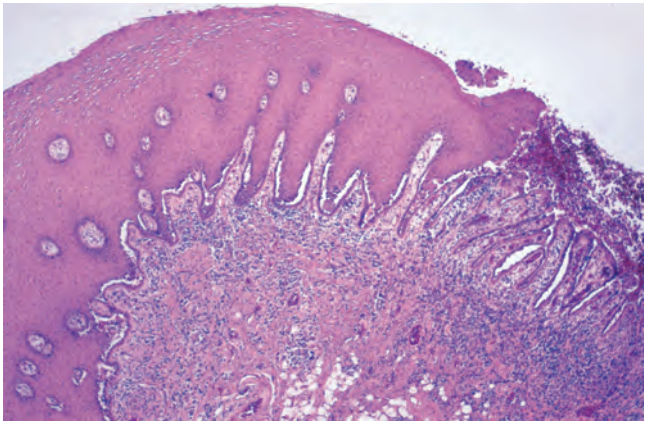
dentlearn.ir

TABLE 16.3 Chronic Vesiculoulcerative Diseases

Condition	Mean Age	Sex Predilection	Clinical Features	Histopathologic Features	Direct Immunofluorescence	Indirect Immunofluorescence
Pemphigus vulgaris	Fourth to sixth decade	Equal	Vesicles, erosions, and ulcerations on any oral mucosal or skin surface	Intraepithelial clefting	Positive intercellular	Positive
Paraneoplastic pemphigus	Sixth to seventh decade	Equal	Vesicles, erosions, and ulcerations on any mucosal or skin surface	Subepithelial and intraepithelial clefting	Positive, intercellular and basement membrane zone	Positive (rat bladder)
Mucous membrane pemphigoid	Sixth to seventh decade	Female	Primarily mucosal lesions	Subepithelial clefting	Positive, basement membrane zone	Negative
Bullous pemphigoid	Seventh to eighth decade	Equal	Primarily skin lesions	Subepithelial clefting	Positive, basement membrane zone	Positive
Erythema multiforme	Third to fourth decade	Male	Skin and mucosa involved; target lesions on skin	Subepithelial edema and perivascular inflammations	Nondiagnostic	Negative
Lichen planus	Fifth to sixth decade	Female	Oral and/or skin lesions; may or may not be erosive	Hyperkeratosis, saw-toothed rete ridges, bandlike infiltrate of lymphocytes	Fibrinogen, basement membrane zone (characteristic, but not specific for lichen planus)	Negative

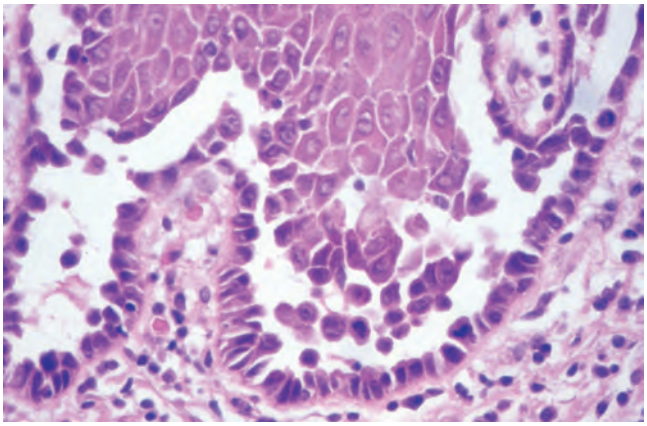
• **Fig. 16.50 Pemphigus Vulgaris.** Multiple erosions of the left buccal mucosa and soft palate.

• **Fig. 16.51 Pemphigus Vulgaris.** Large, irregularly shaped ulcerations involving the floor of the mouth and ventral tongue.

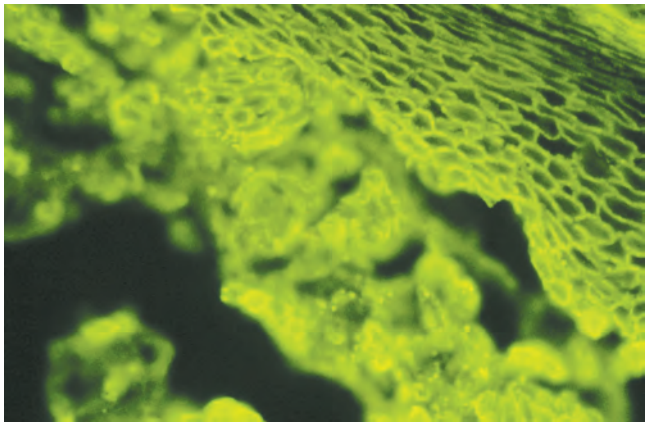


• **Fig. 16.52 Pemphigus Vulgaris.** Multiple erosions affecting the marginal gingiva.

• **Fig. 16.53 Pemphigus Vulgaris.** The patient, with a known diagnosis of pemphigus vulgaris, had been treated with immunosuppressive therapy. The oral erosions shown here were the only persistent manifestation of her disease.



• **Fig. 16.54 Pemphigus Vulgaris.** This flaccid cutaneous bulla is characteristic of skin involvement.



• **Fig. 16.55 Pemphigus Vulgaris.** Low-power photomicrograph of perilesional mucosa affected by pemphigus vulgaris. An intraepithelial cleft is located just above the basal cell layer.

leaving only the basal cells, which have been described as resembling a "row of tombstones." The cells of the spinous layer of the surface epithelium typically appear to fall apart, a feature that has been termed **acantholysis,** and the loose cells tend to assume a rounded shape (Fig. 16.56). This feature of pemphigus vulgaris can be used in making a diagnosis based on the identification of these rounded cells **(Tzanck cells)** in an exfoliative cytologic preparation. A mild-to-moderate chronic inflammatory cell infiltrate is usually seen in the underlying connective tissue.

dentlearn.ir

• **Fig. 16.56 Pemphigus Vulgaris.** High-power photomicrograph showing rounded, acantholytic epithelial cells sitting within the intraepithelial cleft.

• **Fig. 16.57 Pemphigus Vulgaris.** Photomicrograph depicting the direct immunofluorescence pattern of pemphigus vulgaris. Immunoreactants are deposited in the intercellular areas between the surface epithelial cells, resulting in a "chicken wire" pattern.

The diagnosis of pemphigus vulgaris should be confirmed by direct immunofluorescence examination of fresh perilesional tissue or tissue submitted in Michel's solution. With this procedure, antibodies (usually IgG or IgM) and complement components (usually C3) can be demonstrated in the intercellular spaces between the epithelial cells (Fig. 16.57) in almost all patients with this disease. Indirect immunofluorescence is also typically positive in 80% to 90% of cases, demonstrating the presence of circulating autoantibodies in the patient's serum. Enzyme-linked immunosorbent assays (ELISAs) have been developed to detect circulating autoantibodies as well.

It is critical that perilesional tissue be obtained for both light microscopy and direct immunofluorescence to maximize the probability of a diagnostic sample. If ulcerated mucosa is submitted for testing, then the results are often inconclusive because of either a lack of an intact interface between the epithelium and connective tissue or a great deal of nonspecific inflammation.

Treatment and Prognosis

A diagnosis of pemphigus vulgaris should be made as early in its course as possible because control is generally easier to achieve. Pemphigus is a systemic disease; therefore, treatment requires a systemic approach. In the recent past, treatment consisted primarily of systemic corticosteroids (usually prednisone or prednisolone), often in combination with other immunosuppressive drugs (so-called steroid-sparing agents), such as mycophenolate mofetil or azathioprine. Currently the use of rituximab, a monoclonal antibody that targets B-lymphocytes, is often mentioned as a first-line approach to managing this disease, as it targets the cells responsible for producing the autoantibodies that cause pemphigus. Usually rituximab is used in conjunction with a lower dose of systemic corticosteroids, resulting in a more rapid clearing of the lesions, as well as faster and more prolonged remission of the disease. Newer anti-B-cell monoclonal antibodies that are more effective are now being tested to determine their impact on treatment of pemphigus vulgaris. There is interest in these new therapeutic approaches because the potential side effects associated with the long-term use of systemic corticosteroids are significant and include the following:

- Diabetes mellitus
- Adrenal suppression
- Weight gain
- Osteoporosis
- Peptic ulcers
- Severe mood swings
- Increased susceptibility to a wide range of infections

Ideally, a physician with expertise in immunosuppressive therapy should manage the patient. Often the clinician can monitor the success of therapy by measuring the titers of circulating autoantibodies using indirect immunofluorescence, because disease activity frequently correlates with the abnormal antibody levels. Although some clinicians have advocated the use of topical corticosteroids in the management of oral lesions, the observed improvement is undoubtedly because of the absorption of the topical agents, resulting in a greater systemic dose.

Pemphigus may undergo complete resolution, although remissions and exacerbations are common. One study suggested that up to 75% of patients will have disease resolution after 10 years of treatment, although most centers have historically reported a remission rate of approximately 30%.

Before the development of corticosteroid therapy, as many as 60% to 90% of these patients died, primarily as a result of infections and electrolyte imbalances. Currently the mortality rate associated with pemphigus vulgaris is in the range of 5% to 10%, usually because of the complications of long-term systemic corticosteroid use. The mortality rate may improve in the future as anti-B-cell therapeutic approaches become more widely used.

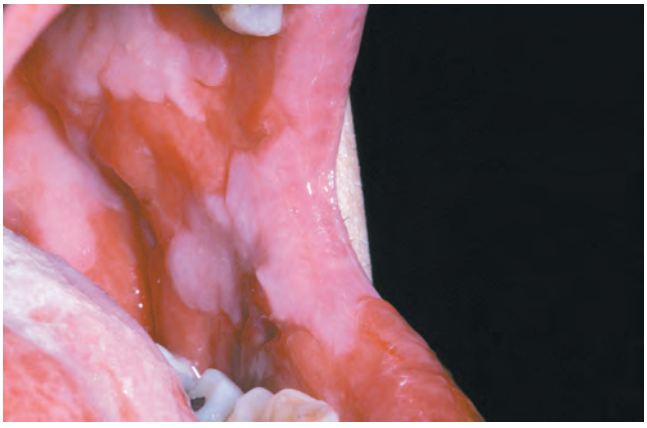
dentlearn.ir

◆ PARANEOPLASTIC PEMPHIGUS (NEOPLASIA-INDUCED PEMPHIGUS; PARANEOPLASTIC AUTOIMMUNE MULTIORGAN SYNDROME)

Paraneoplastic pemphigus is a rare vesiculobullous disorder that affects patients who have a neoplasm, usually **lymphoma** or **chronic lymphocytic leukemia.** Approximately 500 cases have been documented. Although the precise pathogenetic mechanisms are unknown, some evidence suggests abnormal levels of the cytokine, interleukin-6 (IL-6), could be produced by host lymphocytes in response to the patient's tumor. IL-6 may then be responsible for stimulating the abnormal production of antibodies directed against antigens associated with the desmosomal complex and the basement membrane zone of the epithelium. In addition to a variety of different antibodies that attack these epithelial adherence structures, some investigators have described cutaneous and mucosal damage that appears to be mediated by cytotoxic T lymphocytes in some cases of paraneoplastic pemphigus. As a result of this multifaceted immunologic attack, the disease manifests in an array of clinical features, histopathologic findings, and immunopathologic findings that may be perplexing if the clinician is unfamiliar with this condition. Some investigators prefer the term *paraneoplastic autoimmune multiorgan syndrome (PAMS)* because of the much greater array of tissues that are targeted by a variety of immunologic assaults.

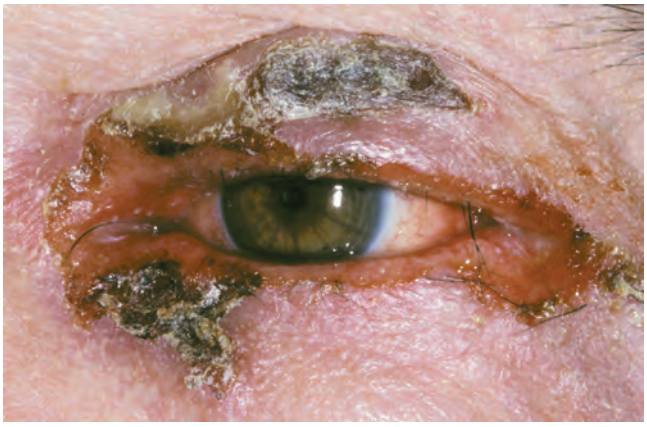
Clinical Features

Patients typically have a history of a malignant lymphoreticular neoplasm, or less commonly, a benign lymphoproliferative disorder such as angiofollicular lymph node hyperplasia (Castleman disease). In approximately one-third of reported cases, paraneoplastic pemphigus developed before a neoplasm was identified, thus signaling the presence of a tumor. The neoplastic disease may or may not be under control at the time of onset of the paraneoplastic condition. Signs and symptoms of paraneoplastic pemphigus usually begin suddenly and may appear polymorphous. In some instances, multiple vesiculobullous lesions affect the skin (Fig. 16.58) and oral mucosa. Palmar or plantar bullae may be evident, a feature that is uncommon in pemphigus vulgaris. For other patients, skin lesions can appear more papular and pruritic, similar to cutaneous lichen planus. The lips often show hemorrhagic crusting similar to that of erythema multiforme (Fig. 16.59). Oral mucosal involvement is an early, consistent feature of paraneoplastic pemphigus, and patients develop multiple areas of erythema and diffuse, irregular ulceration (Fig. 16.60), affecting virtually any oral mucosal surface. If the lesions remain untreated, then they persist and worsen. Some patients may develop only oropharyngeal lesions, without cutaneous involvement.

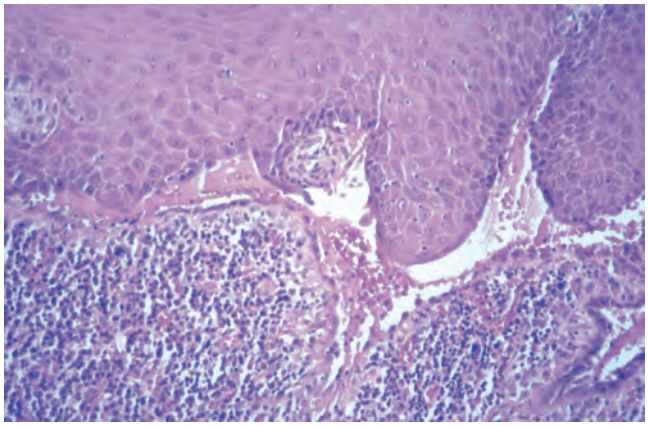


Other mucosal surfaces are also commonly affected, with 70% of patients having involvement of the conjunctival mucosa. In this area, a cicatrizing (scarring) conjunctivitis develops, similar to that seen with mucous membrane pemphigoid (Fig. 16.61). The anogenital, nasopharyngeal, esophageal, and respiratory tract mucosa may also be involved. Involvement of the bronchiolar mucosa is particularly significant because the lining epithelium sloughs and

• **Fig. 16.58 Paraneoplastic Pemphigus.** The bulla and crusted ulcerations on this patient's arm are representative of the polymorphous cutaneous lesions.



• **Fig. 16.59 Paraneoplastic Pemphigus.** Crusted, hemorrhagic lip lesions may be mistaken for erythema multiforme or herpes simplex infection.



• **Fig. 16.60 Paraneoplastic Pemphigus.** These diffuse oral ulcerations are quite painful.

dentlearn.ir

• **Fig. 16.61 Paraneoplastic Pemphigus.** Ocular involvement.

• **Fig. 16.62 Paraneoplastic Pemphigus.** This medium-power photomicrograph shows both intraepithelial and subepithelial clefting.

occludes the bronchiolar lumina and the alveoli of the lung, resulting in a condition known as **bronchiolitis obliterans.**

Histopathologic Features

The features of paraneoplastic pemphigus on light microscopic examination may be as diverse as the clinical features. In most cases, a lichenoid mucositis is seen, usually with subepithelial clefting (like pemphigoid) or intraepithelial clefting (like pemphigus) (Fig. 16.62).

Direct immunofluorescence studies may show a weakly positive deposition of immunoreactants (IgG and complement) in the intercellular zones of the epithelium and/or a linear deposition of immunoreactants at the basement membrane zone. Although antibodies directed against desmoglein 1 and 3, as well as the bullous pemphigoid antigens are often produced, antibodies directed against the plakin family of desmosomal components are more commonly identified and are more specific for paraneoplastic pemphigus. ELISA or immunoblotting techniques are used to confirm the presence of antibodies directed against periplakin or envoplakin specifically. If these tests are not available, then indirect immunofluorescence can be conducted using a transitional type of epithelium (e.g., rat urinary bladder mucosa) as the substrate due to its rich expression of plakins. This technique shows a fairly specific pattern of antibody localization to the intercellular areas of the epithelium. Examples of paraneoplastic pemphigus that show only a lichenoid reaction with no demonstrable autoantibody production have infrequently been described.

Treatment and Prognosis

Paraneoplastic pemphigus is often a very serious condition with a high morbidity and mortality rate, with cases documented in the literature having an overall mortality rate of 60%, although some series have reported a mortality rate of 90%. For the infrequent cases associated with a benign lymphoproliferative condition, surgical removal of the tumor may result in regression of the paraneoplastic pemphigus. For those cases associated with malignancy, treatment usually consists of systemic prednisone combined with cyclosporine. Cyclophosphamide, another immunosuppressive agent, may be added to this regimen, although other immunosuppressive and immune-modulating drugs are also being evaluated. Rituximab, the anti-B-cell monoclonal antibody that has shown very promising results as a treatment for pemphigus vulgaris does not appear to have a significant impact on the course of paraneoplastic pemphigus. As with pemphigus vulgaris, the skin lesions of paraneoplastic pemphigus usually respond more quickly to treatment than the oral lesions. Unfortunately, although the immunosuppressive therapy often manages to control the autoimmune disease, this immunosuppression often seems to trigger a reactivation of the malignant neoplasm. Thus a high mortality rate is seen, with patients succumbing to complications of the vesiculobullous lesions, complications of immune suppressive therapy, respiratory failure due to bronchiolitis obliterans, or progression of malignant disease. Occasionally, long-term survivors are reported, but these seem to be in the minority. As more of these patients are identified, therapeutic strategies can be better evaluated and modified for optimal care in the future.

◆ MUCOUS MEMBRANE PEMPHIGOID (CICATRICIAL PEMPHIGOID; BENIGN MUCOUS MEMBRANE PEMPHIGOID)

Evidence has accumulated to suggest that **mucous membrane pemphigoid** represents a group of chronic, blistering, mucocutaneous autoimmune diseases in which tissue-bound autoantibodies are directed against one or more components of the basement membrane. As such, this condition has a heterogeneous origin, with autoantibodies being produced against any one of a variety of basement membrane components, all of which produce similar clinical manifestations. The precise prevalence is unknown, but most authors believe that it is at least twice as common as pemphigus vulgaris.

dentlearn.ir

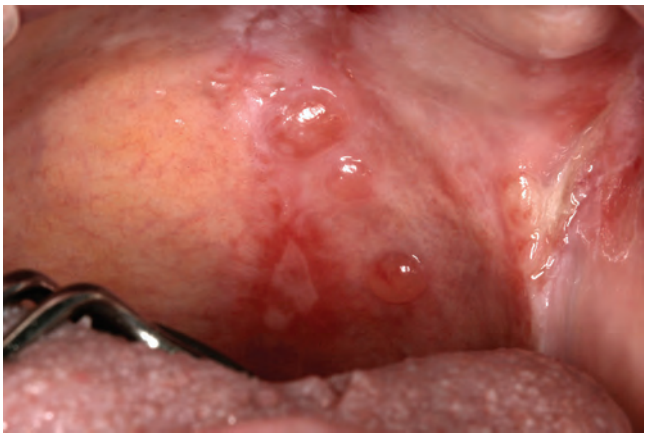
The term **pemphigoid** is used because clinically it often appears similar (the meaning of the *-oid* suffix) to **pemphigus.** The prognosis and microscopic features of pemphigoid, however, are very different.

Although a variety of terms have been used over the decades to designate this condition, a group of experts from both medicine and dentistry met in 1999 and came to an agreement that **mucous membrane pemphigoid** would be the most appropriate name for the disease. **Cicatricial pemphigoid,** another commonly used name for this process, is derived from the word **cicatrix,** meaning *scar.* When the conjunctival mucosa is affected, the scarring that results is the most significant aspect of this disorder because it invariably results in blindness unless the condition is recognized and treated. Interestingly, the oral lesions seldom exhibit this tendency for scar formation.

Clinical Features

Mucous membrane pemphigoid usually affects older adults, with an average age of 50–60 years at the onset of disease. Females are affected more frequently than males by a 2:1 ratio. Oral lesions are seen in most patients, but other sites, such as conjunctival, nasal, esophageal, laryngeal, and vaginal mucosa, as well as the skin (Fig. 16.63), may be involved.

The oral lesions of pemphigoid begin as either vesicles or bullae that may occasionally be identified clinically (Fig. 16.64). In contrast, patients with pemphigus rarely display such blisters. The most likely explanation for this difference is that the pemphigoid blister forms in a subepithelial location, producing a thicker, stronger roof than the intraepithelial, acantholytic pemphigus blister. Eventually, the oral blisters rupture, leaving large, superficial, ulcerated, and denuded areas of mucosa (Fig. 16.65). The ulcerated lesions are usually painful and persist for weeks to months if untreated.



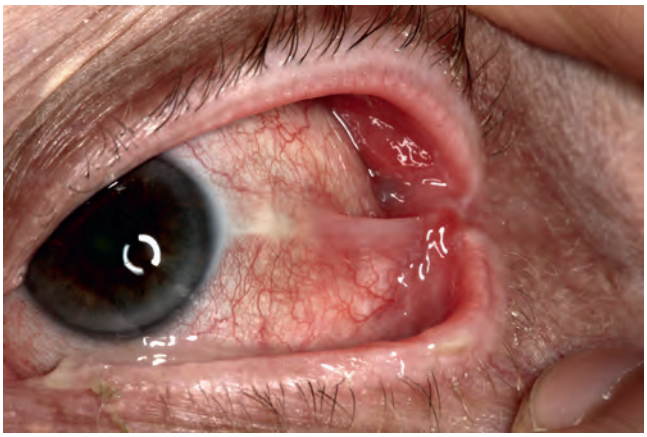
Often this process is seen diffusely throughout the mouth, but it may be limited to certain areas, especially the gingiva (Fig. 16.66). Gingival involvement produces a clinical reaction pattern termed **desquamative gingivitis** (see page 155).

• **Fig. 16.63 Mucous Membrane Pemphigoid.** Although cutaneous lesions are not common, tense bullae such as these may develop on the skin of 20% of affected patients. (Courtesy of Dr. Charles Camisa.)

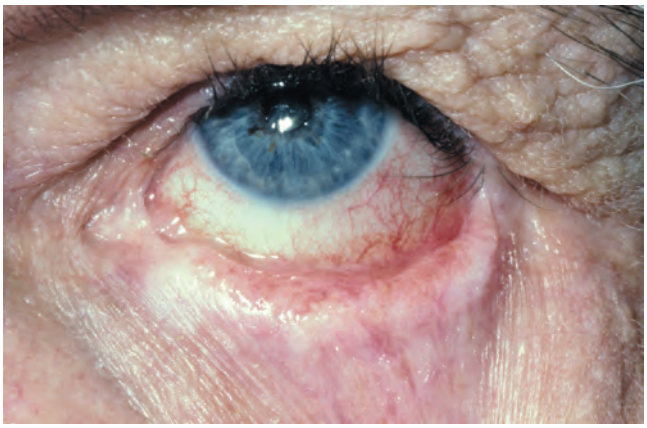
This pattern may also be seen in other conditions, such as **erosive lichen planus** or, much less frequently, **pemphigus vulgaris.**

The most significant complication of mucous membrane pemphigoid, however, is ocular involvement. Although exact figures are not available, up to 25% of patients with oral lesions may eventually develop ocular disease. One eye may be affected before the other. The earliest change is subconjunctival fibrosis, which usually can be detected by an ophthalmologist using slit-lamp microscopic examination. As the disease progresses, the conjunctiva becomes inflamed and eroded. Attempts at healing lead to scarring between the bulbar (lining the globe of the eye) and palpebral (lining the inner surface of the eyelid) conjunctivae. Adhesions called **symblepharons** result (Fig. 16.67). Without treatment the inflammatory changes become more severe, although conjunctival vesicle formation is rarely seen. Scarring can ultimately cause the eyelids to turn inward **(entropion).** This causes the eyelashes to rub against the cornea and globe **(trichiasis)** (Fig. 16.68). The scarring closes off the openings of

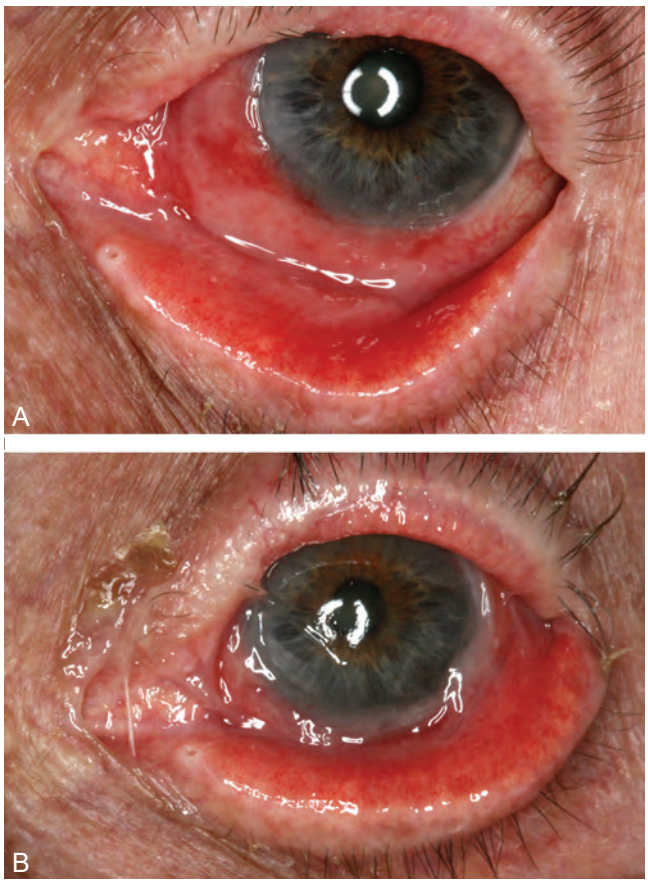
• **Fig. 16.64 Mucous Membrane Pemphigoid.** One or more intraoral vesicles, as seen on the soft palate, may be detected in patients with mucous membrane pemphigoid. Usually, shallow ulcerations of the oral mucosa are also present, as seen in the midline posterior soft palate, where one of the vesicles has ruptured.



• **Fig. 16.65 Mucous Membrane Pemphigoid.** Large, irregular oral ulcerations characterize the lesions after the initial bullae rupture.



dentlearn.ir



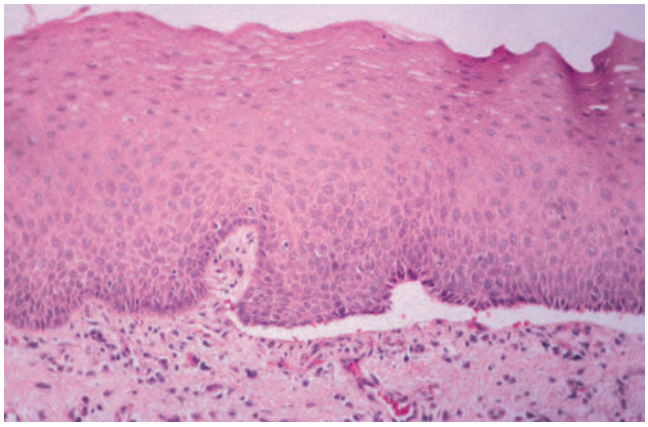
• **Fig. 16.66 Mucous Membrane Pemphigoid.** Often the gingival tissues are the only affected site, resulting in a clinical pattern known as *desquamative gingivitis*. Such a pattern may also be seen with lichen planus and pemphigus vulgaris.

• **Fig. 16.67 Mucous Membrane Pemphigoid.** Although the earliest ocular changes are difficult to identify, patients with ocular involvement may show adhesions (symblepharons) between the bulbar and palpebral conjunctivae before severe ocular damage occurs.

• **Fig. 16.68 Mucous Membrane Pemphigoid.** The disease has caused the upper eyelid of this patient to turn inward (entropion), resulting in the eyelashes rubbing against the eye itself (trichiasis). Also note the obliteration of the lower fornix of the eye.

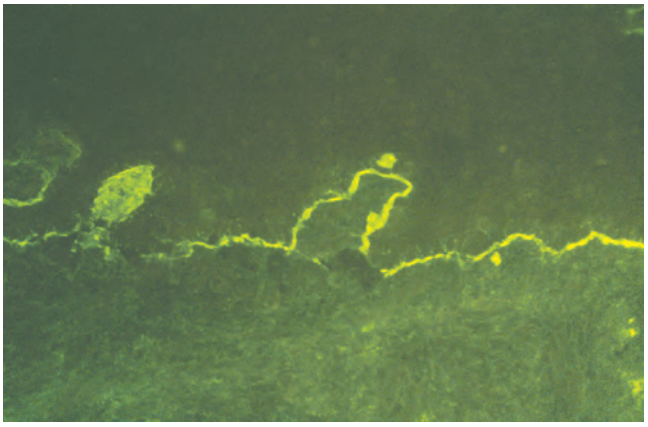
• **Fig. 16.69 Mucous Membrane Pemphigoid. A,** This patient with ocular involvement shows severe conjunctival inflammation. **B,** Four months later, the progression of his conjunctival involvement is striking, with adhesions and scarring involving the cornea.

the lacrimal glands as well, and with the loss of tears, the eye becomes extremely dry. The cornea then produces keratin as a protective mechanism; however, keratin is an opaque material, and blindness ensues (Fig. 16.69, A and B). End-stage ocular involvement may also be characterized by adhesions between the upper and lower eyelids themselves.



Other mucosal sites may also be involved and cause considerable difficulty for the patient. In females, the vaginal mucosal lesions may cause considerable pain during attempts at intercourse **(dyspareunia).**

Laryngeal lesions, which are fairly uncommon, may be especially significant because of the possibility of airway obstruction by the bullae that are formed. Patients who experience a sudden change in vocalization or who have difficulty breathing should undergo examination with laryngoscopy.



Histopathologic Features

Biopsy of perilesional mucosa shows a split between the surface epithelium and the underlying connective tissue in the region of the basement membrane (Fig. 16.70). A mild chronic inflammatory cell infiltrate is present in the superficial submucosa.

dentlearn.ir

• **Fig. 16.70 Mucous Membrane Pemphigoid.** Medium-power photomicrograph of perilesional tissue shows characteristic subepithelial clefting.

• **Fig. 16.71 Mucous Membrane Pemphigoid.** Direct immunofluorescence studies show a deposition of immunoreactants at the basement membrane zone of the epithelium. (Courtesy of Dr. Ronald Grimwood.)

Direct immunofluorescence studies of perilesional mucosa show a continuous linear band of immunoreactants at the basement membrane zone in nearly 90% of affected patients (Fig. 16.71). The immune deposits consist primarily of IgG and C3, although IgA and IgM may also be identified. One study has suggested that, when IgG and IgA deposits are found in the same patient, the disease may be more severe. All of these immunoreactants may play a role in the pathogenesis of the subepithelial vesicle formation by weakening the attachment of the basement membrane through a variety of mechanisms, including complement activation with recruitment of inflammatory cells, particularly neutrophils.

Indirect immunofluorescence is positive in only 5%–25% of these patients, indicating a relatively consistent lack of readily detectable circulating autoantibodies. One type of mucous membrane pemphigoid produces low levels of circulating autoantibodies to epiligrin (laminin-5), a component of the basement membrane. Approximately 30% of patients with this variant of mucous membrane pemphigoid have been shown to have a solid malignancy, and the pemphigoid may be the initial sign that the patient has cancer. Antiepiligrin mucous membrane pemphigoid seems to have more widespread involvement, affecting oral, nasal, ocular, and laryngeal mucosa, compared with other forms of mucous membrane pemphigoid. In contrast, another group of investigators has shown that pemphigoid patients with only oral mucosal involvement have circulating autoantibodies to α6 integrin, a component of the hemidesmosome.

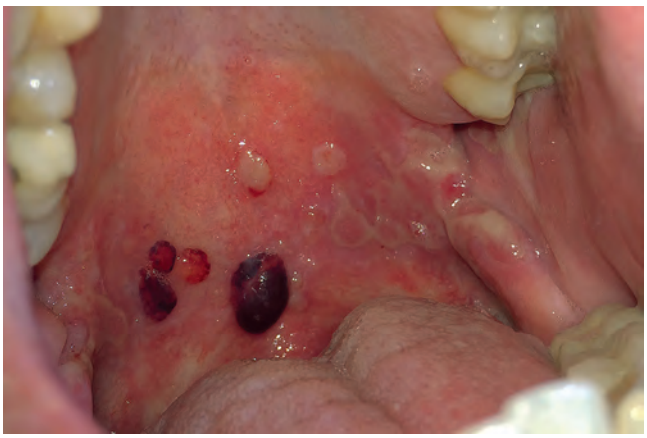
For an accurate diagnosis, perilesional tissue—rather than the ulcerated lesion itself—should be obtained. Often the epithelium in the area of the lesion is so loosely attached that it strips off as the clinician attempts to perform the biopsy. Such tissue is not usually adequate for diagnostic purposes because the interface between the epithelium and connective tissue is no longer intact (although some investigators have shown positive immunofluorescence with this tissue).

Other relatively rare conditions can mimic pemphigoid histopathologically. These include pemphigoid-like reactions to various medications (see page 337), **linear IgA bullous dermatosis, angina bullosa hemorrhagica,** and **epidermolysis bullosa acquisita.**

Linear IgA Bullous Dermatosis

Linear IgA bullous dermatosis, as the name indicates, is characterized by the linear deposition of only IgA along the basement membrane zone. Even though some cases of mucous membrane pemphigoid may have IgA antibodies, linear IgA bullous dermatosis predominantly affects the skin and, therefore, can usually be distinguished from mucous membrane pemphigoid on a clinical basis.

Angina Bullosa Hemorrhagica



Angina bullosa hemorrhagica is a rare, poorly characterized oral mucosal disorder that exhibits variably painful, blood-filled vesicles or bullae, usually affecting the soft palate of middle-aged or older adults (Fig. 16.72). The blisters typically rupture spontaneously and heal without scarring. A subepithelial cleft is noted microscopically. No hematologic or immunopathologic abnormalities have been detected, and although the cause is unknown, many patients have a history of trauma or corticosteroid inhaler use.

Epidermolysis Bullosa Acquisita

Epidermolysis bullosa acquisita is an immunologically mediated condition characterized by autoantibodies directed against type VII collagen, the principal component of the anchoring fibrils. The anchoring fibrils play an important role in bonding the epithelium to the underlying connective tissue. As a result, their immunologic destruction leads to the formation of bullous lesions of the skin and mucosa with minimal trauma. The disease was named epidermolysis bullosa acquisita ("acquisita" means "acquired") because of its clinical resemblance to the inherited condition, dystrophic epidermolysis bullosa. Unlike the inherited disorder, epidermolysis bullosa acquisita typically affects middle-aged or older adults.

Oral lesions are present in up to 50% of the cases, although such lesions are uncommon in the absence of

dentlearn.ir

• **Fig. 16.72 Angina Bullosa Hemorrhagica.** Hemorrhagic blisters on the soft palate in a patient who regularly used a corticosteroid inhaler. (Courtesy of Dr. Peter Lyu.)

cutaneous lesions. To distinguish epidermolysis bullosa acquisita from other immunobullous diseases with subepithelial clefting, a special technique is performed. A sample of the patient's perilesional skin is incubated in a concentrated salt solution; this causes the epithelium to separate from the connective tissue, forming an artificially induced bulla. Immunohistochemical evaluation shows deposition of IgG autoantibodies on the floor (connective tissue side) of the bulla where type VII collagen resides. This finding is in contrast to that of most forms of mucous membrane pemphigoid, in which the autoantibodies are usually localized to the roof of the induced blister.

Treatment and Prognosis

Once the diagnosis of mucous membrane pemphigoid has been established by light microscopy and direct immunofluorescence, the patient should be referred to an ophthalmologist who is familiar with the ocular lesions of this condition for a baseline examination of the conjunctivae. This should be done whether or not the patient is experiencing ocular complaints. In addition, if the patient is experiencing symptoms at other anatomic sites, then the appropriate specialist should be consulted.

Because this condition is characterized by heterogeneous pathogenetic mechanisms, it is not surprising that treatments advocated over the years have been varied. In fact, there is no single good therapy for every patient; treatment must be individualized, depending on lesional distribution, disease activity, and therapeutic response. Perhaps as the various forms of pemphigoid are better defined immunopathologically, more specific, directed therapy can be devised. In addition, most of the therapies are based on empirical recommendations, primarily because mucous membrane pemphigoid is relatively rare, and being able to acquire sufficient numbers of patients for randomized, placebo-controlled treatment studies is quite challenging.

Topical Agents

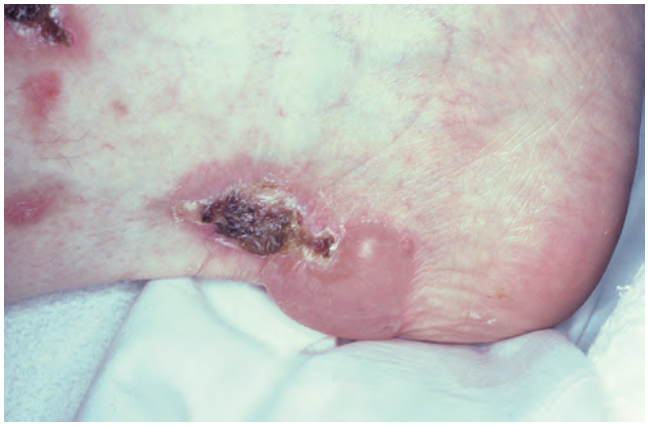
If only oral lesions are present, sometimes the disease can be controlled with application of one of the more potent topical corticosteroid gel preparations to the lesions several times each day. Once control is achieved, the applications can be discontinued, although the lesions are certain to flare up again. Sometimes alternate-day application prevents such exacerbations of disease activity.

Patients with only gingival lesions often benefit from good oral hygiene measures, which can help to decrease the severity of the lesions and reduce the amount of topical corticosteroids required. As an additional aid in treating gingival lesions, a flexible mouth guard may be fabricated to use as a carrier for the corticosteroid medication.

Systemic Agents

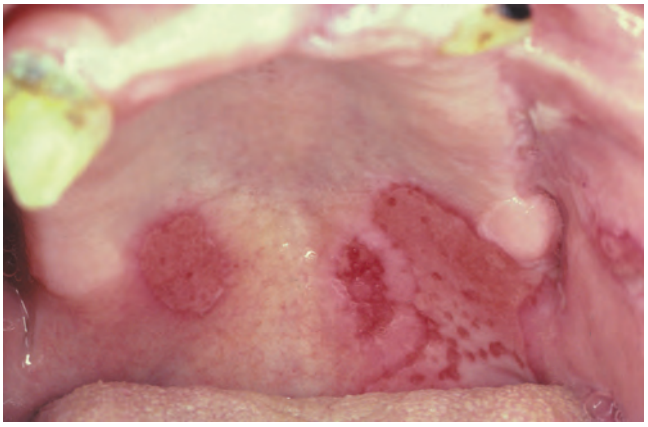
If topical corticosteroids are unsuccessful, systemic treatments are available. Dapsone, which is a sulfa drug derivative, can be used to treat patients with mild-to-moderate involvement by mucous membrane pemphigoid. Systemic treatment with dapsone typically has fewer serious side effects when compared to systemic corticosteroid therapy, for example.

Some centers report good results with dapsone, but others observe that a minority of patients respond adequately. Contraindications to its use include glucose-6-phosphate dehydrogenase deficiency or allergy to sulfa drugs.



Another alternative systemic therapy that may be used for patients with less severe disease is tetracycline or minocycline and niacinamide (nicotinamide). Systemic daily divided doses of 0.5–2.0 g of each drug have been reported (in open-label trials) to be effective in controlling mucous membrane pemphigoid. Double-blind, placebo-controlled studies on larger groups of patients should be done to confirm this form of therapy, however.

For more severely affected patients with mucous membrane pemphigoid, corticosteroids plus other immunosuppressive/immune modulating agents, (such as, rituximab, mycophenolate mofetil, or cyclophosphamide) may be used. This type of aggressive treatment is often indicated in the presence of advancing ocular disease, but it must be realized that many of these patients are older and may have preexisting medical conditions that may preclude aggressive immune suppression. Some studies have suggested that treatment with intravenous (IV) human immunoglobulin (which is very expensive) may be more effective in managing ocular lesions of pemphigoid than systemic corticosteroid therapy. Attempts at surgical correction of any symblepharons that might have formed must be done when the disease is under control or quiescent; otherwise, the manipulation often induces an acute flare of the ocular lesions.



◆ BULLOUS PEMPHIGOID

Bullous pemphigoid is the most common of the autoimmune blistering conditions, occurring at an estimated rate of ten cases per million population per year, although the

dentlearn.ir

• **Fig. 16.73 Bullous Pemphigoid.** Cutaneous vesiculobullous lesions of the heel. The bullae eventually rupture, leaving hemorrhagic crusted areas.

• **Fig. 16.74 Bullous Pemphigoid.** These oral lesions appear as large, shallow ulcerations involving the soft palate.

incidence is much greater in patients over 60 years of age. The disease is characterized by the production of autoantibodies directed against components of the basement membrane. In many respects, bullous pemphigoid resembles **mucous membrane pemphigoid,** but most investigators note that there are enough differences to consider these diseases as distinct but related entities. One significant difference is that the clinical course in patients with bullous pemphigoid is usually characterized by periods of remission followed by relapse, whereas the course in patients with mucous membrane pemphigoid is usually protracted and progressive.

Clinical Features

Bullous pemphigoid typically develops in older people; most patients are between 75 and 80 years of age. No sex or racial predilection is generally reported, although one group of investigators noted that men are overrepresented in this disease by a 2:1 margin when one corrects for the skewing of the aging population toward the female gender. Pruritus is often an early symptom. This is followed by the development of multiple, tense bullae on either normal or erythematous skin (Fig. 16.73). These lesions eventually rupture after several days, causing a superficial crust to form. Eventually, healing takes place without scarring.

Oral mucosal involvement is uncommon, with approximately 10%–20% of patients being affected. The oral lesions, like the skin lesions, begin as bullae, but they tend to rupture sooner, probably as a result of the constant low-grade trauma to which the oral mucosa is subjected. Large, shallow ulcerations with smooth, distinct margins are present after the bullae rupture (Fig. 16.74).

Histopathologic Features

Microscopic examination of tissue obtained from the perilesional margin of a bulla shows separation of the epithelium from the connective tissue at the basement membrane zone, resulting in a subepithelial separation. Modest numbers of both acute and chronic inflammatory cells are typically seen in the lesional area, and the presence of eosinophils within the bulla itself is characteristic.

Direct immunofluorescence studies show a continuous linear band of immunoreactants, usually IgG and C3, localized to the basement membrane zone in 90%–100% of affected patients. These antibodies bind to proteins associated with **hemidesmosomes,** structures that bind the basal cell layer of the epithelium to the basement membrane and the underlying connective tissue. These proteins have been designated as **bullous pemphigoid antigens (BP180 and BP230),** and immunoelectron microscopy has demonstrated the localization of BP180 to the upper portion of the lamina lucida of the basement membrane.

In addition to the tissue-bound autoantibodies, 50%–90% of the patients also have circulating autoantibodies in the serum, producing an indirect immunofluorescent pattern that is identical to that of the direct immunofluorescence. Unlike pemphigus vulgaris, the antibody titers seen in bullous pemphigoid do not appear to correlate with disease activity. The antibodies alone do not appear to be capable of inducing bullae in this disease. Instead, binding of the antibodies to the basement membrane initiates the complement cascade, which in turn results in degranulation of mast cells, with recruitment of neutrophils and eosinophils to the area. The damage to the basement membrane is thought to be mediated by elastases and matrix metalloproteinases released by these inflammatory cells.

Treatment and Prognosis

Treatment of patients with mild or localized bullous pemphigoid consists of application of one of the stronger topical corticosteroid preparations. Management of the patient with moderate-to-severe, widespread bullous pemphigoid consists of systemic immunosuppressive therapy. Moderate daily doses of systemic prednisone usually control the condition, after which alternate-day therapy may be given to reduce the risk of corticosteroid complications. If the lesions do not respond to prednisone alone, then another

dentlearn.ir

immunosuppressive, corticosteroid-sparing agent may be added to the regimen, including azathioprine, methotrexate, mycophenolate mofetil, or an anti-CD20 monoclonal antibody, such as rituximab. Dapsone, a sulfa derivative, may be used as an alternative therapeutic agent, and tetracycline and niacinamide therapy is reported to be effective for some patients. The more severe, resistant cases require prednisone combined with cyclophosphamide; however, this regimen has the potential for significant side effects.

The prognosis is generally good with respect to control of the skin lesions, with many patients experiencing remission. Recent reports based on a relatively large series of bullous pemphigoid patients have suggested that problems frequently develop due to the immunosuppressive therapy used in this older adult population. Mortality rates that are three times that of an age- and sex-matched control population may be seen, with approximately 20% of patients expiring 1 year after diagnosis.

◆ ERYTHEMA MULTIFORME

Erythema multiforme is a blistering, ulcerative mucocutaneous condition of uncertain etiopathogenesis. A cell-mediated (rather than humoral) immunologic attack on the oral mucosa and/or epidermis is thought to play a significant role, although the precise cause is poorly understood. In about 50%–60% of the cases, the clinician can identify an apparent precipitating cause, usually a preceding infection, such as **herpes simplex** or ***Mycoplasma pneumoniae,*** or less commonly, exposure to any one of a variety of drugs and medications, particularly antibiotics or analgesics. These agents may trigger the immunologic derangement that produces the disease. Sophisticated techniques in molecular biology have demonstrated the presence of herpes simplex DNA in patients with recurrent erythema multiforme, thus supporting the concept of an immunologic precipitating event. Interestingly, direct and indirect immunofluorescence studies are nonspecific and are not really very useful diagnostically except to rule out other vesiculobullous diseases.

For many years it was thought that erythema multiforme exhibited a spectrum of severity, ranging from **erythema multiforme minor** through **erythema multiforme major** (traditionally thought to be synonymous with **Stevens-Johnson syndrome**) and **toxic epidermal necrolysis (Lyell disease).** Most authorities currently feel that erythema multiforme minor and major may represent a distinctly different process from the latter two conditions. Therefore, Stevens-Johnson syndrome and toxic epidermal necrolysis will be discussed separately in the next section.

Clinical Features

Erythema multiforme typically has an acute onset and usually affects young adults in their 20s or 30s, with no striking sex predilection. Prodromal symptoms are often present and include fever, malaise, headache, cough, and sore throat, occurring approximately 1 week before onset. The condition may show varying degrees of severity in affected patients. Milder cases, known as **erythema multiforme minor,** usually begin with the development of slightly elevated, round, dusky-red patches on the skin of the extremities. These lesions may have a variety of appearances, however *(multiforme* means *many forms).* Some of these skin lesions develop features that are highly characteristic for the disease. These lesions appear as concentric circular erythematous rings resembling a target or bull's-eye **(target lesions)** (Fig. 16.75). In more severe cases, these may evolve into bullae with necrotic centers.

The oral cavity is the most frequently involved mucosal site, although the conjunctival, genitourinary, and respiratory mucosa also may be affected. Involvement of extraoral mucosal areas is usually associated with the more severe form of this condition, erythema multiforme major.

The frequency of oral involvement is difficult to determine and is reported to range from 25% to 70%. Discrepancies in the prevalence may be due to referral patterns or degree of scrutiny of the oral mucosa. The oral lesions begin as erythematous patches that undergo epithelial necrosis and evolve into large, shallow erosions and ulcerations with irregular borders (Fig. 16.76). Hemorrhagic crusting of the vermilion zone of the lips is common (Fig. 16.77). These oral lesions, like the skin lesions, emerge quickly and are uncomfortable. Sometimes patients are dehydrated because they are unable to ingest liquids as a result of mouth pain. The ulcerations often have a diffuse distribution. The lips, labial mucosa, buccal mucosa, tongue, floor of the mouth, and soft palate are the most common sites of involvement. Usually, the gingivae and hard palate are relatively spared.

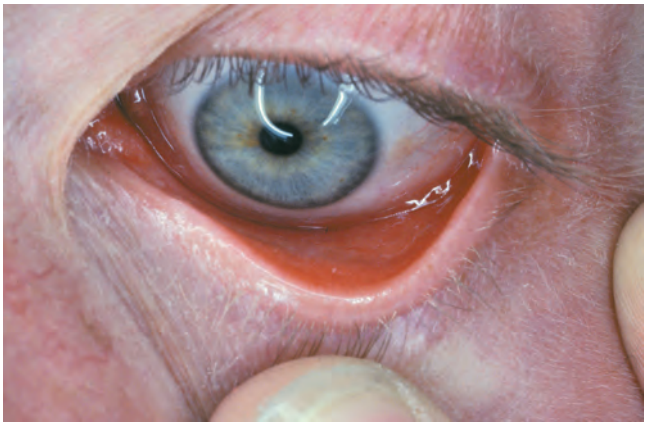
Erythema Multiforme Major

A diagnosis of *erythema multiforme major* can be made if two or more mucosal sites are affected in conjunction with widespread skin lesions. In most cases the oral mucosa is involved in addition to either the ocular (Fig. 16.78) or genital mucosae. With severe ocular involvement, scarring (symblepharon formation) may occur, similar to that in mucous membrane pemphigoid (see page 776).

• **Fig. 16.75 Erythema Multiforme.** The concentric erythematous pattern of the cutaneous lesions on the fingers resembles a target or bull's-eye.

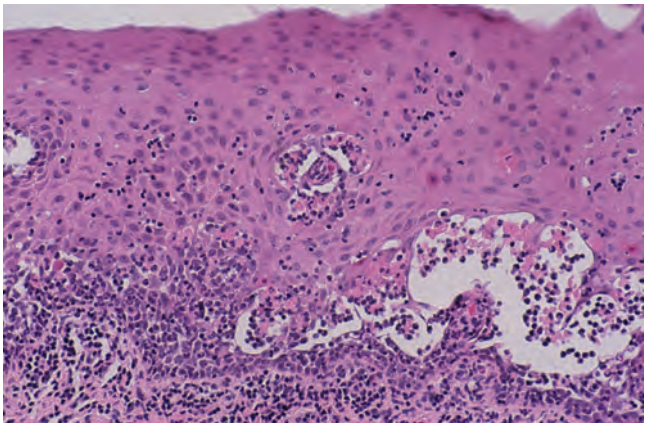
dentlearn.ir

• **Fig. 16.76 Erythema Multiforme.** Focal hemorrhagic crusting of the lips is seen in conjunction with diffuse shallow ulcerations and erosions involving this patient's mandibular labial mucosa.



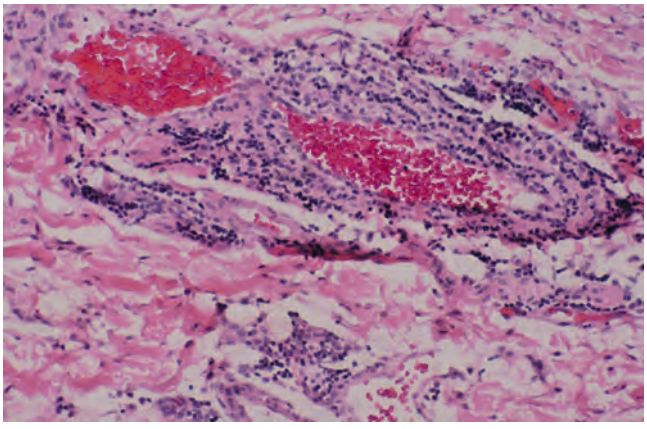
• **Fig. 16.77 Erythema Multiforme.** Same patient as Fig. 16.76. Diffuse shallow ulcerations of varying sizes are noted on the right buccal mucosa. The patient had finished a course of sulfamethoxazole and trimethoprim for a urinary tract infection a few days before the onset of the lesions.

Histopathologic Features



Histopathologic examination of the perilesional mucosa in erythema multiforme reveals a pattern that is characteristic but not pathognomonic. Subepithelial or intraepithelial vesiculation may be seen in association with necrotic basal keratinocytes (Fig. 16.79). A mixed inflammatory infiltrate is present, consisting of lymphocytes, neutrophils, and often eosinophils. Sometimes these cells are arranged in a perivascular orientation (Fig. 16.80). Because the immunopathologic features are also nonspecific, the diagnosis is often based on the clinical presentation and the exclusion of other vesiculobullous disorders.

Treatment and Prognosis



Management of erythema multiforme, in many respects, remains controversial. In the past, the use of systemic or topical corticosteroids was often advocated, especially in the

• **Fig. 16.78 Erythema Multiforme Major.** While involvement of other mucosal surfaces is more frequently seen with Stevens-Johnson syndrome, this patient's condition was preceded by oral herpetic infection. This finding, combined with his cutaneous manifestations, resulted in a diagnosis of erythema multiforme major, in this case causing the severe conjunctivitis depicted in this photograph.

• **Fig. 16.79 Erythema Multiforme.** This medium-power photomicrograph shows inflammation and intraepithelial vesicle formation in the basilar portion of the epithelium. Numerous necrotic and apoptotic eosinophilic keratinocytes are present in the blister area.

• **Fig. 16.80 Erythema Multiforme.** This medium-power photomicrograph shows the perivascular inflammatory infiltrate, typically seen in erythema multiforme.

dentlearn.ir

early stages of the disease. Although there is little good clinical evidence from controlled trials that such treatment is beneficial, this treatment is typically used at most centers. If a causative drug is identified or suspected, then it should be discontinued immediately.

If the patient is dehydrated as a result of an inability to eat because of oral pain, then IV rehydration may be necessary along with topical anesthetic agents to decrease discomfort.

Even though the disease is self-limiting, usually lasting 2–6 weeks, about 20% of patients experience recurrent episodes, usually in the spring and autumn. If recurrent episodes of erythema multiforme are a problem, then an initiating factor, such as recurrent herpesvirus infection or drug exposure, should be sought. If disease is triggered by herpes simplex, then continuous oral acyclovir or valacyclovir therapy can prevent recurrences. Very infrequently patients may have continuous lesions of erythema multiforme. In most cases erythema multiforme is not life-threatening except in its most severe form.

◆ STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

In the past, many dermatologists considered Stevens-Johnson syndrome and toxic epidermal necrolysis to represent the most severe end of the erythema multiforme spectrum. As careful documentation of the clinical features of these uncommon diseases was compiled, it became evident that there were subtle, but distinct, differences between erythema multiforme and Stevens-Johnson/toxic epidermal necrolysis. Although the inciting event in erythema multiforme is usually a herpesvirus infection, Stevens-Johnson syndrome and toxic epidermal necrolysis are almost always triggered by drug exposure, with more than 200 different medications having been implicated. Recent studies have shown that the damage to the epithelium is due to increased apoptosis of the epithelial cells, and several mechanisms have been postulated to account for this phenomenon.

Clinical Features

The difference between Stevens-Johnson syndrome and toxic epidermal necrolysis is the degree of skin involvement, with Stevens-Johnson syndrome having less than 10% of the body surface affected by lesions, and toxic epidermal necrolysis having more than 30% involvement. These severe blistering diseases are rare. Stevens-Johnson syndrome occurs at an average rate of one to seven cases per million population per year, whereas toxic epidermal necrolysis occurs at a rate of about one case per million per year. In contrast to Stevens-Johnson syndrome, which is usually seen in younger patients, toxic epidermal necrolysis tends to occur in people over 60 years of age. A female predilection is observed.

These patients usually have flu-like prodromal signs and symptoms, including fever, malaise, sore throat, headache, and loss of appetite. Within a few days, skin lesions begin to develop, but unlike erythema multiforme, the cutaneous lesions of Stevens-Johnson syndrome and toxic epidermal necrolysis initially appear on the trunk, presenting as erythematous macules (completely flat). Within 1–14 days, however, sloughing of the skin and flaccid bullae develop. Virtually all of these patients will have mucosal sites of involvement (Fig. 16.81), particularly the oral mucosa. Diffuse sloughing of a significant proportion of the skin and mucosal surfaces makes it appear as if the patient had been badly scalded (Figs. 16.82 and 16.83). If the patient survives, then the cutaneous process resolves in 3–5 weeks; however, oral lesions may take longer to heal, and significant residual ocular damage is evident in half of the patients.

Histopathologic Features

Biopsy of a developing bulla of Stevens-Johnson syndrome or toxic epidermal necrolysis typically shows a subepithelial blister that is characterized by degenerating, necrotic basal keratinocytes. The underlying connective tissue usually supports a rather sparse population of chronic inflammatory cells.

• **Fig. 16.81 Stevens-Johnson Syndrome.** Genital ulcerations, demonstrated in this patient by the involvement of the glans penis, may be a component of Stevens-Johnson syndrome, which tends to be more severe than erythema multiforme major.

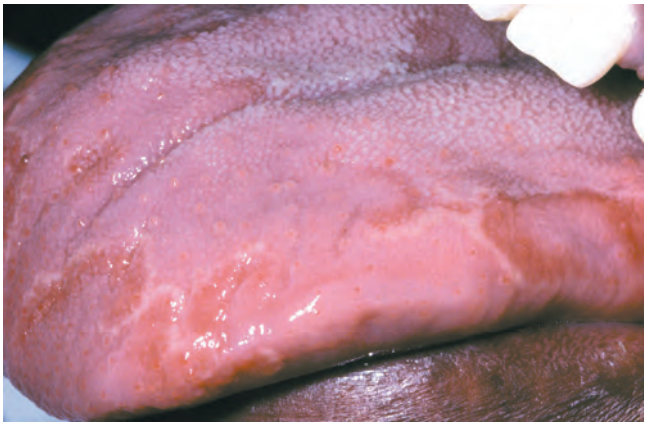
dentlearn.ir

• **Fig. 16.83 Toxic Epidermal Necrolysis.** The desquamation of the skin of the foot is characteristic of the diffuse sloughing cutaneous lesions. (Courtesy of Dr. Peter Larsen.)

Treatment and Prognosis

One of the most important aspects in managing patients with Stevens-Johnson syndrome and toxic epidermal necrolysis is identifying and immediately discontinuing any drug that might be initiating the condition. Because the lesions of toxic epidermal necrolysis are analogous to those suffered by burn patients, management of these patients in the burn unit of the hospital is recommended. Corticosteroids should be avoided in the management of toxic epidermal necrolysis because some investigators have found that such drugs may be detrimental. IV administration of pooled human immunoglobulins has been shown in several open-label trials to produce remarkable resolution of toxic epidermal necrolysis, presumably because of blockade of Fas ligand, which is believed to play a role in inducing epithelial cell apoptosis. The mortality rate in patients with toxic epidermal necrolysis historically has been approximately 25%–30%; the rate in those with Stevens-Johnson syndrome is 1%–5%.



◆ ERYTHEMA MIGRANS (GEOGRAPHIC TONGUE; BENIGN MIGRATORY GLOSSITIS; WANDERING RASH OF THE TONGUE; ERYTHEMA AREATA MIGRANS; STOMATITIS AREATA MIGRANS)

Erythema migrans is a common benign condition that primarily affects the tongue. It is often detected on routine examination of the oral mucosa. The lesion occurs in 1%–3% of the population. Some epidemiologic studies have shown that females are affected more frequently than males by a 2:1 ratio, whereas other series do not identify a gender predilection. Patients occasionally may consult a health care professional if they happen to notice the unusual appearance of their tongue or if the lingual mucosa becomes sensitive to hot or spicy foods as a result of the process.

Even though erythema migrans has been documented for many years, the etiopathogenesis is still unknown. Some investigators have suggested that erythema migrans occurs with increased frequency in atopic individuals; however, one large epidemiologic study in the United States found no statistically significant association between erythema migrans and a variety of conditions that had previously been postulated either to cause or influence this process. Erythema migrans was not seen as frequently in cigarette smokers, while there seemed to be no significant differences in frequency related to age, sex, oral contraceptive use, presence of allergies, diabetes mellitus, or psychological or dermatologic conditions. A similar study in Turkey essentially agreed with these findings, with the exception of an association with a history of allergy or atopy.

• **Fig. 16.84 Erythema Migrans.** The erythematous, well-demarcated areas of papillary atrophy are characteristic of erythema migrans affecting the tongue (benign migratory glossitis). Note the asymmetrical distribution and the tendency to involve the lateral aspects of the tongue.

• **Fig. 16.85 Erythema Migrans.** Lingual mucosa of a different patient than the one in Fig. 16.84. The lateral distribution of the lesions is shown.

Clinical Features

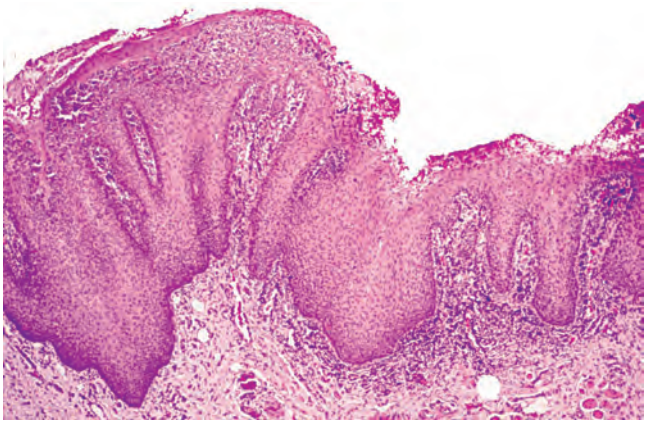
The characteristic lesions of erythema migrans are seen on the anterior two-thirds of the dorsal tongue mucosa. They appear as multiple, well-demarcated zones of erythema (Figs. 16.84 and 16.85), concentrated at the tip and lateral borders of the tongue. This erythema is due to atrophy of the filiform papillae, and these atrophic areas are typically surrounded at least partially by a slightly elevated, yellow-white, serpentine or

dentlearn.ir

scalloped border (Fig. 16.86). The patient who is aware of the process is often able to describe the lesions as appearing quickly in one area, healing within a few days or weeks, and then developing in a very different area. Frequently, the lesion begins as a small white patch, which then develops a central erythematous atrophic zone and enlarges centrifugally. Approximately one-third of patients with **fissured tongue** (see page 11) are affected with erythema migrans as well. Some patients may have only a solitary lesion, but this is uncommon. The lesions are usually asymptomatic, although a burning sensation or sensitivity to hot or spicy foods may be noted when the lesions are active. Only rarely is the burning sensation more constant and severe.

Very infrequently, erythema migrans may occur on oral mucosal sites other than the tongue. In these instances, the tongue is almost always affected; however, other lesions develop on the buccal mucosa, on the labial mucosa, and (less frequently) on the soft palate or floor of the mouth (Figs. 16.87 and 16.88). These lesions typically produce no symptoms and can be identified by a yellow-white serpentine or scalloped border that surrounds an erythematous zone. These features should prevent confusion with such conditions as candidiasis or erythroplakia.

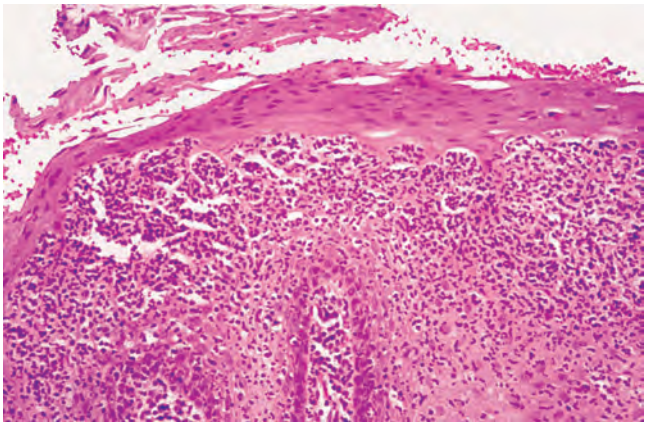
• **Fig. 16.86 Erythema Migrans.** Striking involvement of the dorsal and lateral surfaces of the tongue.



• **Fig. 16.87 Erythema Migrans.** Lesions of the lower labial mucosa.

Histopathologic Features

If a biopsy specimen of the peripheral region of erythema migrans is examined, a characteristic histopathologic pattern is observed. Hyperparakeratosis, spongiosis, acanthosis, and elongation of the epithelial rete ridges are seen (Fig. 16.89). In addition, collections of neutrophils **(Munro abscesses)** are observed within the epithelium (Fig. 16.90); lymphocytes and neutrophils involve the lamina propria. The intense neutrophilic infiltrate may be responsible for the destruction of the superficial portion of the epithelium, thus producing an atrophic, reddened mucosa as the lesion progresses. Because these histopathologic features are reminiscent of **psoriasis,** this is called a **psoriasiform mucositis.** Despite the apparent lack of association between dermatologic conditions and erythema migrans in some reports, at least one case-control study of psoriatic patients showed that erythema migrans occurred at a rate of about 10%; only 2.5% of an age-matched and sex-matched population were affected. A Brazilian study determined that both patients with psoriasis and those with benign migratory glossitis were more likely to have the same human



• **Fig. 16.88 Erythema Migrans.** These palatal lesions show well-demarcated erythematous areas surrounded by a white border, similar to the process involving the tongue.

• **Fig. 16.89 Erythema Migrans.** This low-power photomicrograph shows the elongation of the rete ridges with parakeratosis and neutrophilic infiltration. Such features are also common in psoriasis, which explains why this is known as a *psoriasiform mucositis*.

dentlearn.ir

• **Fig. 16.90 Erythema Migrans.** This medium-power photomicrograph shows collections of neutrophils in the superficial spinous layer of the epithelium.

leukocyte antigen (HLA) group, namely HLA-Cw6. In addition, a Croatian study found that patients with erythema migrans, compared to a control group with no oral lesions, were statistically more likely to have celiac disease, a gluten-sensitive enteropathy. Whether these findings mean that erythema migrans represents oral psoriasis or oral celiac disease is debatable. It may simply reflect an immunologic milieu that predisposes patients to be more susceptible to developing erythema migrans.

Treatment and Prognosis

Generally no treatment is indicated for patients with erythema migrans. Reassuring the patient that the condition is completely benign is often all that is necessary. Infrequently, patients may complain of tenderness or a burning sensation that is so severe that it disrupts their lifestyle. In such cases, topical corticosteroids, such as fluocinonide or betamethasone gel, may provide relief when applied as a thin film several times a day to the lesional areas.

◆ REACTIVE ARTHRITIS (REITER SYNDROME)

Reactive arthritis represents a group of uncommon diseases that most likely have an immunologically mediated cause. Current evidence suggests that these disorders may be triggered by any one of several infectious agents in a genetically susceptible person. In some instances, the arthritis will be accompanied by mucocutaneous findings, including oral lesions. A classic triad of signs has been described:

1. Nongonococcal urethritis
2. Arthritis
3. Conjunctivitis

However, most patients do not exhibit all three of these signs. Although reactive arthritis with a mucocutaneous component is also known as **Reiter syndrome,** some authors have advocated removing the *Reiter* eponym because of Hans Reiter's Nazi criminal activities during World War II, and he was not the first to describe this syndrome.

It is interesting that reactive arthritis has been reported with some frequency in patients infected with the human immunodeficiency virus (HIV).

Clinical Features

Reactive arthritis is particularly prevalent in young adult men. In some series, a male-to-female ratio of up to 9:1 has been reported. The majority (60%–80%) of these patients are positive for HLA-B27, a haplotype present in only 10% of the population. The syndrome usually develops 1–4 weeks after an episode of dysentery or venereal disease; in fact, two French physicians published a description of this entity affecting four postdysenteric soldiers 1 week before Reiter's paper appeared.

Urethritis is often the first sign and is seen in both affected males and females. Females may also have inflammation of the uterine cervix. Conjunctivitis usually appears concurrently with the urethritis, and after several days, arthritis ensues. The arthritis usually affects the joints of the lower extremities, although TMJ involvement has been identified in one-third of these patients, typically as erosion of the condylar head. Skin lesions often take the form of a characteristic lesion of the glans penis **(balanitis circinata).** These lesions develop in about 20%–30% of patients with reactive arthritis, and they appear as well-circumscribed erythematous erosions with a scalloped, whitish linear boundary.

The oral lesions, which occur in slightly less than 20% of patients with this disorder, are described in various ways. Some reports mention painless erythematous papules distributed on the buccal mucosa and palate; other reports describe shallow, painless ulcers that affect the tongue, buccal mucosa, palate, and gingiva. Some authors have even implied that **geographic tongue** may be a component of reactive arthritis, probably because geographic tongue bears a superficial resemblance to the lesions of balanitis circinata.

The American Rheumatism Association has defined reactive arthritis based on the clinical findings of a peripheral arthritis that lasts longer than 1 month in conjunction with urethritis, cervicitis, or both.

Histopathologic Features

The histopathologic findings of the cutaneous lesions in patients with reactive arthritis are frequently similar to those found in patients with **psoriasis,** particularly with respect to the presence of microabscesses within the superficial layers of the surface epithelium. Other features in common with psoriasis include hyperparakeratosis with elongated, thin rete ridges.

Treatment and Prognosis

Some patients with reactive arthritis experience spontaneous resolution of their disease after 3–12 months, but many others have chronic symptoms that may wax and wane. Treatment may not be necessary for the milder cases. NSAIDs are initially used for managing arthritis, and sulfasalazine may be helpful in resolving cases that do not

dentlearn.ir

respond. Immunosuppressive or immune modulating agents, including corticosteroids, azathioprine, etanercept, and methotrexate, are reserved for the most resistant cases if they are not associated with HIV infection.

Physical therapy probably helps to reduce joint fibrosis associated with arthritis. About 15%–20% of patients with this disorder have severe disability, usually from arthritis.

◆ LICHEN PLANUS

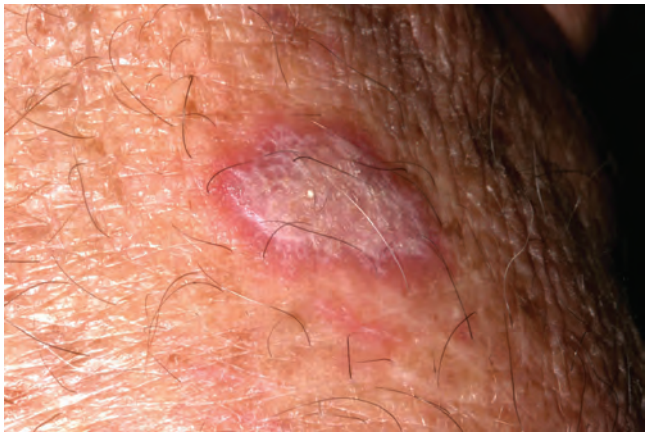
Lichen planus is a relatively common, chronic dermatologic disease that often affects the oral mucosa. The strange name of the condition was provided by the British physician Erasmus Wilson, who first described it in 1869. Lichens are primitive plants composed of symbiotic algae and fungi. The term *planus* is Latin for *flat.* Wilson probably thought that the skin lesions looked similar enough to the lichens growing on rocks to merit this designation. Even though the term *lichen planus* suggests a flat, fungal condition, current evidence indicates that this is an immunologically mediated mucocutaneous disorder.

A variety of medications may induce lesions that can appear clinically very similar to the idiopathic form of the condition; however, the term **lichenoid mucositis** (or **lichenoid dermatitis,** depending on the site involved) is probably a better name for the drug-related alterations (see page 337). Similarly, foreign material that becomes inadvertently embedded in the gingiva may elicit a host response that is termed **lichenoid foreign body gingivitis** (see page 154). Reports of hepatitis C infection associated with oral lichen planus occasionally have appeared in the literature, usually from the Mediterranean countries, but this does not appear to be a significant association in the United States or Great Britain. More recent, carefully controlled epidemiologic studies do not appear to support an association of oral lichen planus with hepatitis C. However, genetic influences presumably may have an effect on the expression of lichen planus in select populations.

The relationship of stress or anxiety to the development of lichen planus is controversial, and most cited cases appear to be anecdotal or lack appropriate controls. Those studies that have applied psychologic questionnaires often find increased levels of anxiety in these patients; however, many patients who have been told that they have lichen planus are aware that anxiety has been linked to the disorder. Whether this awareness may influence the manner in which they answer the psychologic questionnaires could be debated. In one study that used psychologic questionnaires to attempt to resolve this question, patients with oral lichen planus had no greater degree of stress in their lives than did age-matched and sex-matched control patients. It might be that stress has no bearing on the pathogenesis of lichen planus; however, an alternative explanation might be that those patients who have lichen planus simply respond in this fashion to levels of stress that do not induce lesions in other people.

Recently some investigators have identified a link between hypothyroidism and oral lichen planus, including the association of thyroid medication and oral lichen planus. Autoantibodies directed against thyroid tissue may also play a role in the pathogenesis of oral lichen planus in some patients.

Clinical Features

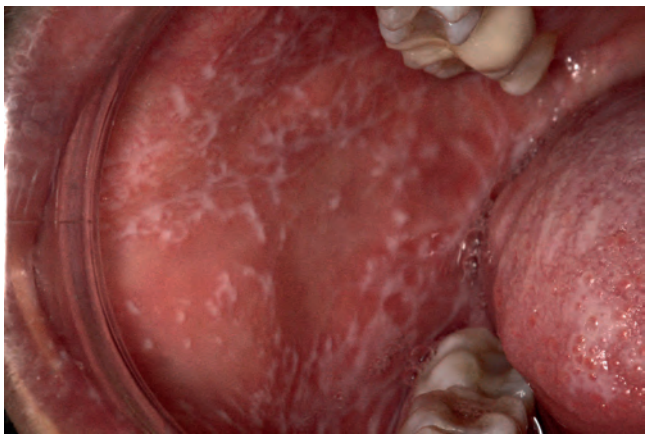


Most patients with lichen planus are middle-aged adults. It is rare for children to be affected. Women predominate in most series of cases, usually by a 3:2 ratio over men. Approximately 1% of the population may have cutaneous lichen planus. The prevalence of oral lichen planus is between 0.1% and 2.2%.

The skin lesions of lichen planus have been classically described as purple, pruritic, polygonal papules (Fig. 16.91). These usually affect the flexor surfaces of the extremities. Excoriations may not be visible, despite the fact that the lesions itch, because it hurts the patient when he or she scratches them.

Careful examination of the surface of the skin papules reveals a fine, lacelike network of white lines **(Wickham striae)** (Fig. 16.92). Other sites of extraoral involvement include the glans penis, the vulvar mucosa, and the nails. Essentially there are two forms of oral lesions: reticular and erosive.

• **Fig. 16.91 Lichen Planus.** The cutaneous lesions on the wrist appear as purple, polygonal papules.



• **Fig. 16.92 Lichen Planus.** Closer view of a skin lesion of lichen planus. Careful examination shows a network of fine white lines (Wickham striae) on the surface of the papules.

dentlearn.ir

Reticular Lichen Planus

Reticular lichen planus is much more common than the erosive form, but the erosive form predominates in several studies. This is probably because of referral bias (because the erosive form is symptomatic and, therefore, the patient is more likely to be referred to an academic center for evaluation). The reticular form usually causes no symptoms and involves the posterior buccal mucosa bilaterally (Fig. 16.93). Post-inflammatory melanosis occasionally accompanies the reticular striae, particularly in persons of color (Fig. 16.94). Other oral mucosal surfaces may also be involved concurrently, such as the lateral and dorsal tongue, the gingivae, the palate, and vermilion border (Fig. 16.95).

Reticular lichen planus is thus named because of its characteristic pattern of interlacing white lines (also referred to as *Wickham striae*); however, the white lesions may appear as papules in some instances. These lesions are typically not static but wax and wane over weeks or months (Fig. 16.96). The reticular pattern may not be as evident in some sites, such as the dorsal tongue, where the lesions appear more as keratotic plaques with atrophy of the papillae (Fig. 16.97). In addition, superficial mucoceles may develop within, or adjacent to, mucosal areas that are involved by lichen planus.

• **Fig. 16.93 Lichen Planus.** The interlacing white lines and papules are typical of reticular lichen planus involving the buccal mucosa, the most common site of oral involvement.

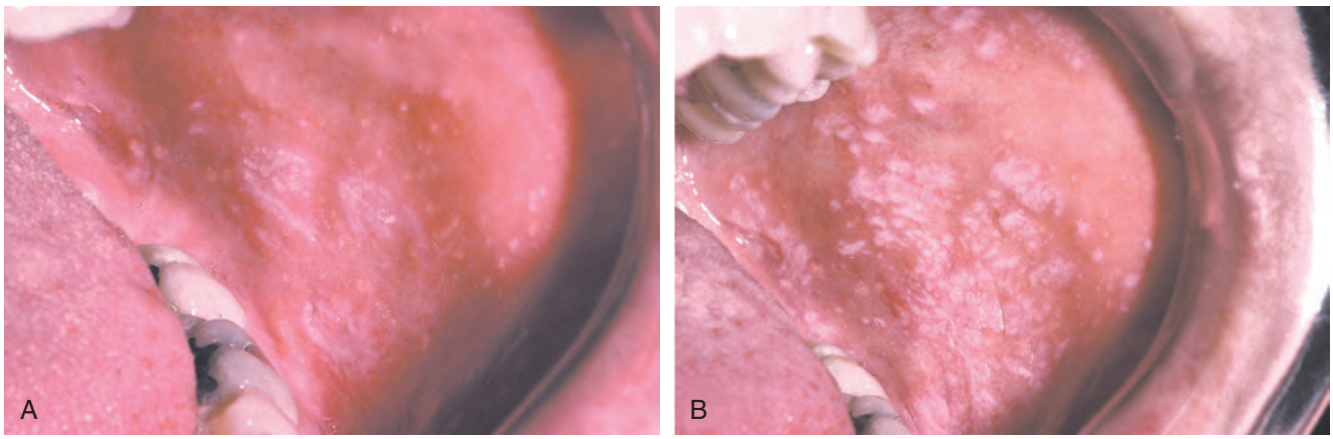
• **Fig. 16.94 Lichen Planus.** In persons of color who develop lichen planus, it is not unusual to see patchy areas of reactive (benign) melanosis develop in the lesions, presumably due to stimulation of the melanocytes in this area by the inflammatory cells that cause this condition.

Erosive Lichen Planus

Erosive lichen planus, although not as common as the reticular form, is more significant for the patient because the lesions are usually symptomatic. Clinically, there are atrophic, erythematous areas with central ulceration of varying degrees. The periphery of the atrophic regions is usually bordered by fine, white radiating striae (Figs. 16.98 and 16.99). Sometimes the atrophy and ulceration are confined to the gingival mucosa, producing the reaction pattern called **desquamative gingivitis** (see page 155) (Fig. 16.100). In such cases, biopsy specimens should be obtained for light microscopic and immunofluorescent studies of perilesional tissue, because mucous membrane pemphigoid (see page 775) and pemphigus vulgaris (see page 769) may appear in a similar fashion.

If the erosive component is severe, epithelial separation from the underlying connective tissue may occur. This results in the relatively rare presentation of **bullous lichen planus.**

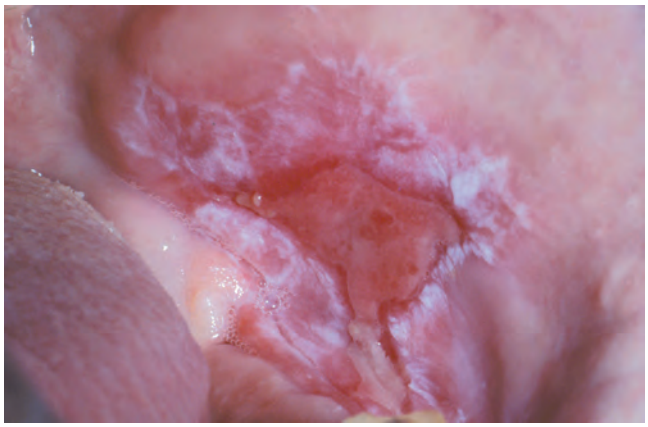
Histopathologic Features



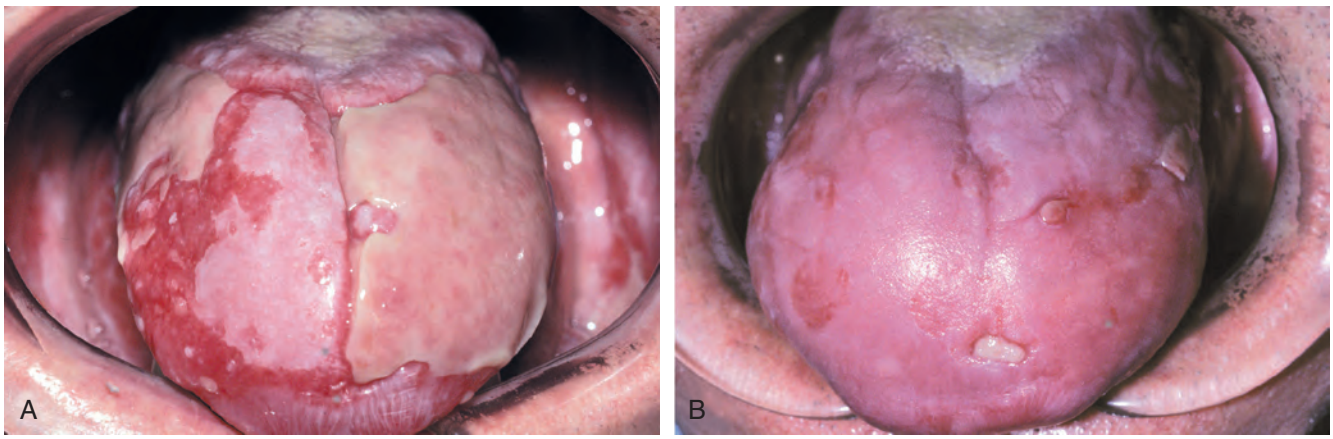
The histopathologic features of lichen planus are characteristic but may not be specific, because other conditions, such as **lichenoid drug reaction, lichenoid amalgam reaction, lichenoid foreign body gingivitis, oral graft-versus-host disease (GVHD), lupus erythematosus (LE), chronic ulcerative stomatitis, oral mucosal cinnamon reaction,** and the incipient phase of **proliferative verrucous leukoplakia** may also show a similar histopathologic pattern. Varying degrees of orthokeratosis and parakeratosis may be present on the surface of the epithelium, depending on whether the biopsy specimen is taken from an erosive or reticular lesion.

The thickness of the spinous layer can also vary. The rete ridges may be absent or hyperplastic, but they classically have a pointed or "saw-toothed" shape (Fig. 16.101).

• **Fig. 16.95 Lichen Planus.** Reticular lesions of the lower lip vermilion.



dentlearn.ir

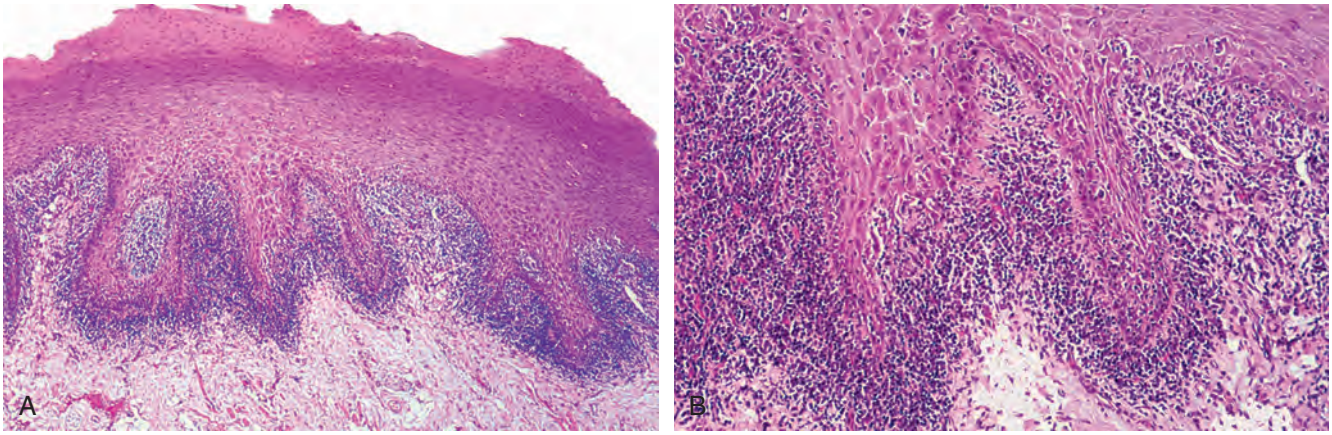


• **Fig. 16.96 Lichen Planus. A,** A middle-aged woman with mild reticular lichen planus of the left buccal mucosa. **B,** Same patient 2 weeks later, showing exacerbation of the lesions. Such waxing and waning is characteristic of lichen planus.

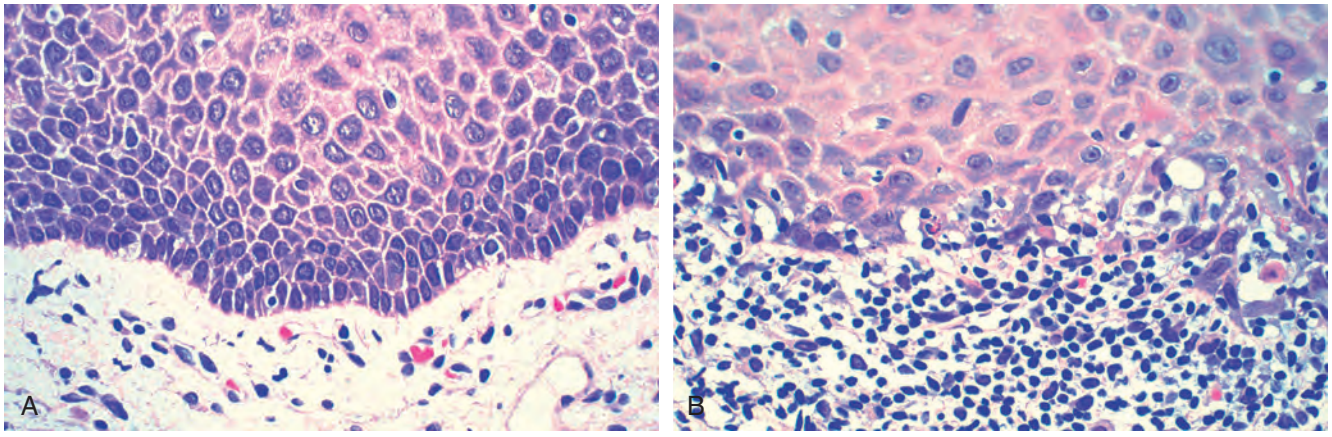
• **Fig. 16.97 Lichen Planus.** With involvement of the dorsal tongue by reticular lichen planus, the characteristic interlacing striae seen in the buccal mucosal lesions are usually not present. Instead, smooth white plaques are typically observed replacing the normal papillary surface of the tongue.

• **Fig. 16.98 Lichen Planus.** Ulceration of the buccal mucosa shows peripheral radiating keratotic striae, characteristic of oral erosive lichen planus.

• **Fig. 16.99 Lichen Planus. A,** The dorsal surface of the tongue shows extensive ulceration caused by erosive lichen planus. Note the fine white streaks at the periphery of the ulcerations. **B,** Same patient after systemic corticosteroid therapy. Much of the mucosa has reepithelialized, with only focal ulcerations remaining.



dentlearn.ir



• **Fig. 16.100 Lichen Planus.** Erosive lichen planus often appears as a desquamative gingivitis, producing gingival erythema and tenderness.

Destruction of the basal cell layer of the epithelium **(hydropic degeneration)** is also evident. This is accompanied by an intense, bandlike infiltrate of predominantly T lymphocytes immediately subjacent to the epithelium (Fig. 16.102). Degenerating keratinocytes may be seen in the area of the epithelium and connective tissue interface and have been termed **colloid, cytoid, hyaline,** or **Civatte bodies.** No significant degree of epithelial atypia is expected in oral lichen planus, although lesions having a superimposed candidal infection may appear worrisome. These should be reevaluated histopathologically after the candidal infection is treated. On occasion, the chronic inflammatory host response to the atypical cells of **epithelial dysplasia** can appear virtually indistinguishable histopathologically from lichen planus, particularly in milder cases of epithelial dysplasia. Such ambiguity may contribute to the controversy related to the malignant transformation potential of lichen planus.

The immunopathologic features of lichen planus are nonspecific. Most lesions show the deposition of a shaggy band of fibrinogen at the basement membrane zone, however a similar pattern of fibrinogen deposition can be found with epithelial dysplasia.

• **Fig. 16.101 Lichen Planus. A,** This low-power photomicrograph of an oral lesion shows hyperkeratosis, saw-toothed rete ridges, and a bandlike infiltrate of lymphocytes immediately subjacent to the epithelium. **B,** Higher-power view showing migration of lymphocytes into the lower epithelium with interface degeneration of the basal cell layer.

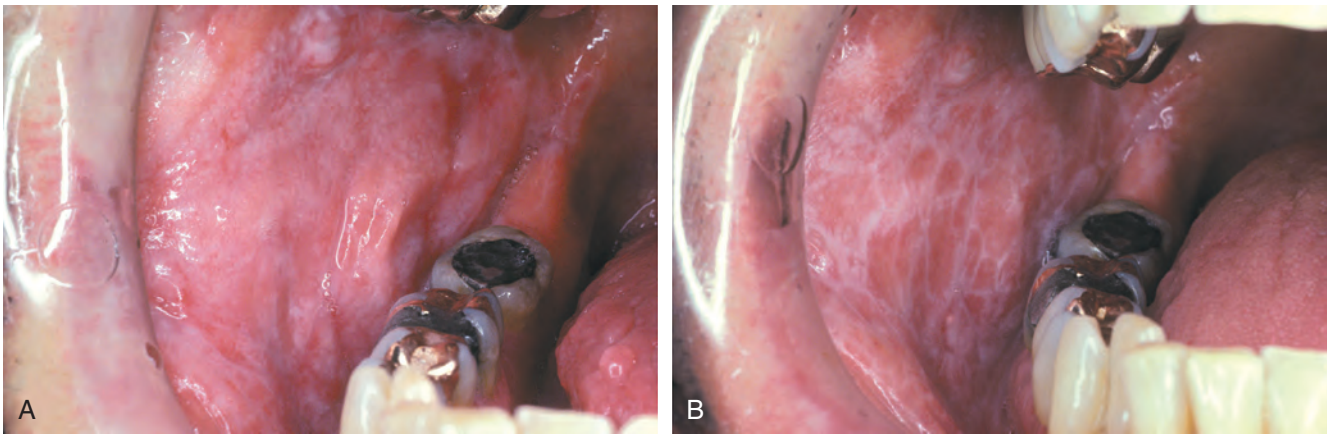
dentlearn.ir

Diagnosis

The diagnosis of **reticular lichen planus** can often be made based on the clinical findings alone. The interlacing white striae appearing bilaterally on the posterior buccal mucosa are virtually pathognomonic, however if the clinical features are not completely characteristic, biopsy would be appropriate. In addition, difficulties in diagnosis may arise if candidiasis is superimposed on the lesions because the organism may alter the characteristic reticular pattern of the lichen planus (Fig. 16.103).

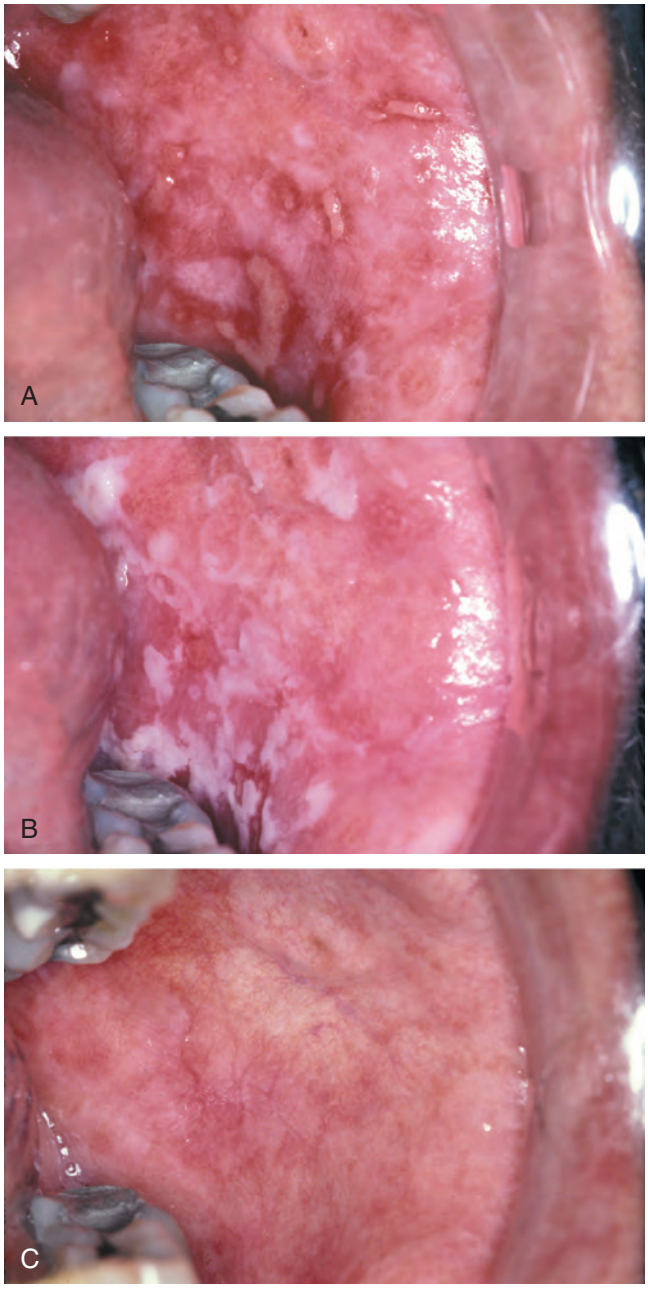
Erosive lichen planus is sometimes more challenging to diagnose (based on clinical features alone) than the reticular form. If the typical radiating white striae and erythematous, atrophic mucosa are present at the periphery of well-demarcated ulcerations on the posterior buccal mucosa bilaterally, then the clinician may certainly consider a diagnosis of erosive lichen planus. However, a biopsy may be necessary to rule out other ulcerative or erosive diseases, such as lupus erythematosus or chronic ulcerative stomatitis. If the diagnosis is still in question, then direct immunofluorescence studies sometimes prove helpful in distinguishing between these diseases.



Specimens of isolated erosive lichenoid lesions, particularly those of the soft palate, the lateral and ventral tongue, or the floor of the mouth, should be obtained for biopsy to rule out premalignant changes or malignancy. Another condition that may mimic an isolated lesion of lichen planus, both clinically and histopathologically, is a **lichenoid reaction to dental amalgam** (see page 346).

Treatment and Prognosis

Reticular lichen planus typically produces no symptoms, and no treatment is needed. Occasionally, affected patients may have superimposed candidiasis, in which case they may complain of a burning sensation of the oral mucosa at the site of the lesion. Antifungal therapy is necessary in such a case. Some investigators recommend annual reevaluation of the reticular lesions of oral lichen planus.



Erosive lichen planus is often bothersome because of the open sores in the mouth. Because it is an immunologically mediated condition, corticosteroids are recommended. The lesions respond to systemic corticosteroids, but such drastic therapy is usually not necessary. One of the stronger topical corticosteroids (e.g., fluocinonide, betamethasone, or clobetasol gel) applied as a thin film several times per day to the most symptomatic areas is usually sufficient to induce healing within 1 or 2 weeks. The patient should be warned that the condition will undoubtedly flare up again, in which case the corticosteroids should be reapplied. In addition, the possibility of iatrogenic candidiasis associated with corticosteroid use should be monitored (Fig. 16.104). Some investigators have recommended compounding corticosteroid ointments with an adhesive methylcellulose base, but patient compliance may be reduced because this material is difficult to apply. Although the use of other agents (such as, topical retinoids, tacrolimus, mycophenolate mofetil, or cyclosporine) has occasionally been advocated for recalcitrant cases of erosive lichen planus, reports of their efficacy have usually been limited to small series of cases or have been contradictory. Furthermore, their side effects can be significant, and in the case of tacrolimus or cyclosporine, the cost of the drug may be prohibitive. Some investigators suggest that patients with oral erosive lichen planus be evaluated every 3–6 months, particularly if the lesions are not typical.

The question of the malignant potential of lichen planus, particularly the erosive form, is yet to be resolved. Most cases of reported malignant transformation are rather poorly documented. Some of these reported cases may not have been true lichen planus, but rather they may have actually been dysplastic leukoplakias with a secondary lichenoid inflammatory infiltrate that mimicked lichen planus, such as proliferative verrucous leukoplakia. In addition, the argument can be made that because both lichen planus and squamous cell

• **Fig. 16.103 Lichen Planus. A,** These relatively nondescript white lesions affected the buccal mucosa of a patient who had complained of a burning sensation. Histopathologic evaluation of the lesion showed a lichenoid mucositis with superimposed candidiasis. **B,** Same patient 2 weeks after antifungal therapy. Once the mucosal reaction to the candidal organism was eliminated, the characteristic white striae of reticular lichen planus were identified.

dentlearn.ir

• **Fig. 16.104 Lichen Planus. A,** This patient was diagnosed with erosive lichen planus affecting the buccal mucosa and was treated with topical corticosteroids. **B,** Same patient 2 weeks later. carcinoma are not rare, some people may have both problems simultaneously, and the two processes may be unrelated to one another. Conversely, some investigators say that the atrophic epithelium of lichen planus may be more susceptible to the action of carcinogens, resulting in an increased risk of malignant transformation. Two studies have examined the molecular characteristics of classic reticular lichen planus, comparing the loss of heterozygosity at purported tumor suppressor gene loci in these lesions with that of varying grades of oral epithelial dysplasia, squamous cell carcinoma, normal oral mucosa, and oral reactive lesions. The molecular profile of oral lichen planus more closely resembled that of normal or reactive oral mucosa, a finding that provides less support for the concept of lichen planus being precancerous. Another study evaluated the malignant transformation rate of typical oral lichen planus compared with oral "lichenoid" lesions. The lichenoid lesions had some features of lichen planus, but were not completely representative, either clinically or histopathologically, of that disease. These investigators found that there was no transformation of characteristic lichen planus, although several of the "lichenoid" lesions developed into squamous cell carcinoma. Additional prospective clinical studies with strict clinical and histopathologic criteria for the definition of oral lichen planus will need to be performed to resolve this question. If the potential for malignant transformation exists, then it appears to be small. Most of the reported cases have been confined to patients with either the erosive or so-called plaque-type form of lichen planus.

◆ CHRONIC ULCERATIVE STOMATITIS

Chronic ulcerative stomatitis is another immune-mediated disorder that affects the oral mucosa. This condition was initially described in 1990, and slightly more than 70 cases have been reported. Although the precise pathogenetic mechanisms are unknown, these patients develop autoantibodies against a 70-kDa nuclear protein, ΔNp63α, an isoform of p63, and *in vitro* studies suggest that these antibodies play a role in development of this disease by interrupting the normal maintenance of the epithelium/connective tissue interface.

The prevalence of this disease may be more common than is realized. Because of its clinical similarity to erosive lichen planus, it is possible that only a clinical diagnosis is made when an affected patient is encountered, and a biopsy is not performed. Even if a biopsy is done, the tissue is often submitted for routine light microscopy alone, and the direct immunofluorescence studies that are required for its diagnosis are not ordered. Distinction from lichen planus should be made because chronic ulcerative stomatitis typically does not respond as well to corticosteroid therapy, and just as is the case with lupus erythematosus (LE), chronic ulcerative stomatitis has been reported to improve using antimalarial drugs.

Clinical Features

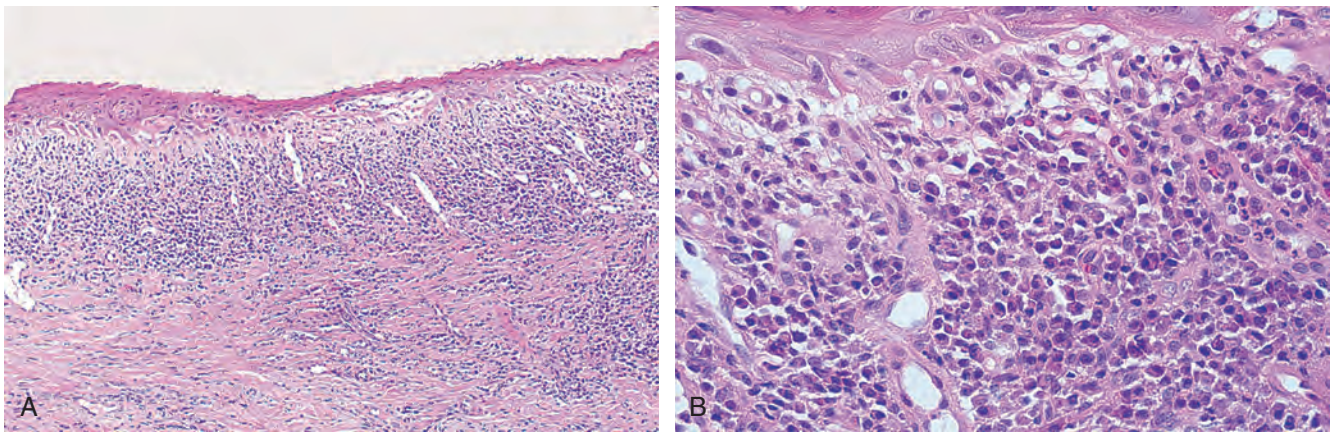
Chronic ulcerative stomatitis usually affects adult women, and the mean age at diagnosis is late in the sixth decade of life. The condition may appear as desquamative gingivitis, although ulcerations or erosions of the tongue or buccal mucosa are also quite common (Fig. 16.105). The ulcers are generally surrounded by patchy zones of erythema and streaky keratosis that somewhat resemble lichen planus, although classic striae formation usually is not evident. The ulcers heal without scarring and often migrate around

dentlearn.ir

• **Fig. 16.105 Chronic Ulcerative Stomatitis. A,** Gingival lesions having a "desquamative gingivitis" presentation, requiring biopsy with direct immunofluorescence studies for diagnosis. **B,** Buccal mucosal involvement. The lesions appear somewhat lichenoid, although classic Wickham striae are not evident.

the oral mucosa. As is typical with most immune-mediated conditions, the severity of the oral lesions tends to wax and wane. Fewer than 20% of affected patients will develop concurrent lichenoid skin lesions.

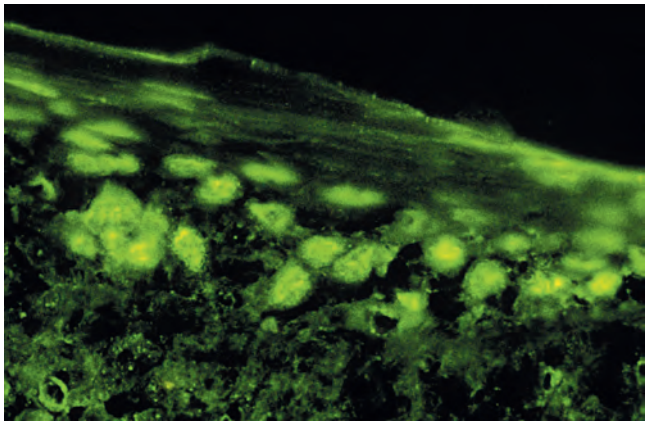
Histopathologic Features



Although the histopathologic features of chronic ulcerative stomatitis are similar to those of lichen planus, the epithelium is generally more atrophic and the inflammatory infiltrate usually contains significant numbers of plasma cells in addition to lymphocytes (Fig. 16.106). Artifactual epithelial separation from the underlying connective tissue is not unusual.

Diagnosis

The diagnosis of chronic ulcerative stomatitis is essentially based on its characteristic immunopathologic pattern. Although it may not be economically feasible to do immunologic testing on every case of lichen planus, this procedure should be considered for erosive lichenoid lesions that do not have a characteristic appearance or distribution, as well as for erosive lesions that do not respond to topical corticosteroid therapy. With direct immunofluorescence studies, autoantibodies (usually IgG) that are directed against the nuclei of stratified squamous epithelial cells in the basal and parabasal regions of the epithelium are detected (Fig. 16.107). Indirect immunofluorescence studies are also positive for these stratified epithelium-specific antinuclear antibodies (ANAs), and some investigators believe that confirmation of the diagnosis is necessary using serum for indirect immunofluorescence evaluation. An ELISA test has been developed, and if it becomes commercially available, this should make screening for this condition much more cost-effective. Other immune-mediated conditions (e.g., systemic sclerosis and LE) may show ANA deposition with direct immunofluorescence; however, nuclei throughout the entire thickness of the epithelium are positive with those diseases.



Treatment and Prognosis

Unlike the lesions of erosive lichen planus, the lesions associated with chronic ulcerative stomatitis may not respond as well to topical or systemic corticosteroid therapy. If the

• **Fig. 16.106 Chronic Ulcerative Stomatitis. A,** Low-power photomicrograph showing epithelial atrophy with a heavy chronic inflammatory cell infiltrate in the superficial lamina propria. **B,** High-power photomicrograph showing interface degeneration of the basilar epithelium in association with the inflammation. Unlike lichen planus, this infiltrate includes numerous plasma cells, as well as lymphocytes.

• **Fig. 16.107 Chronic Ulcerative Stomatitis.** Direct immunofluorescence studies show presence of IgG in the basal and parabasal epithelial nuclei.

lesions are not adequately controlled with corticosteroids, then management with hydroxychloroquine, an antimalarial drug, should be considered. Hydroxychloroquine therapy, however, requires both periodic ophthalmologic evaluation to monitor for drug-related retinopathy and periodic hematologic evaluation.

◆ GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease (GVHD) occurs mainly in recipients of allogeneic bone marrow transplantation, a procedure performed on approximately 8000 patients in the United States each year. Such transplants are performed at major medical centers to treat life-threatening diseases of the blood or bone marrow, such as leukemia, lymphoma, multiple myeloma, aplastic anemia, thalassemia, sickle cell anemia, or disseminated metastatic disease. Cytotoxic drugs, radiation, or both may be used to destroy the malignant cells, but in the process the normal hematopoietic cells of the patient are destroyed. To provide the patient with an immune system, an HLA-matched donor must be found. The donor supplies hematopoietic stem cells obtained from bone marrow, peripheral blood, or umbilical cord blood. These stem cells are transfused into the patient, whose own hematopoietic and immune cells have been destroyed. The transfused hematopoietic cells make their way to the recipient's bone marrow and begin to reestablish normal function.

Unfortunately, the HLA match is not always exact, and despite the use of immunomodulating and immunosuppressive drugs (such as, cyclosporine, methotrexate, and prednisone), the engrafted cells often recognize that they are not in their native environment. When this happens, these cells start attacking what they perceive as a foreign body. The result of this attack is GVHD, and it can be quite devastating to the patient.

In recent years, oncologists have taken advantage of this type of immunologic attack when treating leukemia patients, and often a beneficial "graft-versus-leukemia" effect is seen when the donor cells interpret the leukemic cells as being foreign. For older patients, who tend to have more significant side effects with traditional bone marrow transplantation, the concept of a "mini-allograft" has been developed. Not all of the patient's white blood cells (WBCs) are destroyed in this procedure, which is also known as *nonmyeloablative allogenic hematopoietic cell transplantation,* to allow the donor cells to mount a more aggressive assault on the patient's leukemic cells.

Autologous stem cell transplantation has also become an increasingly popular method of treatment for some of these life-threatening diseases. Because these cells are derived from the patient, there is no risk of GVHD in this setting.

Clinical Features

The systemic signs of GVHD are varied, depending on the organ system involved and whether the problem is acute or chronic. The severity of GVHD depends on several factors, with milder disease seen in patients who have a better histocompatibility match, are younger, have received cord blood, and are female. In addition, wide ranges in the percentage of patients who develop GVHD and its oral manifestations are to be expected, given the variety of disorders that are treated with bone marrow transplantation and the spectrum of conditioning regimens.

Acute GVHD is typically observed within the first few weeks after bone marrow transplantation. Although acute GVHD has arbitrarily been defined as occurring within 100 days after the procedure, most investigators make this diagnosis based on the clinical features rather than a specific time point. The disease affects about 50% of bone marrow transplant patients. The skin lesions that develop may range from a mild rash to a diffuse severe sloughing that resembles toxic epidermal necrolysis (see page 783). These signs may be accompanied by diarrhea, nausea, vomiting, abdominal pain, and liver dysfunction.

Chronic GVHD may represent a continuation of a previously diagnosed case of acute GVHD, or it may develop later than 100 days after bone marrow transplantation, sometimes not appearing for several years after the procedure. Chronic GVHD can be expected to develop in 30% to 70% of bone marrow transplant recipients, and it often mimics any one of a variety of autoimmune conditions, such as systemic lupus erythematosus (SLE), Sjögren syndrome, or primary biliary cirrhosis. Skin involvement, which is the most common manifestation, may resemble lichen planus or even systemic sclerosis.

The oral mucosal manifestations of GVHD can also vary, depending on the duration and severity of the attack and the targeted oral tissues. Of patients with acute GVHD, 33%–75% will have oral involvement; of patients with chronic GVHD, 80% or more will have oral lesions. Sometimes the oral lesions of GVHD are the only sign of the disorder. In most patients with oral GVHD, there is a fine, reticular network of white striae that resembles oral lichen planus, although a more diffuse pattern of pinpoint white papules has also been described (Figs. 16.108–16.110). The tongue, the gingivae, the labial mucosa, and the buccal mucosa are

dentlearn.ir

the oral mucosal sites most frequently involved. Patients often complain of a burning sensation of the oral mucosa, and care must be taken not to overlook possible candidiasis. Atrophy of the oral mucosa may be present, and this can contribute to the mucosal discomfort. Ulcerations that are related to the chemotherapeutic conditioning and neutropenic state of the patient often develop during the first 2 weeks after bone marrow transplantation. Ulcers that persist longer than 2 weeks may represent acute GVHD, and these should be differentiated from intraoral herpesvirus infection or bacterial infection. Bone marrow transplant patients have a small but increased risk for the development of both oral and cutaneous epithelial dysplasia and squamous cell carcinoma. Demarcated white or red plaques of the oral mucosa that do not have the characteristic lichenoid features should be biopsied to rule out preneoplastic or neoplastic changes (Fig. 16.111).

Xerostomia is also a common complaint. If the patient is not taking drugs that dry the mouth, it is likely that the immunologic response is destroying the salivary gland tissue. Other evidence of salivary gland involvement includes the development of small superficial mucoceles, particularly on the soft palate.

• **Fig. 16.108 Graft-Versus-Host Disease (GVHD).** Confluent, interlacing white linear lesions of the vermilion zone superficially resemble oral lichen planus.

• **Fig. 16.109 Graft-Versus-Host Disease (GVHD).** Lichenoid and erosive lesions of the left buccal mucosa.

• **Fig. 16.110 Graft-Versus-Host Disease (GVHD).** Involvement of the tongue showing erosions and ulcerations that resemble erosive lichen planus.

• **Fig. 16.111 Squamous Cell Carcinoma Arising in Graft-Versus-Host Disease (GVHD).** Erythematous, ulcerated mass arising on the lateral border of the tongue. Note the surrounding mucosal erosions, which represent GVHD.

Histopathologic Features

The histopathologic features of GVHD resemble those of oral lichen planus to a certain degree. Both lesions display hyperorthokeratosis, short and pointed rete ridges, and degeneration of the basal cell layer. The inflammatory response in GVHD is usually not as intense as in lichen planus. With advanced cases, an abnormal deposition of collagen is present, similar to the pattern in systemic sclerosis. Minor salivary gland tissue usually shows periductal inflammation in the early stages, with gradual acinar destruction and extensive periductal fibrosis appearing later.

Diagnosis

The diagnosis of GVHD may be difficult because of the varied clinical manifestations. Such a diagnosis is of great clinical significance to the patient because complications

dentlearn.ir

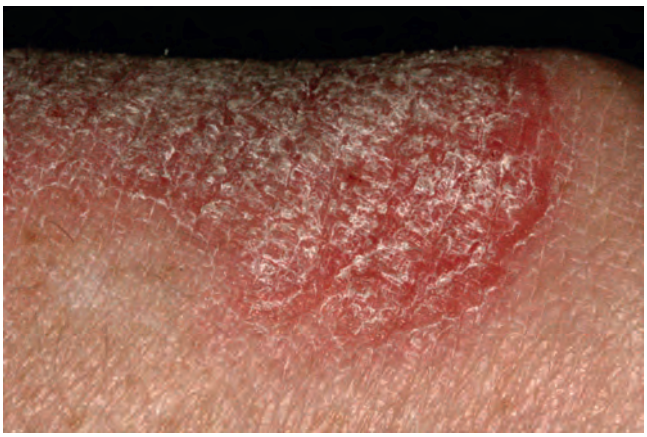
of the condition and its treatment may be lethal. Although the diagnosis of GVHD is based on the clinical and histopathologic findings, each patient may have a different constellation of signs and symptoms. Oral lesions appear to have value as a highly predictive index of the presence of GVHD.

Treatment and Prognosis

The primary strategy for dealing with GVHD is to reduce or prevent its occurrence. Careful tissue histocompatibility matching is performed, and the patient is given prophylactic therapy with immunomodulatory and immunosuppressive agents, such as prednisone in combination with either cyclosporine or tacrolimus. If GVHD develops, then the doses of these drugs may be increased or similar pharmacologic agents may be added, although detailed description of the medical management of systemic GVHD is beyond the scope of this text. Suffice it to say that a wide range of treatment modalities are available and their selection and frequency of use varies among tertiary care centers. A partial list would include mycophenolate mofetil, azathioprine, extracorporeal photopheresis, mTOR inhibitors (sirolimus and everolimus), JAK inhibitors (ruxolitinib and tofacitinib), and anti-CD20 monoclonal antibody (rituximab) .

With respect to oral lesions, topical corticosteroids may facilitate the healing of focal oral ulcerations associated with GVHD, and some reports have suggested that topical tacrolimus may be useful in managing ulcers that are resistant to corticosteroids. Topical anesthetic agents are administered to provide patient comfort while the lesions are present, although narcotic analgesics may be required in some cases. The use of **p**soralen and **u**ltra**v**iolet **A** (PUVA) therapy also has been shown to improve the cutaneous and oral lesions of patients with the lichenoid form of GVHD. If significant xerostomia is present in a dentulous patient, then topical fluorides should be used daily to prevent xerostomia-related caries. If significant amounts of salivary acinar tissue remain, then treatment with pilocarpine hydrochloride or cevimeline hydrochloride may improve the salivary flow. Current recommendations are to evaluate the oral status of patients before bone marrow transplantation and eliminate any potential sources of infection. Interestingly, one study showed no differences in posttransplant infections or survival between a group of patients who received dental treatment before their transplant and a group who did not.

In general, some degree of GVHD is expected in most allogeneic bone marrow transplant recipients. The prognosis depends on the extent to which the condition progresses and whether or not it can be controlled. The significance of this complication is reflected in the survival of more than 70% of patients with relatively mild GVHD at 6 years posttransplant, compared with approximately 15% of patients with severe GVHD.



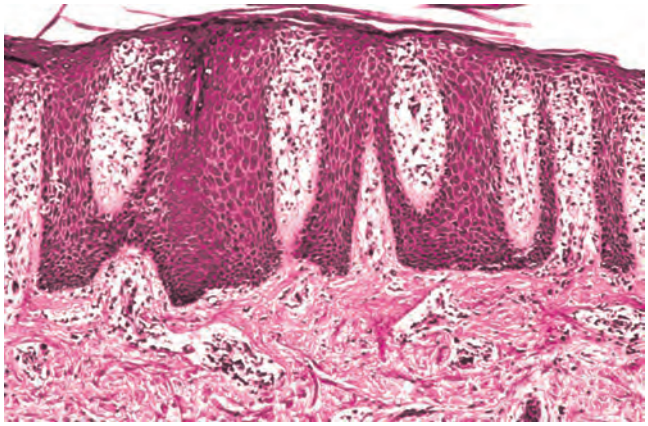
◆ PSORIASIS

Psoriasis is a common chronic skin disease affecting approximately 3% of people in the United States. According to some estimates, roughly 8 million people in this country have psoriasis, and more than 250,000 new cases are diagnosed each year.

Psoriasis is characterized by an increased proliferative activity of the cutaneous keratinocytes. Recent advances in cell kinetics, immunology, and molecular biology have increased the understanding of the etiopathogenesis of the keratinocyte proliferation in this disorder. Although the triggering agent has yet to be identified, activated T lymphocytes appear to orchestrate a complex scenario that includes abnormal production of cytokines, adhesion molecules, chemotactic polypeptides, and growth factors. Genetic factors also seem to play a role, because as many as one-third of these patients have affected relatives. Currently nine different genetic loci have been identified that may be related to the development of psoriasis. If one twin in a set of identical twins has psoriasis, there is a 35%–72% chance that the other twin will have it. This suggests that genetic factors are not entirely responsible for the condition, and that one or more unidentified environmental agents must influence its pathogenesis.

Clinical Features

Psoriasis often has its onset during the second or third decade of life and tends to persist for years, with periods of exacerbation and quiescence. Patients frequently report that the lesions improve during the summer and worsen during the winter, an observation that may be related to lesional exposure to UV light. The lesions are typically symmetrically distributed in certain favored locations, such as the scalp, elbows, and knees. The classic description is a well-demarcated, erythematous plaque with a silvery scale on its surface (Fig. 16.112). The lesions are often asymptomatic, but it is not unusual for a patient to complain of itching—in fact, the term *psoriasis* is



• **Fig. 16.112 Psoriasis.** Characteristic cutaneous lesion, characterized by an erythematous plaque surmounted by silvery keratotic scales.

dentlearn.ir

• **Fig. 16.113 Psoriasis.** This is an example of relatively rare involvement of the oral mucosa by psoriasis. The erythematous linear patches tended to flare with the patient's cutaneous lesions. (Courtesy of Dr. George Blozis.)

• **Fig. 16.114 Psoriasis.** Low-power photomicrograph showing elongation of the rete ridges, hyperkeratosis, and inflammation of the papillary dermis.

derived from the Greek word for itching. An unfortunate complication affecting approximately 25%–30% of these patients is **psoriatic arthritis,** which may involve the TMJ. Other co-morbidities that have been described in patients with psoriasis include inflammatory bowel disease, nonalcoholic liver disease, mood disorders, and cardiovascular disease. A recent study found that periodontitis is more prevalent among psoriatic patients as well.

Oral lesions may occur in patients with psoriasis, but they are distinctly uncommon. Because descriptions of these lesions have ranged from white plaques to red plaques to ulcerations, it is difficult to determine the true nature of intraoral psoriasis (Fig. 16.113). To render a diagnosis of intraoral psoriasis, some investigators say that the activity of the oral lesions should parallel that of the cutaneous lesions. Some authors refer to **erythema migrans** (see page 784) as *intraoral psoriasis,* and the prevalence of erythema migrans in psoriatic patients appears to be slightly greater than that seen in the rest of the population. It is difficult, however, to prove a direct correlation of that common mucosal alteration with psoriasis.

Histopathologic Features

Microscopically, psoriasis has a characteristic pattern. The surface epithelium shows marked parakeratin production, and the epithelial rete ridges are elongated (Fig. 16.114). The connective tissue papillae, which contain dilated capillaries, approach close to the epithelial surface, and a perivascular chronic inflammatory cell infiltrate is present. In addition, collections of neutrophils **(Munro abscesses),** are seen within the parakeratin layer.

With respect to oral lesions, good correlation with skin disease activity should be seen in addition to the characteristic histopathologic features, because other intraoral lesions, such as erythema migrans and oral mucosal cinnamon reaction (see page 344), exhibit a psoriasiform microscopic appearance.

Treatment and Prognosis

The treatment of psoriasis depends on the severity of the disease activity, as well as the presence or absence of psoriatic arthritis. For mild lesions, which generally means that no more than 3%–5% of the skin surface is affected, no treatment may be necessary.

For patients with moderate skin involvement (5%–10% skin surface involvement), or for mild lesions that are bothersome or cosmetically unacceptable, topical corticosteroids are commonly prescribed in the United States. Coal tar derivatives and keratolytic agents also may be used. Other topical drugs that have proven effective include vitamin D_3 analogues (calcipotriene, calcipotriol, and calcitriol), and tazarotene, a retinoid (vitamin A) compound. Newer topical biologic agents include the calcineurin inhibitors, tacrolimus and pimecrolimus, although these are usually reserved for recalcitrant lesions. Exposure to UV radiation may also be helpful for mild to moderate disease.

The treatment approach related to moderate or severe (greater than 10% skin surface involvement) psoriasis has changed dramatically over the past several years and is continuing to evolve due to development of newer systemic biologic agents that target specific disease-related components of the psoriatic pathophysiologic pathways. A relatively brief listing would include certolizumab, infliximab, adalimumab, and etanercept (directed against tumor necrosis factor-alpha [TNF-α]); alefacept (directed against T-cell receptors); guselkumab, tildrakizumab-asmn, risankizumab-rzaa, and mirikizumab (directed against IL-23); secukinumab, ixekizumab, brodalumab, and bimekizumab (directed against IL-17); or ustekinumab (directed against IL-12 and IL-23). For severe cases, psoralen and ultraviolet A (PUVA) therapy or ultraviolet B (UVB) therapy may be needed. Methotrexate or cyclosporine may also be used as systemic treatments for severe disease; however, these drugs have significant side effects.

Although the mortality rate is not increased in patients with psoriasis, the condition often persists for years despite therapy. A 30-year prospective study has shown a definite increase in the risk for cutaneous squamous cell carcinoma in psoriasis patients who have received over 350 life-time

dentlearn.ir

PUVA treatments, but those who received fewer than 150 had a very modest increase. Interestingly, the risk for development of basal cell carcinoma did not seem to be significantly elevated. Broad-band UV-B treatment has much less carcinogenic potential compared to PUVA, and narrow-band UV-B treatment has the least of the three phototherapies.

◆ LUPUS ERYTHEMATOSUS

Lupus erythematosus (LE) is a classic example of an immunologically mediated condition, and is the most common of the so-called collagen vascular or connective tissue diseases in the United States, with more than 1.5 million people affected. It may exhibit any one of several clinicopathologic forms.

Systemic lupus erythematosus (SLE) is a serious multisystem disease with a variety of cutaneous and oral manifestations. There is an increase in the activity of the humoral limb (B lymphocytes) of the immune system in conjunction with abnormal function of the T lymphocytes. Although genetic factors probably play a role in the pathogenesis of SLE, the precise cause is unknown. Undoubtedly, interplay between genetic and environmental factors occurs, for if SLE develops in one monozygotic (identical) twin, then the other twin has a 24% chance of having SLE as well. In contrast, if one dizygotic (fraternal) twin has SLE, then the other twin has only a 2% chance of being affected.

Chronic cutaneous lupus erythematosus (CCLE) may represent a different, but related, process. It primarily affects the skin and oral mucosa, and the prognosis is good.

Subacute cutaneous lupus erythematosus (SCLE) is a third form of the disease, which has clinical features intermediate between those of SLE and CCLE.

Clinical Features

Systemic Lupus Erythematosus

SLE can be a very difficult disease to diagnose in its early stages because it often appears in a nonspecific, vague fashion, frequently with periods of remission or disease inactivity. Women are affected nearly 8–10 times more frequently than men. The average age at diagnosis is 31 years. Common findings include fever, weight loss, arthritis, fatigue, and general malaise. In 40% to 50% of affected patients, a characteristic rash, having the pattern of a butterfly, develops over the malar area and nose (Fig. 16.115), typically sparing the nasolabial folds. Sunlight often makes the lesions worse.

The kidneys are affected in approximately 40%–50% of SLE patients. This complication may ultimately lead to kidney failure; thus it is typically the most significant aspect of the disease.

Cardiac involvement is also common, with pericarditis being the most frequent complication. At autopsy nearly 50% of SLE patients display warty vegetations affecting the heart valves **(Libman-Sacks endocarditis).** Its significance is debatable, although some patients may develop superimposed subacute bacterial endocarditis on these otherwise sterile outgrowths of fibrinoid material and connective tissue cells.

• **Fig. 16.115 Systemic Lupus Erythematosus (SLE).** The erythematous patches seen in the malar regions are a characteristic sign.

• **Fig. 16.116 Systemic Lupus Erythematosus (SLE).** This ulceration of the buccal mucosa exhibits fine radiating white striae at its periphery, clinically appearing similar to erosive lichen planus.

Oral lesions of SLE develop in 5%–25% of these patients, although some studies indicate prevalence as high as 40%. The lesions usually affect the palate, buccal mucosa, and gingivae. Sometimes they appear as lichenoid areas, but they may also look nonspecific or even somewhat granulomatous (Fig. 16.116). Involvement of the vermilion zone of the lower lip **(lupus cheilitis)** is sometimes seen. Varying degrees of ulceration, pain, erythema, and hyperkeratosis may be present. Other oral complaints such as xerostomia, stomatodynia, candidiasis, periodontal disease, and dysgeusia have been described, but the direct association of these problems with SLE remains to be proven. In some cases, the oral problems may be related directly or indirectly to medications that are used to treat SLE.

Confirming the diagnosis of SLE can often be difficult, particularly in the early stages. Criteria for making the diagnosis of SLE were established by the American College of Rheumatology in 1997, however the Systemic Lupus International Collaborating Clinic Criteria, published in 2012, have also been frequently applied diagnostically. Both of these diagnostic approaches to SLE have considerable overlap, with both requiring certain specific clinical and laboratory findings in order to confirm the diagnosis of SLE (Table 16.4).

dentlearn.ir

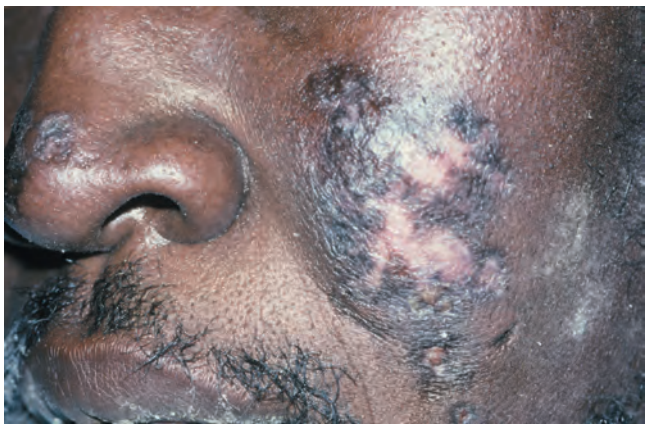


TABLE 16.4 Prevalence of Clinical and Laboratory Manifestations of Systemic Lupus Erythematosus

Findings	Affected Patients (%)
Systemic Signs and Symptoms: Fatigue, Malaise, Fever, Anorexia, Weight Loss	**95%**
MUSCULOSKELETAL SYMPTOMS	**95%**
Arthralgia/myalgia	95%
Nonerosive polyarthritis	60%
CUTANEOUS SIGNS	**80%**
Photosensitivity	70%
Malar rash	50%
Oral ulcers	40%
Discoid rash	20%
HEMATOLOGIC SIGNS	**85%**
Anemia (chronic disease)	70%
Leukopenia (<4000/μL)	65%
Lymphopenia (<1500/μL)	50%
Thrombocytopenia (<100,000/μL)	15%
Hemolytic anemia	10%
NEUROLOGIC SIGNS AND SYMPTOMS	**60%**
Cognitive disorder	50%
Headache	25%
Seizures	20%
CARDIOPULMONARY SIGNS	**60%**
Pleurisy, pericarditis, effusions	30%–50%
Myocarditis, endocarditis	10%
RENAL SIGNS	**30%–50%**
Proteinuria >500 mg/24 h, cellular casts	30%–50%
Nephrotic syndrome	25%
End-stage renal disease	5%–10%

Adapted from Hahn BH: Systemic lupus erythematosus. In Jameson JL, Fauci AS, Kasper DL, et al., editors: *Harrison's principles of internal medicine,* ed 20, New York, 2018, McGraw-Hill, pp 2515–2526. Reproduced with permission of The McGraw-Hill Companies.

Chronic Cutaneous Lupus Erythematosus

Patients with CCLE usually have few or no systemic signs or symptoms, with lesions being limited to skin or mucosal surfaces. The skin lesions of CCLE most commonly present as **discoid lupus erythematosus.** They begin as scaly, round ("discoid") erythematous patches that are frequently distributed on sun-exposed skin, especially in the head and neck area (Fig. 16.117). Patients may indicate that the lesions are exacerbated by sun exposure. With time, the lesions may heal spontaneously in one area, only to appear in another area. The healing process usually results in cutaneous atrophy with scarring and hypopigmentation or hyperpigmentation of the resolving lesion. Conjunctival involvement by CCLE has rarely been reported to cause cicatrizing conjunctivitis, clinically similar to mucous membrane pemphigoid.

• **Fig. 16.117 Chronic Cutaneous Lupus Erythematosus (CCLE).** The skin lesions are characterized by scaling, atrophy, and pigmentary disturbances, which are most evident on sun-exposed skin.

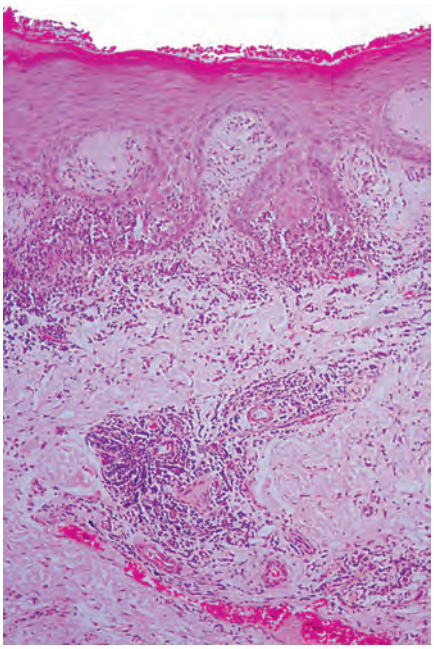
In most cases the oral manifestations of CCLE essentially appear clinically identical to the lesions of erosive lichen planus. Unlike the oral lesions of lichen planus, however, the oral lesions of CCLE seldom occur in the absence of skin lesions. An ulcerated or atrophic, erythematous central zone, surrounded by white, fine, radiating striae, characterizes the oral lesion of CCLE (Figs. 16.118 and 16.119). Sometimes the erythematous, atrophic central region of a lesion may show a fine stippling of white dots. As with erosive lichen planus, the ulcerative and atrophic oral lesions of CCLE may be painful, especially when exposed to acidic or salty foods.

• **Fig. 16.118 Chronic Cutaneous Lupus Erythematosus (CCLE).** Radiating keratotic striae surround erythematous zones of the buccal mucosa. These features are similar to those of erosive lichen planus.

dentlearn.ir

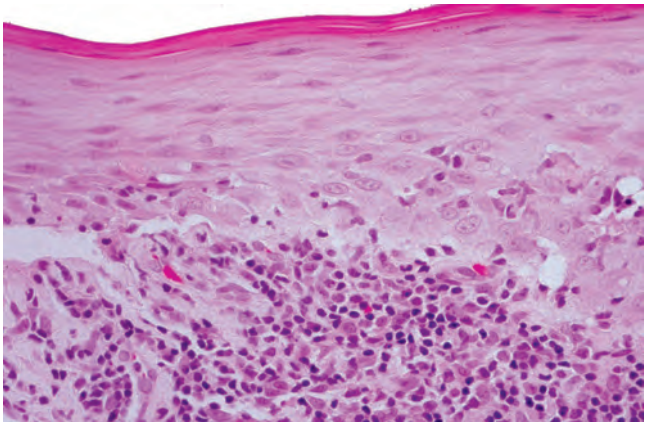
• **Fig. 16.119 Chronic Cutaneous Lupus Erythematosus (CCLE).** Oral involvement may also include relatively nondescript erythematous patches, such as this one in the palate.

Subacute Cutaneous Lupus Erythematosus



Patients with SCLE have clinical manifestations intermediate between those of SLE and CCLE. The skin lesions are the most prominent feature of this variation. They are characterized by photosensitivity and are, therefore, generally present in sun-exposed areas. These lesions do not show the induration and scarring seen with the skin lesions of CCLE. Oral lesions similar to those of CCLE have been described in this variant of lupus as well. Usually, the renal or neurologic abnormalities associated with SLE are not present, although most patients will have arthritis or musculoskeletal problems. SCLE may be triggered by any one of a variety of medications (see page 337).

Histopathologic Features



The histopathologic features of the skin and oral lesions of the various forms of LE show some features in common but are different enough to warrant separate discussions.

The skin lesions of CCLE are characterized by hyperkeratosis, often displaying keratin packed into the openings of hair follicles ("follicular plugging"). In all forms of LE, degeneration of the basal cell layer is frequently observed, and the underlying connective tissue supports patchy to dense aggregates of chronic inflammatory cells (Figs. 16.120 and 16.121). In the deeper connective tissue, the inflammatory infiltrate often surrounds the small blood vessels.

The oral lesions demonstrate hyperkeratosis, alternating atrophy and thickening of the spinous cell layer, degeneration of the basal cell layer, and subepithelial lymphocytic infiltration. These features may also be seen in oral lichen planus; however, the two conditions can usually be distinguished by the presence in LE of patchy deposits of a periodic acid-Schiff (PAS)-positive material in the basement membrane zone, subepithelial edema (sometimes to the point of vesicle formation), and a more diffuse, deep inflammatory infiltrate, often in a perivascular orientation. Some authorities, however, feel that differentiating lichen planus from LE is best done by direct immunofluorescence studies or histopathologic examination of the cutaneous lesions.

• **Fig. 16.120 Lupus Erythematosus (LE).** Low-power photomicrograph showing hyperparakeratosis with interface mucositis and perivascular inflammation.

• **Fig. 16.121 Lupus Erythematosus (LE).** High-power photomicrograph of the interface mucositis.

Diagnosis

In addition to the clinical and microscopic features, a number of additional immunologic studies may be helpful in making the diagnosis of LE.

Direct immunofluorescence testing of lesional tissue shows deposition of one or more immunoreactants (usually IgM, IgG, or C3) in a shaggy or granular band at the basement membrane zone. In addition, direct immunofluorescence testing of clinically normal skin of SLE patients often shows a similar deposition of IgG, IgM, or complement components. This finding is known as a **positive lupus band test.** Although a positive lupus band test is consistent with the diagnosis of LE, it is now known that other conditions, such as rheumatoid arthritis, Sjögren syndrome, and systemic sclerosis, may also have similar positive findings.

dentlearn.ir

TABLE 16.5 Selected Abnormal Immunologic Findings in Lupus Erythematosus

Findings	Frequency	Significance
Direct immunofluorescence, lesional skin	CCLE: 90% SLE: 95%	May help distinguish among the various types of LE
Direct immunofluorescence, normal skin	CCLE: 0% SLE: 25%–60%	Lupus band test
Antinuclear antibodies (ANAs)	CCLE: 0%–10% SLE: 98%	Very sensitive for SLE, but not very specific; not useful for CCLE diagnosis
Anti-double-stranded DNA antibodies	CCLE: 0% SLE: 70%	Specific for SLE; may indicate disease activity or kidney involvement
Anti-Sm antibodies	CCLE: 0% SLE: 25%	Specific for SLE

CCLE, Chronic cutaneous lupus erythematosus; *SLE,* systemic lupus erythematosus; *LE,* lupus erythematosus.

Furthermore, some patients with LE may not have a positive lupus band test; therefore, this study must always be interpreted in the context of other clinical signs.

Evaluation of serum obtained from a patient with SLE shows various immunologic abnormalities. Approximately 95% of these patients have antibodies directed against multiple nuclear antigens (i.e., antinuclear antibodies [ANAs]). Although this is a nonspecific finding that may be seen in other autoimmune diseases, as well as in otherwise healthy older individuals, it is nevertheless useful as a screening study. Furthermore, if results are negative on multiple occasions, then the diagnosis of SLE should probably be doubted. Antibodies directed against double-stranded DNA are noted in 70% of patients with SLE, and these are more specific for the disease. Another 30% of patients show antibodies directed against Sm, a protein that is complexed with small nuclear RNA. This finding is very specific for SLE.

A summary of selected immunologic findings in LE is shown in Table 16.5.

Treatment and Prognosis

Patients with SLE should avoid excessive exposure to sunlight because UV light may precipitate disease activity. Mild active disease may be effectively managed using NSAIDs combined with antimalarial drugs, such as hydroxychloroquine. For more severe, acute episodes that involve arthritis, pericarditis, thrombocytopenia, or nephritis, systemic corticosteroids are generally indicated; these may be combined with other immunosuppressive and immunomodulating agents. If oral lesions are present, they typically respond to the systemic therapy.

As with SLE patients, patients with CCLE should avoid excessive sunlight exposure. Because most of the manifestations of CCLE are cutaneous, topical corticosteroids are often reasonably effective. Topical calcineurin inhibitors (tacrolimus or pimecrolimus) may also be used, although these medications are relatively expensive. For cases that are resistant to topical therapy, systemic antimalarial drugs, immunosuppressive drugs, immunomodulating drugs, or low-dose thalidomide may produce a response. Topical corticosteroids are also helpful in treating the oral lesions of CCLE.

The prognosis for the patient with SLE is variable. For patients undergoing treatment today, the 5-year survival rate is approximately 95%; however, by 20 years, the survival rate falls to 78%. Ultimately, the prognosis depends on which organs are affected and how frequently the disease is reactivated. The most common cause of death is renal failure; however, chronic immunosuppression also predisposes these patients to increased mortality because of infection and development of malignancy. For reasons that are poorly understood, the prognosis is worse for men than for women. In addition, blacks tend to fare more poorly than whites.

The prognosis for patients with CCLE is considerably better than that for patients with SLE, although transformation to SLE may be seen in approximately 5%–15% of CCLE patients. Usually, CCLE remains confined to the skin, but it may persist and be quite a nuisance. For about 50% of CCLE patients, the problem eventually resolves after several years.

◆ SYSTEMIC SCLEROSIS (PROGRESSIVE SYSTEMIC SCLEROSIS; SCLERODERMA; DIFFUSE CUTANEOUS SYSTEMIC SCLEROSIS; HIDE-BOUND DISEASE)

Systemic sclerosis is a relatively rare condition that probably has an immunologically mediated pathogenesis involving abnormal interactions among vascular tissue, connective tissue, and immune cells in genetically predisposed individuals. For reasons that are not understood, dense collagen is deposited in the tissues of the body in extraordinary amounts. Although its most dramatic effects are seen in association

dentlearn.ir

with the skin, the disease is often quite serious, with most organs of the body affected.

Clinical and Radiographic Features

Systemic sclerosis affects approximately 10–40 persons per million population each year. Women have the condition three to five times more frequently than do men. Most patients are adults. The onset of the disease is generally insidious, with the cutaneous changes often responsible for bringing the problem to the patient's attention.

Often one of the first signs of the disease is **Raynaud phenomenon**, a vasoconstrictive event triggered by emotional distress or exposure to cold. Raynaud phenomenon (see CREST syndrome, on page 805) is not specific for systemic sclerosis, however, because it may be present in other immunologically mediated diseases and in otherwise healthy people. Resorption of the terminal phalanges **(acro-osteolysis)** and flexion contractures produce shortened, clawlike fingers (Fig. 16.122). The vascular events and the abnormal collagen deposition contribute to the production of ulcerations on the fingertips (Fig. 16.123).

• **Fig. 16.122 Systemic Sclerosis.** The tense, shiny appearance of the skin is evident. Note that the fingers are fixed in a claw-like position, with some showing shortening as a result of acro-osteolysis.

• **Fig. 16.123 Systemic Sclerosis.** Ulcerations of the fingertips.

• **Fig. 16.124 Systemic Sclerosis.** The involvement of the facial skin with abnormal collagen deposition produces a mask-like facies. Note the loss of the alae of the nose.

The skin develops a diffuse, hard texture (*sclero* = hard; *derma* = skin), and its surface is usually smooth. Involvement of the facial skin by subcutaneous collagen deposition results in the characteristic smooth, taut, masklike facies (Fig. 16.124). Similarly, the nasal alae become atrophied, resulting in a pinched appearance to the nose, called a *mouse facies.* When the skin changes are confined to the hands, face, feet, and lower portions of the limbs, the designation of *limited cutaneous systemic sclerosis* is applied. If these changes progress rapidly to involve the skin of the trunk and the proximal limbs, or if the changes begin in these areas, then the process is termed *diffuse cutaneous systemic sclerosis.* These two presentations seem to have different prognoses.

Involvement of other organs may be subtle at first, but the results are more serious. Fibrosis of the lungs, heart, kidneys, and gastrointestinal tract are seen primarily in patients with diffuse cutaneous systemic sclerosis, and the abnormal collagen deposition leads to organ failure, typically within the first 3 years after the diagnosis is made. Pulmonary fibrosis is particularly significant, leading to pulmonary hypertension and heart failure, a primary cause of death for these patients. Patients with limited cutaneous systemic sclerosis tend to develop pulmonary hypertension later than those with a diffuse presentation.

The oral manifestations occur in varying degrees. **Microstomia** often develops as a result of collagen deposition in the perioral tissues. This causes a limitation of opening the mouth

dentlearn.ir

• **Fig. 16.125 Systemic Sclerosis.** Same patient as depicted in Fig. 16.124. Because of the associated microstomia, this is the patient's maximal opening.

in nearly 70% of these patients (Fig. 16.125). Characteristic furrows radiating from the mouth produce a "purse string" appearance. Loss of attached gingival mucosa and multiple areas of gingival recession may occur in some patients. Dysphagia often develops as a result of deposition of collagen in the lingual and esophageal submucosa, producing a firm, hypomobile (boardlike) tongue and an inelastic esophagus, thus hindering swallowing. Xerostomia is frequently identified in these patients, and the possibility of concurrent secondary Sjögren syndrome may require consideration.

On dental radiographs, diffuse widening of the periodontal ligament space is often present throughout the dentition. The extent of the widening may vary, with some examples being subtle and others quite dramatic (Fig. 16.126). Varying degrees of resorption of the posterior ramus of the mandible, the coronoid process, the chin, and the condyle may be detected on panoramic radiographs, affecting approximately 10%–20% of patients (Fig. 16.127). In theory, these areas are resorbed because of the increased pressure associated with the abnormal collagen production. Individual tooth resorption has also been reported to occur at a higher frequency in these patients.

• **Fig. 16.126 Systemic Sclerosis.** Diffuse widening of the periodontal ligament space is often identified on evaluation of periapical radiographs.

A milder condition that resembles cutaneous systemic sclerosis has been called **localized scleroderma** or **morphea,** and it usually affects only a solitary patch of skin. Because these lesions often look like scars, the name *en coup de sabre* ("strike of the sword") is used to describe them (Fig. 16.128). This problem is primarily cosmetic and, unlike systemic sclerosis, it is rarely life threatening. For this reason, many authorities now feel that this disorder may be unrelated to systemic sclerosis.

Histopathologic Features

Microscopic examination of tissue involved by systemic sclerosis shows diffuse deposition of dense collagen within and around the normal structures (Fig. 16.129). This abnormal collagen replaces and destroys the normal tissue, causing the loss of normal tissue function.

Diagnosis

During the early phases, it may be difficult to make a diagnosis of systemic sclerosis. Generally, the clinical signs of stiffened skin texture along with the development of Raynaud phenomenon are suggestive of the diagnosis. A skin biopsy may be supportive of the diagnosis if abundant collagen deposition is observed microscopically.

Laboratory studies may be helpful to the diagnostic process if anticentromere antibodies, anti-RNA polymerase III, or anti-Scl 70 (topoisomerase I) is detected. Anti-topoisomerase I and anti-RNA polymerase III antibodies are seen more often with diffuse cutaneous systemic sclerosis and development of pulmonary fibrosis; anticentromere antibodies are usually associated with limited cutaneous systemic sclerosis (including **CREST syndrome**—see next topic), as well as development of late-onset pulmonary hypertension.

Treatment and Prognosis

The management of systemic sclerosis is difficult. Unfortunately, many of the recommended treatments have not been examined in controlled trials, and the natural waxing and waning course of the disease makes it difficult to assess the effectiveness of a given treatment in an open-label trial. Systemic medications, such as penicillamine, are prescribed in an attempt to inhibit collagen production. One double-blind study, however, showed no difference in measured patient outcomes with high-dose versus low-dose penicillamine, suggesting that perhaps this medication has limited efficacy. Surprisingly, corticosteroids are of little benefit, and some studies have suggested that their use may increase the risk of renal disease. For patients in the early stages of diffuse cutaneous systemic sclerosis, treatment with relatively low doses of methotrexate has been shown to improve the skin changes. Extracorporeal photopheresis also has been shown to have some beneficial effect on the skin lesions.

Other management strategies are directed at controlling symptoms. Such techniques as esophageal dilation are used,

• **Fig. 16.127 Systemic Sclerosis.** Panoramic radiographic evaluation may show a characteristic resorption of the ramus, coronoid process, or condyle.

• **Fig. 16.128 Localized Scleroderma (Morphea).** The cutaneous alteration on the patient's forehead represents a limited form of scleroderma called *en coup de sabre,* because the lesion resembles a scar that might result from a cut with a sword.

for example, to temporarily correct esophageal strictures. Proton pump inhibitors can reduce gastric acid production and improve symptoms of gastroesophageal reflux disease. Calcium channel blocking agents or phosphodiesterase type 5 inhibitors help to increase peripheral blood flow and lessen the symptoms of Raynaud phenomenon, but many patients can reduce episodes by keeping warm (especially their hands and feet) or by stopping cigarette smoking. Angiotensin-converting enzyme (ACE) inhibitors often effectively control hypertension if kidney involvement is prominent.

• **Fig. 16.129 Systemic Sclerosis.** Medium-power photomicrograph of an oral biopsy specimen. Diffuse deposition of collagen is apparent throughout the lamina propria.

From a dental standpoint, problems may develop for patients who wear prostheses because of the microstomia and inelasticity of the mouth. Collapsible dental appliances with special hinges have been made to facilitate the insertion and removal of dentures. Microstomia and inelastic soft

dentlearn.ir

tissue also hamper the maintenance of good oral hygiene, and affected patients have a decreased ability to manipulate a manual toothbrush as a result of sclerotic changes in the fingers and hands. In such situations, the use of an electric toothbrush should be considered in order to optimize dental plaque control. Reduced salivary flow is not uncommon in these patients, and daily application of a 1% neutral sodium fluoride gel will help prevent cervical dental caries. Surgical correction of open bite associated with condylar resorption has been described. Infrequently, the resorption of the mandible may become so great as to cause a pathologic fracture.

The prognosis is poor, although the outlook is better for patients with limited cutaneous involvement than for those with diffuse involvement. If the heart is affected, then the prognosis is particularly poor, but most patients die because of pulmonary involvement. Overall survival figures are difficult to calculate due to a variety of factors, including the rarity of the disease, the inherent variability of its natural course, and the variation in treatments provided at medical centers around the world. With current treatment regimens, it is estimated that 10-year survival rates for patients with limited cutaneous systemic sclerosis approach 75%–80%, whereas survival drops to 55%–60% for patients with diffuse cutaneous systemic sclerosis.

◆ CREST SYNDROME (ACROSCLEROSIS; LIMITED SCLERODERMA; LIMITED CUTANEOUS SYSTEMIC SCLEROSIS)

CREST syndrome is an uncommon condition that many authorities now believe represents a variant of limited cutaneous systemic sclerosis. The term *CREST* is an acronym for **C**alcinosis cutis, **R**aynaud phenomenon, **E**sophageal dysfunction, **S**clerodactyly, and **T**elangiectasia.

Clinical Features

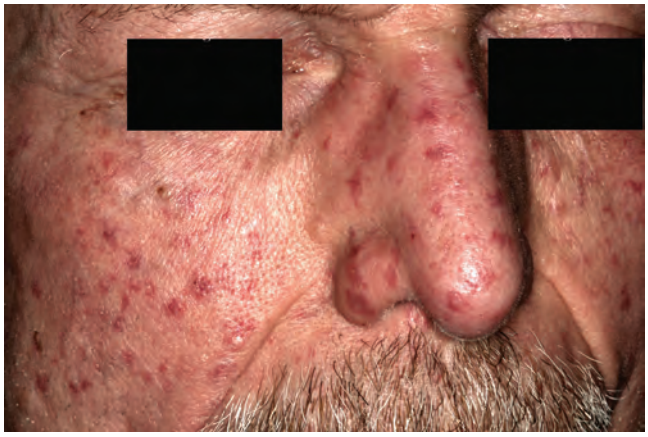
As with all types of systemic sclerosis, most patients with CREST syndrome are women in the sixth or seventh decade of life. The characteristic signs may not appear synchronously but instead may develop sequentially over a period of months to years.

Calcinosis cutis occurs in the form of movable, nontender, subcutaneous nodules, 0.5–2.0 cm in size, which are usually multiple (Fig. 16.130). Larger, more numerous or superficial calcifications may occasionally become bothersome and require removal.

Raynaud phenomenon may be observed when a person's hands or feet are exposed to cold temperatures. The initial clinical sign is a dramatic blanching of the digits, which appear dead-white in color as a result of severe vasospasm. A few minutes later, the affected extremity takes on a bluish color because of venous stasis. After warming, increased blood flow results in a dusky-red hue with the return of hyperemic blood flow. This may be accompanied by varying degrees of throbbing pain.

• **Fig. 16.130 CREST Syndrome.** The subcutaneous nodules on this patient's arm represent deposition of calcium salts (calcinosis cutis). (Courtesy of Dr. Román Carlos.)

Esophageal dysfunction, caused by abnormal collagen deposition in the esophageal submucosa, may not be noticeable in the early phases of CREST syndrome. Often the subtle initial signs of this problem must be demonstrated by barium swallow radiologic studies.



The **sclerodactyly** of CREST syndrome is rather remarkable. The fingers become stiff, and the skin takes on a smooth, shiny appearance. Often the fingers undergo permanent flexure, resulting in a characteristic "claw" deformity (Fig. 16.131). As with other forms of cutaneous systemic sclerosis, this change is due to abnormal deposition of collagen within the dermis in these areas.

The **telangiectasias** in this syndrome are similar to those seen in hereditary hemorrhagic telangiectasia (HHT) (see page 759). As with that condition, significant bleeding from the superficial dilated capillaries may occur. The facial skin and the vermilion zone of the lips are commonly affected (Fig. 16.132).

• **Fig. 16.131 CREST Syndrome.** Claw-like deformity affecting the hands (sclerodactyly).

dentlearn.ir

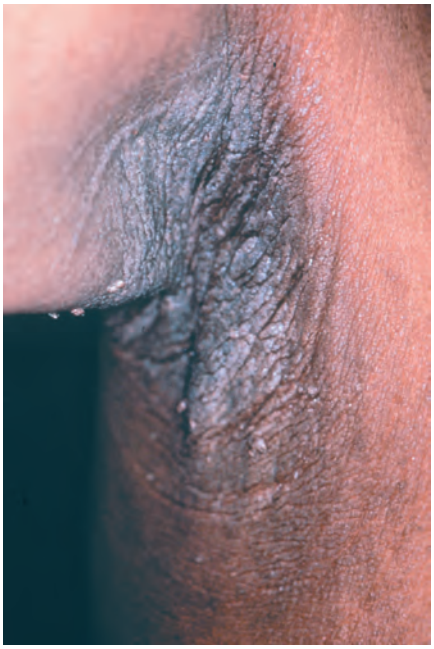
• **Fig. 16.132 CREST Syndrome.** The patient shows numerous red facial macules representing telangiectatic blood vessels.

Histopathologic Features

The histopathologic findings in CREST syndrome are similar, although milder, to those seen in systemic sclerosis. Superficial dilated capillaries are observed if a telangiectatic vessel is included in the biopsy specimen.

Diagnosis

Sometimes, HHT may be considered in the differential diagnosis if the history is unclear and the other signs of CREST syndrome are not yet evident. In these cases, laboratory studies directed at identifying anticentromere antibodies may be useful, because this test is relatively specific for CREST syndrome and other types of limited cutaneous systemic sclerosis.



Treatment and Prognosis

The treatment of patients with CREST syndrome is essentially the same as that of those with systemic sclerosis. Because CREST syndrome usually is not as severe, the treatment does not have to be as aggressive. Although the prognosis for this condition is much better than that for systemic sclerosis, patients should be monitored for an increased risk of developing pulmonary hypertension or primary biliary cirrhosis, generally more than 10 years after the initial diagnosis.

◆ ACANTHOSIS NIGRICANS

Acanthosis nigricans is an acquired dermatologic problem characterized by the development of a velvety, brownish alteration of the skin. In rare instances, this unusual condition develops in conjunction with a malignancy, usually gastrointestinal cancer, and is termed **malignant acanthosis nigricans.** The cutaneous lesion itself is benign, yet it is significant because it represents a cutaneous marker for internal malignancy. The cause of malignant acanthosis nigricans is unknown, although a cytokine-like peptide capable of affecting the epidermal cells may be produced by the malignancy.

Most cases, estimated to affect as many as 5% of adults, are not associated with a malignancy and are termed **benign acanthosis nigricans.** A clinically similar form, **pseudoacanthosis nigricans,** may occur in some obese people. Some benign forms of acanthosis nigricans may be inherited or may occur in association with various endocrinopathies, such as diabetes mellitus, Addison disease, hypothyroidism, and acromegaly. Furthermore, benign acanthosis nigricans may occur with certain syndromes (e.g., Crouzon syndrome) or drug ingestion (e.g., oral contraceptives or corticosteroids). These forms of the condition are typically associated with resistance of the tissues to the effects of insulin, similar to the insulin resistance seen in non–insulin-dependent diabetes mellitus (NIDDM). Even though the affected individuals may not have overt diabetes mellitus, they often show increased levels of insulin or an abnormal response to exogenously administered insulin.

• **Fig. 16.133 Acanthosis Nigricans.** The lesions are characterized by numerous fine, almost velvety, confluent papules. The lesions most often affect the flexural areas, such as the axilla depicted in this photograph. (From Hall JM, Moreland A, Cox GJ, et al: Oral acanthosis nigricans: report of a case and comparison of oral and cutaneous pathology, *Am J Dermatopathol* 10:68–73, 1988.)

Clinical Features

The malignant form of acanthosis nigricans develops in association with an internal malignancy, particularly adenocarcinoma of the gastrointestinal tract. Approximately 20% of the cases of malignant acanthosis nigricans are identified before the malignancy is found, but most appear at about the same time as discovery of the gastrointestinal tumor or thereafter.

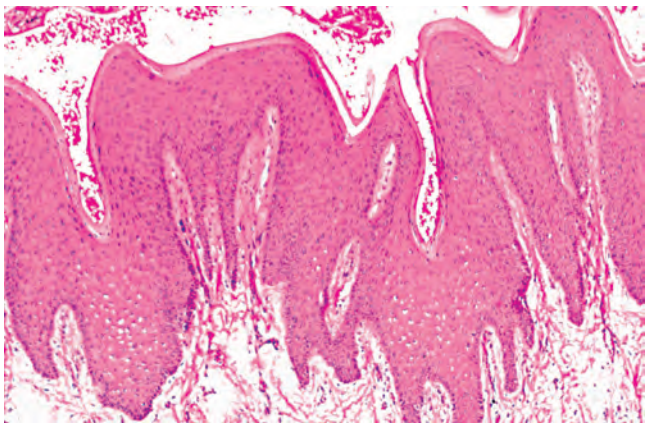
Both forms of acanthosis nigricans affect the intertriginous and flexural areas of the skin predominantly, appearing as finely papillary, hyperkeratotic, brownish patches that are usually asymptomatic (Fig. 16.133). The texture of the lesions has been variably described as either velvety or leathery.

Oral lesions of acanthosis nigricans have also been reported and may occur in 25% to 50% of affected patients, especially

dentlearn.ir

• **Fig. 16.134 Acanthosis Nigricans.** The vermilion zone of the lips is affected. (Courtesy of Dr. George Blozis.)

• **Fig. 16.135 Acanthosis Nigricans.** Same patient as depicted in Fig. 16.134. Note involvement of the palatal mucosa. (Courtesy of Dr. George Blozis.)



those with the malignant form. These lesions appear as diffuse, finely papillary areas of mucosal alteration that most often involve the tongue or lips, particularly the upper lip (Figs. 16.134 and 16.135). The buccal mucosa may also be affected. The brownish pigmentation associated with the cutaneous lesions is usually not seen in oral acanthosis nigricans.

Histopathologic Features

The histopathologic features of the various forms of acanthosis nigricans are essentially identical. The epidermis exhibits hyperorthokeratosis and papillomatosis. Usually, some degree of increased melanin deposition is noted, but the extent of acanthosis (thickening of the spinous layer) is really rather mild. The oral lesions have much more acanthosis, but show minimal increased melanin pigmentation (Fig. 16.136).

Treatment and Prognosis

Although acanthosis nigricans itself is a harmless process, the patient should be evaluated to ascertain which form of the disease is present. Abrupt onset of acanthosis nigricans in an adult who has none of the benign predisposing factors related to this condition should trigger medical evaluation to rule out internal malignancy. Identification and treatment of the underlying malignancy obviously are important for patients with the malignant type; unfortunately, the prognosis for these individuals is very poor. Interestingly, malignant acanthosis nigricans may resolve when the cancer is treated. Keratolytic agents may improve the appearance of the benign forms.

• **Fig. 16.136 Acanthosis Nigricans.** Medium-power photomicrograph of an oral lesion showing papillomatosis, mild hyperkeratosis, and acanthosis of the epithelium.

17 Oral Manifestations of Systemic Diseases

MUCOPOLYSACCHARIDOSIS

The **mucopolysaccharidoses** are a heterogeneous group of metabolic disorders that are usually inherited in an autosomal recessive fashion. These disorders are all characterized by the lack of any one of several normal enzymes needed to process the important intercellular substances known as *glycosaminoglycans.* These substances used to be known as *mucopolysaccharides,* thus the term *mucopolysaccharidosis.* Examples of glycosaminoglycans include the following:

- Heparan sulfate
- Dermatan sulfate
- Keratan sulfate
- Chondroitin sulfate

The type of mucopolysaccharidosis that is seen clinically depends on which of these substrates lacks its particular enzyme. The mucopolysaccharidoses as a group occur with a frequency of approximately 1 in 15,000 to 29,000 live births, although some types are much less common.

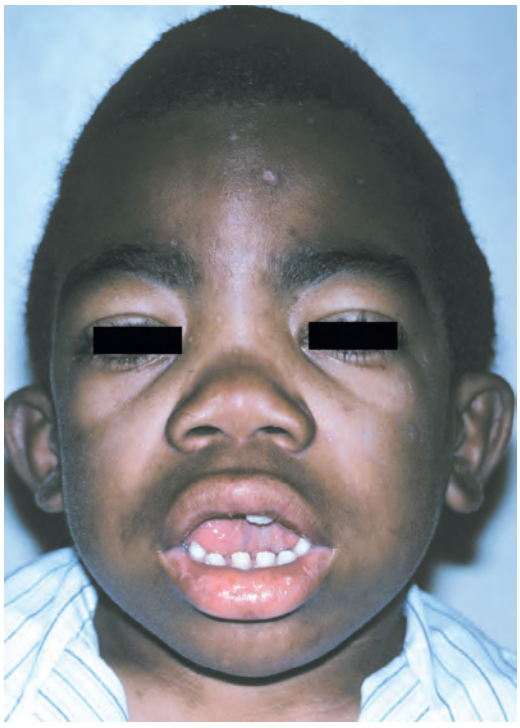
Clinical and Radiographic Features

The clinical features of the mucopolysaccharidoses vary, depending on the particular syndrome that is examined (Table 17.1). Furthermore, affected patients with a particular type of this disorder often exhibit a wide range of severity of involvement. Most types of mucopolysaccharidosis are associated with some degree of intellectual disability. Often the facial features of affected patients are somewhat coarse, with heavy brow ridges (Fig. 17.1), and there are other skeletal changes, such as stiff joints. Cloudy degeneration of the corneas, a problem that frequently leads to blindness, is seen in several forms of mucopolysaccharidosis.

The oral manifestations vary according to the particular type of mucopolysaccharidosis. Most types show some degree of macroglossia. Gingival hyperplasia may be present, particularly in the anterior regions, as a result of the drying and irritating effects of mouth breathing. The dental changes include thin enamel with pointed cusps on the posterior teeth, although this seems to be a feature unique to mucopolysaccharidosis type IVA. Other dental manifestations include numerous impacted teeth with prominent follicular spaces (Fig. 17.2), possibly caused by the accumulation of glycosaminoglycans in the follicular connective tissue. Some investigators have reported the occurrence of multiple impacted teeth that are congregated in a single large follicle, forming a rosette pattern radiographically. Taurodonts (see page 92) are seen with increased frequency in affected individuals, and deformities of the condylar head, described as flattening or distortion, have been identified in these patients.

Although the clinical findings may suggest that a patient is affected by one of the mucopolysaccharidoses, the diagnosis is confirmed by finding elevated levels of glycosaminoglycans in the urine, as well as deficiencies of the specific enzymes in the patient's leukocytes and fibroblasts.

Treatment and Prognosis



No satisfactory systemic treatment of the mucopolysaccharidoses exists at this time. Several forms of mucopolysaccharidosis are associated with a markedly reduced life span and with intellectual disability. Attempts to improve the survival and quality of life of these patients using hematopoietic stem cell transplantation have met with some success. Unfortunately, not all aspects of the disease are corrected, and the complications associated with transplantation must be addressed. Such complications are associated with a 15%–20% mortality rate. Enzyme replacement therapy currently is available for mucopolysaccharidosis types I, II, and VI. Initiation of the respective recombinant human enzymes—laronidase, idursulfase, and galsulfase—early in the patient's life appears to improve significantly many of the aspects of the disease, although complete resolution does not occur. Because of the rarity of these conditions and the expense of developing the treatments, the annual cost for such therapy can range from $176,000 for laronidase to $657,000 for idursulfase, which currently has the dubious distinction of being the most expensive prescription medication. Genetic counseling is indicated for the parents and siblings of a patient affected by one of the mucopolysaccharidosis syndromes. Prenatal diagnosis is available for family planning as well.

dentlearn.ir

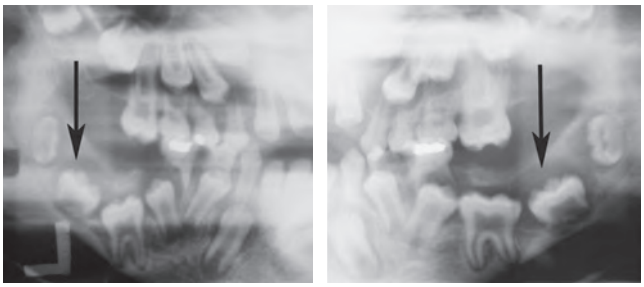


TABLE 17.1 Features of Selected Mucopolysaccharidosis Syndromes

Type	Eponym	Inheritance	Enzyme Deficiency	Stored Substrate	Clinical Features
I-H	Hurler	AR	α-L-Iduronidase	HS and DS	Appears in infancy; cloudy corneas, growth impairment, reduced intelligence, coronary artery disease; rarely live 10 years
I-S	Scheie	AR	α-L-Iduronidase	HS and DS	Onset in late childhood; cloudy corneas, normal intelligence, aortic regurgitation; survive to adulthood
II	Hunter	X-linked R	Iduronate-2-sulfatase	HS and DS	Appears at 1–2 years of age; clear corneas, reduced intelligence, growth impairment, stiff joints
III-A	Sanfilippo-A	AR	Heparan *N*-sulphatase	HS	Appears at 4–6 years of age; clear corneas, reduced intelligence, mild skeletal changes; death in adolescence
III-B	Sanfilippo-B	AR	α-*N*-acetylglucosaminidase	HS	Generally same as Sanfilippo-A
IV-A	Morquio-A	AR	Galactose-6-sulfatase	KS and CS	Appears at 1–2 years of age; cloudy corneas, normal intelligence, lax joints; may survive to middle age
IV-B	Morquio-B	AR	β-Galactosidase	KS	Generally similar to Morquio-A
VI	Maroteaux-Lamy	AR	Arylsulphatase B	DS and CS	Appears at 2–6 years of age; cloudy corneas, normal intelligence, growth impairment, stiff joints; may survive to adulthood

AR, Autosomal recessive; *CS*, chondroitin sulfate; *DS*, dermatan sulfate; *HS*, heparan sulfate; *KS*, keratan sulfate; *R*, recessive.

• **Fig. 17.1 Mucopolysaccharidosis.** This patient affected by Hunter syndrome exhibits the characteristic facial features of this disorder.

• **Fig. 17.2 Mucopolysaccharidosis.** Radiographic examination of the dentition of a child affected by Hunter syndrome typically shows radiolucencies *(arrows)* associated with the crowns of unerupted teeth.

Management of the dental problems of these patients is essentially no different from that of other patients. However, several factors may have to be taken into account:

- Degree of intellectual disability (if any)
- Presence or absence of a seizure disorder
- Degree of joint stiffening
- Extent of other related medical problems

Depending on which of these factors is present and the extent of involvement, dental care may warrant sedation, hospitalization, or general anesthesia of the patient for optimal results. General anesthesia and sedation may be challenging, however, because of excess amounts of pharyngeal tissues that often produce a smaller than normal airway. In severely affected patients, general anesthesia probably should be considered only in life-threatening situations.

dentlearn.ir

◆ LIPID RETICULOENDOTHELIOSES

The **lipid reticuloendothelioses** are a relatively rare group of inherited disorders. These include the following conditions:

- Gaucher disease
- Niemann-Pick disease
- Tay-Sachs disease

These conditions are seen with increased frequency in patients with Ashkenazi Jewish heritage. Affected patients lack certain enzymes necessary for processing specific lipids; this results in an accumulation of the lipids within a variety of cells. Because of this accumulation, it appeared that cells were attempting to store these substances; therefore, the term *storage disease* was commonly used for these disorders.

In **Gaucher disease** (the most common of the reticuloendothelioses), a lack of glucocerebrosidase results in the accumulation of glucosylceramide, particularly within the lysosomes of cells of the macrophage and monocyte lineage. Three types of Gaucher disease are now recognized: type 1 (nonneuronopathic) is seen primarily in the Ashkenazi Jewish population, and types 2 and 3 (neuronopathic) have a panethnic distribution.

Niemann-Pick disease is characterized by a deficiency of acid sphingomyelinase, resulting in the accumulation of sphingomyelin, also within the lysosomes of macrophages.

Tay-Sachs disease is caused by a lack of β-hexosaminidase A, which results in the accumulation of a ganglioside, principally within the lysosomes of neurons.

All these disorders are inherited as autosomal recessive traits. The genetic mutation known to cause Gaucher disease has been evaluated for the Ashkenazi Jewish population, and approximately 1 in 12–17 persons carry the defective gene. Most of the individuals identified as having the gene, however, were heterozygous and, therefore, asymptomatic.

Clinical and Radiographic Features

Gaucher Disease

The clinical features of Gaucher disease are generally the result of the effects of the abnormal storage of glucosylceramide. Macrophages laden with this glucocerebroside are typically rendered relatively nonfunctional, and they tend to accumulate within the liver, spleen, and bone marrow of the affected patient. Bone marrow accumulation displaces the normal hematopoietic cells and produces anemia and thrombocytopenia. In addition, these patients are susceptible to bone infarctions. The resulting bone pain is often the presenting complaint. Characteristic *Erlenmeyer flask* deformities of the long bones, particularly of the femur, are often identified. Accumulations of the macrophages in the spleen and liver result in visceral enlargement. Many affected patients show a significant degree of growth impairment. Neurologic deterioration occurs in patients with the less common types 2 and 3 Gaucher disease. Jaw lesions typically appear as ill-defined radiolucencies that usually affect the mandible, producing thinning of the cortical bone without causing devitalization of the teeth or significant resorption of the lamina dura. The walls of the mandibular canal may also be obliterated by the disease process. Decreased salivary flow has been documented for patients with Gaucher disease compared with an age- and sex-matched population, although this decrease may not be clinically important.

Niemann-Pick Disease

Niemann-Pick disease occurs as three different types, each associated with a different clinical expression and prognosis. Types A and B are caused by a deficiency of acid sphingomyelinase, whereas type C is primarily the result of mutations of either *NPC-1* or *NPC-2,* genes involved with cholesterol processing. Types A and C have **neuronopathic** features, characterized by psychomotor impairment, dementia, spasticity, and hepatosplenomegaly, with death occurring during the first or second decade of life. Type B patients normally survive into adulthood and exhibit **visceral signs,** primarily hepatosplenomegaly, and sometimes pulmonary involvement.

Tay-Sachs Disease

Tay-Sachs disease may have a wide clinical range because the condition is genetically heterogeneous. Some forms are mild, with patients surviving into adulthood. In the severe infantile form, however, rapidly progressive neuronal degeneration develops shortly after birth. Signs and symptoms include blindness, developmental impairment, and intractable seizures. Death usually occurs by 3–5 years of age.

Histopathologic Features

Histopathologic examination of an osseous lesion of Gaucher disease shows sheets of lipid-engorged macrophages (Gaucher cells) exhibiting abundant bluish cytoplasm, which has a fine texture resembling wrinkled silk. In Niemann-Pick disease, the characteristic cell seen on examination of a bone marrow aspirate is the "sea blue" histiocyte.

Treatment and Prognosis

Gaucher Disease

For patients with a mild expression of Gaucher disease, no treatment may be necessary. For more severe forms of Gaucher disease, enzyme replacement therapy with one of the macrophage-targeted glucocerebrosidases, including imiglucerase, velaglucerase alfa, and taliglucerase alfa, is used. All of these medications require intravenous (IV) infusion and are quite expensive, often costing more than $150,000 per year for treatment. After 9–12 months of therapy, patients exhibit improvement in the status of their anemia, a decrease in plasma glucocerebroside levels, and a decrease in hepatosplenomegaly. Resolution of the radiographic bone changes takes place over a longer period. Children treated with this regimen may show significant gain in height. Unfortunately enzyme replacement therapy has shown minimal effect on the neuronopathic Gaucher disease types 2 and 3, primarily because the medication cannot cross the blood-brain barrier. Bone marrow transplantation has also been attempted;

dentlearn.ir

however, the problems inherent in graft-versus-host disease (GVHD) are still present with that form of therapy, and thus it is not recommended. A case-control study showed that adults with Gaucher disease have an increased risk for hematologic malignancies, particularly lymphoma and multiple myeloma. Genetic counseling should be provided to all affected patients.

Niemann-Pick and Tay-Sachs Disease

The neuronopathic forms of Niemann-Pick disease and the infantile form of Tay-Sachs disease are associated with a poor prognosis. Genetic counseling should be provided for affected families. Molecular markers of these disorders have been developed to identify carriers. Such identification allows earlier intervention in terms of counseling, and targeted population screening for the gene that causes Tay-Sachs disease has resulted in a marked decrease in affected patients during the past three decades.

◆ LIPOID PROTEINOSIS (HYALINOSIS CUTIS ET MUCOSAE; URBACH-WIETHE SYNDROME)

A rare condition, **lipoid proteinosis** is inherited as an autosomal recessive trait. It is characterized by the deposition of a waxy material in the dermis and submucosal connective tissue of affected patients. The earliest thorough description of lipoid proteinosis was by Urbach and Wiethe in 1929, and more than 300 patients, most being of European background, have been reported to date. Mutations of the *ECM1* gene, which encodes a glycoprotein known as *extracellular matrix protein 1*, have been identified as the cause for this condition.

Clinical Features

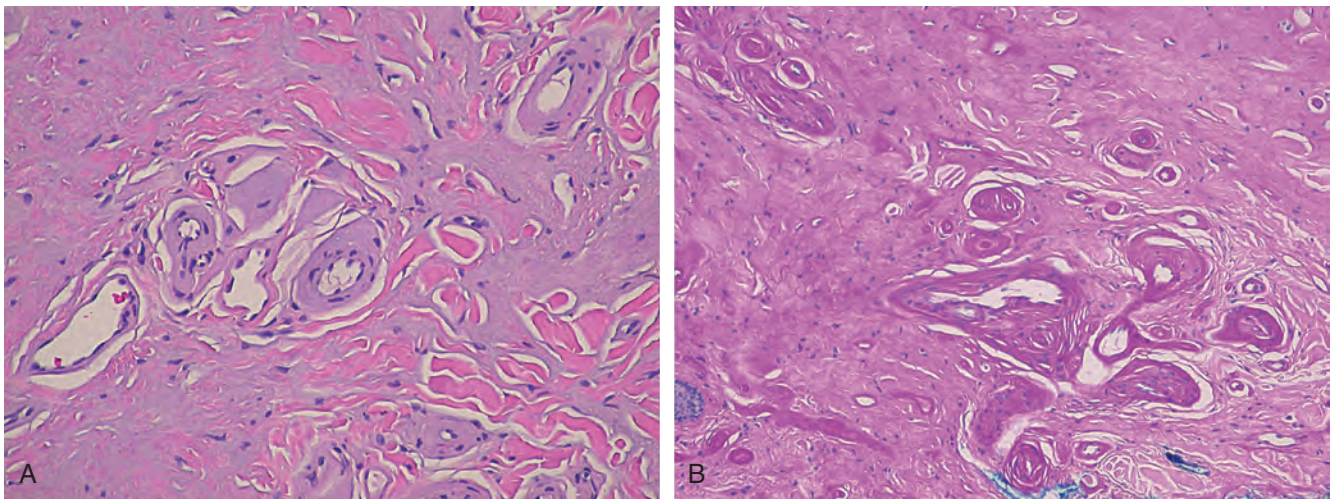
The laryngeal mucosa and vocal cords are usually the sites that are initially affected by lipoid proteinosis. Therefore, the first sign of the disease may be one of the following:

- An inability of the infant to make a crying sound
- A hoarse cry in infancy
- The development of a hoarse voice during early childhood

The vocal cords become thickened as the accumulation of an amorphous material begins to affect the laryngeal mucosa. This infiltrative mucosal process may also involve the pharynx, esophagus, tonsils, vulva, and rectum. Skin lesions also develop early in life, appearing as thickened, yellowish, waxy papules; plaques; or nodules that often affect the face, particularly the lips and the margins of the eyelids (Fig. 17.3). Some lesions may begin as dark-crusted vesicles that heal as atrophic hyperpigmented patches.

Eventually, most patients exhibit a thickened, furrowed appearance of the skin. Other areas of the skin that may be involved include the neck, palms, axillae, elbows, scrotum, knees, and digits. In those areas subjected to chronic trauma, a hyperkeratotic, verrucous surface often develops. In addition to the cutaneous manifestations, symmetrical intracranial calcifications of the medial temporal lobes have been identified in approximately 70% of affected patients. These lesions are usually asymptomatic, although a few patients with such calcifications have been reported to have a seizure disorder.

• **Fig. 17.3 Lipoid Proteinosis.** Thickened papules are present along the margin of the eyelid. (Courtesy of Dr. Maria Copete.)



• **Fig. 17.4 Lipoid Proteinosis.** The vermilion zone of the upper lip exhibits yellow-white, nodular thickenings.

The oral mucosal abnormalities typically become evident in the second decade of life. The tongue, labial mucosa, and buccal mucosa become nodular, diffusely enlarged, and thickened because of infiltration with waxy, yellow-white plaques and nodules (Fig. 17.4). The dorsal tongue papillae are eventually destroyed, and the tongue develops a smooth surface. The accumulation of the amorphous material within the tongue may result in its being bound to the floor of the mouth. Therefore, the patient may not be able to protrude the tongue, and the lack of oral soft tissue mobility may hinder the delivery of optimal dental care in some instances. Gingival enlargement appears to be an infrequent finding.

Histopathologic Features

A biopsy specimen of an early lesion of lipoid proteinosis typically reveals the deposition of a lamellar material around the blood vessels, nerves, hair follicles, and sweat glands. This

dentlearn.ir

• **Fig. 17.5 Lipoid Proteinosis. A,** This medium-power photomicrograph shows perivascular deposition of a lamellar, acellular material. **B,** The periodic acid-Schiff (PAS) method is used to stain and highlight the perivascular deposits. (Courtesy of Dr. Maria Copete.)

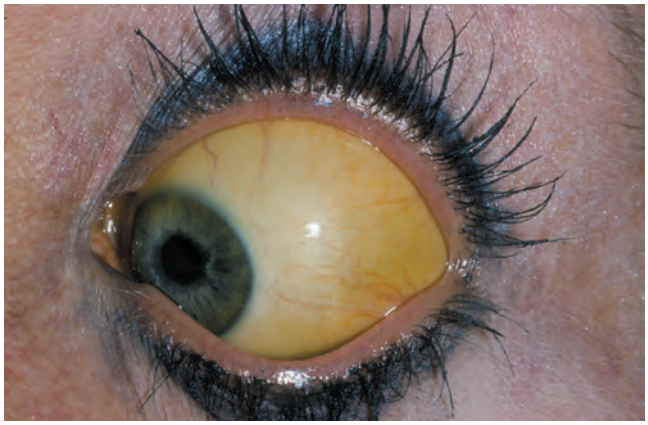
material stains positively with the periodic acid-Schiff (PAS) method and is not digested by diastase. The location of this material, its staining properties, and the presence of increased laminin, type IV collagen, and type V collagen suggest a basement membrane origin.

A biopsy specimen of a lesion in its later stages usually shows not only the lamellar material but also deposition of an amorphous substance within the dermal connective tissue (Fig. 17.5).

Treatment and Prognosis

Generally, no specific treatment is available for lipoid proteinosis other than genetic counseling. In rare instances, the infiltration of the laryngeal mucosa may produce difficult breathing for some infants, in which case debulking of the mucosal lesions may be necessary. Most patients with lipoid proteinosis have a normal life span. Certainly, however, the vocal hoarseness and the appearance of the skin may influence the quality of life for affected patients. As is the case with several other hyperkeratotic genodermatoses, the rough, scaly skin lesions may respond to systemic retinoid therapy, but the deposits of abnormal material in the dermis and submucosa do not.

◆ JAUNDICE (ICTERUS)



Jaundice is a condition characterized by excess bilirubin in the bloodstream. The bilirubin accumulates in the tissues, which results in a yellowish discoloration of the skin and mucosa. To understand jaundice, it is important to know something about the metabolism of bilirubin. Most bilirubin is derived from the breakdown of hemoglobin, the oxygen-carrying pigment of erythrocytes. The average life span of an erythrocyte in the circulation is 120 days. After this time, it undergoes physiologic breakdown. The hemoglobin is degraded and processed by the cells of the reticuloendothelial system, and bilirubin is liberated into the bloodstream in an unconjugated state. In the liver, bilirubin is taken up by the hepatocytes and conjugated with glucuronic acid, which produces conjugated bilirubin, a soluble product that can be excreted in the bile.

There are numerous causes for increased serum levels of bilirubin; some are physiologic, and many are pathologic. Therefore, the presence of jaundice is not a specific sign and generally necessitates physical examination and laboratory studies to determine the precise cause. The basic disturbances associated with increased bilirubin levels include an increased production of bilirubin. This occurs when the red blood cells (RBCs) are being broken down at such a rapid rate that the liver cannot keep pace with processing. This breakdown is seen in such conditions as **autoimmune hemolytic anemia** or **sickle cell anemia.**

In addition, the liver may not be functioning correctly, resulting in decreased uptake of the bilirubin from the circulation or decreased conjugation of bilirubin in the liver cells. Jaundice is frequently present at birth as a result of the low level of activity of the enzyme system that conjugates bilirubin. Defects in this enzyme system may also be seen with certain inherited problems, one of the more common of which is **Gilbert syndrome.** This innocuous condition is often detected on routine examination, and it is estimated to affect up to 5% of people in the United States. Because most of these examples of jaundice occur with impaired processing of bilirubin, laboratory studies usually show unconjugated bilirubin in the serum.

The presence of conjugated bilirubinemia in jaundice can usually be explained by the reduced excretion of bilirubin into the bile ducts. This can be the result of swelling of the hepatocytes (resulting in an occlusion of the bile canaliculi) or hepatocyte necrosis, with disruption of the bile canaliculi and liberation of conjugated bilirubin. Thus liver function may be disturbed because of any one of a variety of infections (e.g., viruses) or toxins (e.g., alcohol).

dentlearn.ir

• **Fig. 17.6 Jaundice.** The yellow color of the sclera represents a common finding.

Occlusion of the bile duct from gallstones, stricture, or cancer can also force conjugated bilirubin into the bloodstream.

Clinical Features

The patient affected by jaundice exhibits a diffuse, uniform, yellowish discoloration of the skin and mucosa. The color varies in intensity, depending on the serum level of bilirubin and the anatomic site. Because elastin fibers have an affinity for bilirubin, tissues that have a high content of elastin, including the sclera, lingual frenum, and soft palate, are prominently affected. The sclera of the eye is often the first site at which the yellow color is noted (Fig. 17.6). The yellow discoloration caused by **hypercarotenemia** (resulting from excess ingestion of carotene, a vitamin-A precursor found in yellow vegetables and fruits) may be confused with jaundice, but the sclera is not involved in that condition.

Other signs and symptoms associated with jaundice vary with the underlying cause of the hyperbilirubinemia. For example, patients with viral hepatitis usually have a fever, abdominal pain, anorexia, and fatigue. The patient with jaundice typically requires a complete medical evaluation to determine the precise cause of the condition so that proper therapy can be instituted.

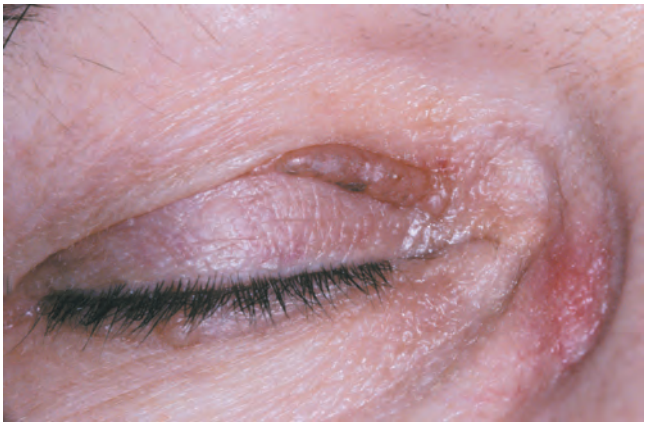
Treatment and Prognosis

The treatment and prognosis of the patient with jaundice vary with the cause. The jaundice that is commonly noted at birth often resolves spontaneously; however, if the infant is placed under special lights, then the clearing will occur more quickly because conjugation of the bilirubin molecule is triggered by exposure to blue light. If the episode of jaundice is due to significant liver damage, as may be seen with viral hepatitis B or hepatotoxic chemical injury, then the prognosis will vary, depending on the extent of liver damage. The prognosis for patients with jaundice secondary to liver damage associated with metastatic malignancy is poor.

◆ AMYLOIDOSIS

Amyloidosis represents a heterogeneous group of conditions characterized by the deposition of an extracellular proteinaceous substance called **amyloid.** Virchow coined the term *amyloid* in the middle of the nineteenth century because he believed it to be a starch-like material (*amyl* = starch; *oid* = resembling). We now understand that amyloid can be formed in a variety of settings, each with its own specific type of amyloid protein. Many of these amyloid proteins have been identified precisely with respect to their biochemical composition, and ideally an attempt should be made to categorize the type of amyloid specifically when this diagnosis is made. The various amyloid proteins are designated with an *A*, to indicate amyloid, followed by an abbreviation for the specific amyloid protein. For example, *AL* would identify amyloid composed of immunoglobulin light (L) chain molecules. Although amyloid may have several sources, all types of amyloid have the common feature of a β-pleated sheet molecular configuration, which can be seen with X-ray diffraction crystallographic analysis. Because of this similarity of molecular structure, the different types of amyloid have similar staining patterns with special stains.

Amyloidosis can produce a variety of effects, depending on the organ of involvement and the extent to which the amyloid is deposited. With limited cutaneous forms of amyloidosis, virtually no effect on survival is seen. With some forms of systemic amyloidosis, however, death may occur within a few years of the diagnosis as a result of cardiac or renal failure. Furthermore, the presence of amyloid may be associated with other problems, such as multiple myeloma or chronic infections.



Clinical Features

Several classifications of amyloidosis have been proposed in the past decade, each evolving as the knowledge of this unusual condition increases. None of the classifications is completely satisfactory, although in recent years, the biochemical makeup of these proteins has figured more prominently in most classifications. This discussion attempts to be as concise and direct as possible. Essentially, amyloidosis may be divided into **organ-limited** and **systemic** forms from a clinical standpoint.

Organ-Limited Amyloidosis

Although organ-limited amyloidosis may occur in a variety of organs, it has infrequently been reported in the oral soft tissues. An example of a limited form of amyloidosis is the amyloid nodule, which appears as a solitary, otherwise asymptomatic, submucosal deposit. Most of the organ-limited forms of amyloidosis consist of aggregates of immunoglobulin light chains, which in some cases are produced by a focal collection of monoclonal plasma cells. By definition, such amyloid deposits are not associated with any systemic alteration.

dentlearn.ir

• **Fig. 17.8 Amyloidosis.** The patient exhibits an enlarged and crenated tongue. (Courtesy of Dr. Gregory Erena.)

Systemic Amyloidosis

Systemic amyloidosis may occur in several forms:

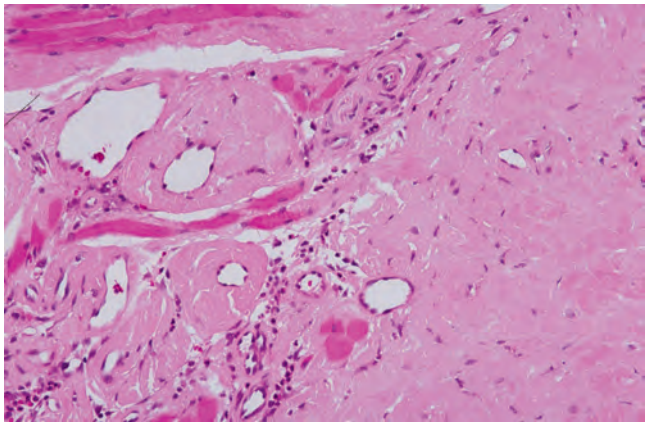
- Primary
- Myeloma associated
- Secondary
- Hemodialysis associated
- Heredofamilial

Primary and Myeloma-Associated Amyloidosis

The primary and myeloma-associated forms of amyloidosis usually affect older adults (average age, 65 years), and a slight male predilection is present. These types of amyloidosis are caused by deposition of light chain molecules (thus the designation *AL*), with most cases being idiopathic, although approximately 15%–20% are associated with multiple myeloma. The initial signs and symptoms may be nonspecific, often resulting in a delayed diagnosis. Fatigue, weight loss, paresthesia, hoarseness, edema, and orthostatic hypotension are among the first indications of this disease process. Eventually, carpal tunnel syndrome, mucocutaneous lesions, hepatomegaly, and macroglossia develop as a result of the deposition of the amyloid protein. The skin lesions appear as smooth-surfaced, firm, waxy papules and plaques. These most commonly affect the eyelid region (Fig. 17.7), the retroauricular region, the neck, and the lips. The lesions are often associated with petechiae and ecchymoses. Macroglossia has been reported in 10%–40% of these patients and may appear as diffuse or nodular enlargement of the tongue (Fig. 17.8). Sometimes oral amyloid nodules show ulceration and submucosal hemorrhage overlying the lesions. Infrequently, patients may complain of dry eyes or dry mouth, which is secondary to amyloid infiltration and destruction of the lacrimal and salivary glands. When significant blood vessel infiltration has occurred, claudication of the jaw musculature may be noticed.

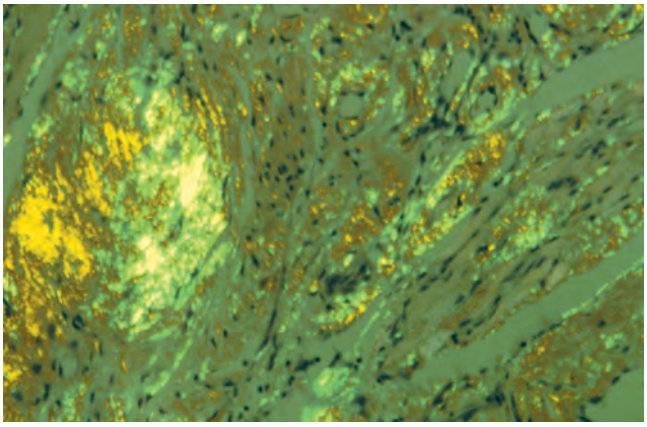
Secondary Amyloidosis

Secondary amyloidosis is so named because it characteristically develops as a result of a chronic inflammatory process, such as long-standing osteomyelitis, tuberculosis, or sarcoidosis. Cleavage fragments of a circulating acute-phase reactant protein appear to comprise this type of amyloidosis, which is thus designated *AA*. The heart is usually not affected as in other forms of amyloidosis. Liver, kidney, spleen, and adrenal involvement are typical, however. With the advent of modern antibiotic therapy, this form of amyloidosis has become much less common in the United States.



Hemodialysis-Associated Amyloidosis

Patients who have undergone long-term renal dialysis also are susceptible to amyloidosis, although in this case the amyloid protein has been identified as β_2-microglobulin, and this type of amyloidosis is designated as $A\beta_2M$. β_2-Microglobulin is a normally occurring protein that usually is not removed by the dialysis procedure, and it accumulates in the plasma. Eventually, it forms deposits, particularly in the bones and joints. Often, carpal tunnel syndrome occurs, as well as cervical spine pain and dysfunction. Tongue involvement has been reported. This type of amyloidosis may become less of a problem in the future because of increased use of dialyzers with larger pores that permit removal of the large β_2-microglobulin molecule.



Heredofamilial Amyloidosis

Heredofamilial amyloidosis is an uncommon but significant form of the disease. Several kindred have been identified in Swedish, Portuguese, and Japanese populations, and most types are inherited as autosomal dominant traits. Hereditary transthyretin amyloidosis is one example of this type of amyloidosis, and this form of amyloid deposition is characterized by gradual onset of both sensory and motor nerve polyneuropathy. Affected patients develop a variety of signs and symptoms, including difficulty walking, bilateral carpel tunnel syndrome, paroxysmal intense pain affecting their extremities, cardiomyopathy, and gastrointestinal disturbances. An autosomal recessive form, known as *familial Mediterranean fever*, has also been described. Other inherited forms of amyloidosis may also present with polyneuropathies, and other manifestations, such as cardiac arrhythmias, congestive heart

dentlearn.ir

• **Fig. 17.9 Amyloidosis.** This medium-power photomicrograph shows the eosinophilic, acellular deposits that are characteristic of amyloid deposition.

failure, and renal failure, eventually develop as the amyloid deposition continues.

Histopathologic Features

Biopsy of rectal mucosa has classically been used to confirm a diagnosis of primary or myeloma-associated amyloidosis, with up to 80% of such biopsy specimens being positive. Aspiration biopsy of abdominal subcutaneous fat is a simpler procedure, however, and the sensitivity of this technique has been reported to range from 55% to 75%. Alternative tissue sources, however, are the gingiva and labial salivary glands. Histopathologic examination of gingival tissue that has been affected by amyloidosis shows extracellular deposition in the submucosal connective tissue of an amorphous, eosinophilic material, which may be arranged in a perivascular orientation or may be diffusely present throughout the tissue (Fig. 17.9). Relatively low sensitivity has been reported for gingival biopsies, whereas labial salivary gland tissue shows deposition of amyloid in a periductal or perivascular location in more than 80% of the cases.

If the amorphous eosinophilic material represents amyloid, it will be stained by the dye, Congo red, which has an affinity for the abnormal protein. In tissue sections stained with Congo red, the amyloid appears red. When the tissue that takes up the Congo red stain is viewed with polarized light, it exhibits an apple-green birefringence (Fig. 17.10). This Congo red staining method is considered to be the "gold standard" for identifying the presence of amyloid. Other techniques have been used, but these are less sensitive or specific. Microscopic sections stained with crystal violet reveal a characteristic metachromasia; this normally purple dye appears more reddish when it reacts with amyloid. Staining with thioflavine T, a fluorescent dye, also gives positive results if amyloid is present. Ultrastructurally, amyloid is seen as a collection of 7.5- to 10-nm diameter, nonbranching, linear fibrils.

Diagnosis

Once the histopathologic diagnosis of amyloidosis has been made, the patient must be evaluated medically to determine the type of amyloidosis that is present. This often entails a workup that includes serum immunoelectrophoresis to determine whether a monoclonal gammopathy exists so that multiple myeloma can be ruled out. Immunohistochemical studies are proving to be very useful in distinguishing the specific type of amyloid protein. Family history and physical examination findings are also important.

Treatment and Prognosis

In most instances, no effective therapy is available for amyloidosis. Surgical debulking of amyloid deposition in the tongue has met with limited success. Selected forms of amyloidosis may respond to treatment, or at least their progression may be slowed, depending on the underlying cause. In cases of secondary amyloidosis associated with an infectious agent, treatment of the infection and reduction of the inflammation often result in clinical improvement. Renal transplantation may arrest the progression of the bone lesions in hemodialysis-associated amyloidosis, but this procedure apparently does not reverse the process. Liver transplantation has been shown to improve the prognosis of several forms of inherited amyloidosis, particularly the transthyretin variant. Newly approved treatments for transthyretin amyloidosis include inotersen and patisiran, which disrupt the intracellular molecular synthesis of transthyretin amyloid, resulting in reduction in symptoms and markedly improving the prognosis of this condition. Familial Mediterranean fever may respond to systemic colchicine therapy. Genetic counseling is also appropriate for patients affected by the inherited forms of amyloidosis. Treatment of primary amyloidosis (AL) with colchicine, prednisone, and melphalan appears to improve the prognosis of patients who do not have cardiac or renal

dentlearn.ir

involvement, although the outlook is guarded to poor in most instances. Autologous stem cell transplantation has shown to improve survival rates, but unfortunately only 20%–25% of AL amyloid patients meet the criteria for undergoing this rigorous form of therapy. Most patients die of cardiac failure, arrhythmia, or renal disease within months to a few years after the diagnosis.

◆ XANTHELASMA (XANTHELASMA PALPEBRARUM)

Xanthelasma is the most common of the cutaneous xanthomas, occurring in approximately 4% of the adult population. The condition is mentioned because these lesions appear somewhat similar to cutaneous amyloid deposits. In addition, the presence of xanthelasma has been related to an increased risk of atherosclerosis as well as elevated serum lipids.

Clinical Features

Xanthelasma is typically identified in middle-aged or older adults, presenting as one or more soft, yellowish plaques associated with the periocular skin (Fig. 17.11). The lesions tend to develop on the medial aspect of the upper eyelid. Their soft consistency and yellow color clinically should help distinguish xanthelasma from amyloid deposits.

Histopathologic Features

Biopsy of xanthelasma shows a collection of lipid-laden histiocytes in the superficial to mid-dermal connective tissue.

Treatment and Prognosis

Treatment of xanthelasma itself is not necessary and is generally considered a cosmetic procedure. If the patient has not been evaluated recently with respect to their cholesterol levels, referral to a primary care physician for serum lipid assessment would be prudent. The lesions can be surgically removed, or they can be removed by laser ablation. Both techniques have similar acceptable cosmetic results, although recurrence is not unusual, even if serum lipids are controlled.

• **Fig. 17.11 Xanthelasma.** These soft yellowish plaques on the medial aspect of the skin of the upper eyelid are characteristic of xanthelasma.

◆ VITAMIN DEFICIENCY

In the United States today, significant vitamin deficiencies are not common. Patients with malabsorption syndromes or eating disorders, persons who follow "fad diets," and alcoholics are the groups most commonly affected.

Vitamin A (retinol) is essential for the maintenance of vision, and it also plays a role in growth and tissue differentiation. Vitamin A can be obtained directly from dietary sources, such as organ meats (particularly liver), or the body can synthesize it from β-carotene, which is abundant in dark green, red, or yellow vegetables.

Vitamin B_1 (thiamin) acts as a coenzyme for several metabolic reactions and is thought to maintain the proper functioning of neurons. Thiamin is found in many animal and vegetable food sources.

Vitamin B_2 (riboflavin) is necessary for cellular oxidation-reduction reactions. Foods that contain significant amounts of riboflavin include milk, green vegetables, lean meat, fish, legumes, and eggs.

Vitamin B_3 (niacin) acts as a coenzyme for oxidation-reduction reactions. Rich sources include food from animal sources, especially lean meat and liver, milk, eggs, whole grains, peanuts, yeast, and cereal bran or germ.

Vitamin B_6 (pyridoxine) serves as a cofactor associated with enzymes that participate in amino acid synthesis. It is found in many animal and vegetable food sources.

Vitamin C (ascorbic acid) is necessary for the proper synthesis of collagen. This vitamin is present in a wide variety of vegetables and fruits, although it is particularly abundant in citrus fruits.

Vitamin D, which is now considered to be a hormone, can be synthesized in adequate amounts within the epidermis if the skin is exposed to a moderate degree of sunlight. Most milk and processed cereal is fortified with vitamin D in the United States today, however. Appropriate levels of vitamin D and its active metabolites are necessary for calcium absorption from the gut.

Vitamin E (α-tocopherol) is a fat-soluble vitamin that is widely stored throughout the body. It probably functions as an antioxidant. Vegetable oils, meats, nuts, cereal grains, and fresh greens and vegetables are good sources of vitamin E.

Vitamin K is a fat-soluble vitamin found in a wide variety of green vegetables, as well as milk, butter, and liver; intestinal bacteria also produce it. This vitamin is necessary for the proper synthesis of various proteins, including the clotting factors II, VII, IX, and X.

dentlearn.ir

Clinical Features

Vitamin A

A severe deficiency of vitamin A during infancy may result in blindness, and is considered one of the leading causes of childhood blindness in underdeveloped parts of the world. The early changes associated with a lack of this vitamin later in life include an inability of the eye to adapt to reduced light conditions (i.e., night blindness). With more severe, prolonged deficiency, dryness of the skin and conjunctiva develop, and the ocular changes may progress to ulceration of the cornea, leading to blindness.

Thiamin

A deficiency of thiamin results in a condition called **beriberi,** a problem that is relatively uncommon in the Western world except in alcoholics or other individuals who do not receive a balanced diet. Thiamin deficiency has also been documented in patients who have had gastric bypass surgery for weight control, presumably because an adequate amount of the vitamin is not obtained in the diet. The condition became prevalent in Southeast Asia when the practice of removing the outer husks of the rice grain by machine was introduced. Because these outer husks contained nearly all of the thiamin, people who subsisted on the "polished" rice became deficient in this vitamin. The disorder is manifested by cardiovascular problems (e.g., peripheral vasodilation, heart failure, and edema) and neurologic problems (including peripheral neuropathy and Wernicke encephalopathy). Patients with Wernicke encephalopathy experience vomiting, nystagmus, and progressive mental deterioration, which may lead to coma and death.

Riboflavin

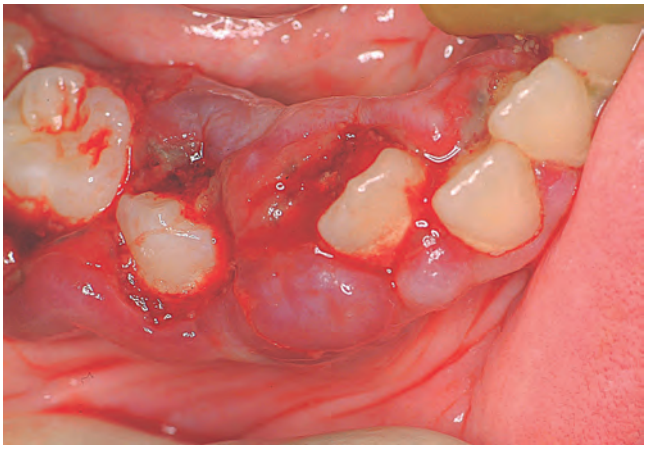
A diet that is chronically deficient in riboflavin causes a number of oral alterations, including glossitis, angular cheilitis, sore throat, and swelling and erythema of the oral mucosa. A normocytic, normochromic anemia may be present, and seborrheic dermatitis may affect the skin.

Niacin

A deficiency of niacin causes a condition known as **pellagra,** a term derived from the Italian words *pelle agra,* meaning *rough skin.* This condition may occur in populations that use maize as a principal component of their diets, because corn is a poor source of niacin. Pellagra was once common in the southeastern United States and may still be seen in some parts of the world. The classic systemic signs and symptoms include the triad of dermatitis, dementia, and diarrhea. The dermatitis is distributed symmetrically; sun-exposed areas, such as the face, neck, and forearms, are affected most severely (Fig. 17.12). The oral manifestations have been described as stomatitis and glossitis, with the tongue appearing red, smooth, and raw. Without correction of the niacin deficiency, the disease may evolve and persist over a period of years, eventually leading to death.

• **Fig. 17.12 Pellagra.** The skin on the foot is rough and hyperpigmented, except for a central band that was protected from sunlight by a sandal strap. (Courtesy of Dr. Sylvie Brener.)

Pyridoxine



A deficiency of pyridoxine is unusual because of its widespread occurrence in a variety of foods. A number of drugs, such as the antituberculosis drug isoniazid, act as pyridoxine antagonists; therefore, patients who receive these medications may have a deficiency state. Because the vitamin plays a role in neuronal function, patients may show weakness, dizziness, or seizure disorders. Cheilitis and glossitis, reported in people with pellagra, are also reported in patients with pyridoxine deficiency.

Vitamin C

A deficiency of vitamin C is known as **scurvy,** and its occurrence in the United States is usually limited to people whose diets lack fresh fruits and vegetables. Commonly affected groups include inner-city infants (whose diets often consist entirely of milk), children affected by autism or other neurodevelopmental disorders (due to limited diet that is chosen), bone marrow transplant recipients (due to oral mucositis related to graft-vs-host disease), children with iron overload related to multiple transfusions (due to sickle cell anemia and thalassemia), and older edentulous men, particularly those who live alone.

The clinical signs of scurvy are typically related to inadequate collagen synthesis. For example, weakened vascular walls may result in widespread petechial hemorrhage and ecchymosis. Similarly, wound healing is delayed, and recently healed wounds may break down. In childhood, painful subperiosteal hemorrhages may occur.

dentlearn.ir

• **Fig. 17.13 Scurvy.** Hemorrhagic gingival enlargement (scorbutic gingivitis) because of capillary fragility. (Courtesy of Dr. James Hargan.)

• **Fig. 17.14 Vitamin D Deficiency.** Hypocalcification of the teeth is seen in this child who had vitamin D deficiency related to a diet of breast milk exclusively and lack of adequate sunlight exposure. (Courtesy of Dr. Pamela McDonald.)

The oral manifestations are well documented and include generalized gingival swelling with spontaneous hemorrhage, ulceration, tooth mobility, and increased severity of periodontal infection and periodontal bone loss. The gingival lesions have been termed **scorbutic gingivitis** (Fig. 17.13). If untreated, scurvy may ultimately lead to death, often as a result of intracranial hemorrhage.

Vitamin D

A deficiency of vitamin D during infancy results in a condition called **rickets;** adults who are deficient in this vitamin develop **osteomalacia.** With the vitamin-D supplementation of milk and cereal, rickets is a relatively uncommon disease today in the United States. In past centuries, however, rickets was often seen, particularly in the temperate zones of the world, which often do not receive adequate sunlight to ensure physiologic levels of vitamin D. Even today in the United States, children who are dark-skinned and do not receive adequate sun exposure, as well as solely breast-fed infants, remain at risk for developing rickets. Nutritional rickets remains a problem in many developing countries, although the condition is thought to be associated more with calcium deficiency than vitamin-D deficiency.

Clinical manifestations of rickets include irritability, growth impairment, and prominence of the costochondral junctions (*rachitic rosary*). As the child ages and begins to put weight on the long bones of the legs, significant bowing results because of the poor mineralization of the skeleton. Vitamin-D deficiency occurring during the period of tooth development will result hypomineralization of the teeth (Fig. 17.14).

A similar pattern of poorly mineralized bone is seen in osteomalacia in adults. Bone normally undergoes continuous remodeling and turnover, and the osteoid that is produced during this process does not have sufficient calcium to mineralize completely. Thus a weak, fragile bone structure results. Patients affected by osteomalacia frequently complain of diffuse skeletal pain, and their bones are susceptible to fracture with relatively minor injury.

Vitamin E

A deficiency of vitamin E is rare and occurs primarily in children who suffer from chronic cholestatic liver disease. These patients have severe malabsorption of all fat-soluble vitamins, but particularly vitamin E. Multiple neurologic signs develop as a result of abnormalities in the central nervous system (CNS) and peripheral nervous system.

Vitamin K

A deficiency of vitamin K may be seen in patients with malabsorption syndromes or in those whose intestinal microflora has been eliminated by long-term broad-spectrum antibiotic use. Oral anticoagulants in the dicumarol family also inhibit the normal enzymatic activity of vitamin K. A deficiency or inhibition of synthesis of vitamin K leads to a coagulopathy because of the inadequate synthesis of prothrombin and other clotting factors. Intraorally, this coagulopathy is most often manifested by gingival bleeding. If the coagulopathy is not corrected, death may result from uncontrolled systemic hemorrhage.

Treatment and Prognosis

Replacement therapy is indicated for vitamin deficiencies. However, such deficiencies are uncommon in most developed countries, except for the situations described earlier. In fact, vitamin excess is perhaps more likely to be encountered in the United States today because so many people self-medicate with unnecessary and potentially harmful vitamin supplements. For example, excess vitamin A may cause abdominal pain, vomiting, headache, joint pain, and exostoses, whereas excess vitamin C may induce the formation of additional kidney stones in individuals with a history of nephrolithiasis. Similarly, an increased prevalence of kidney stones can be seen with excess oral intake of vitamin D.

dentlearn.ir

◆ IRON-DEFICIENCY ANEMIA

Iron-deficiency anemia is the most common cause of anemia in the United States and throughout the world. This form of anemia develops when the amount of iron available to the body cannot keep pace with the need for iron in the production of red blood cells (RBCs). This type of anemia develops under four conditions:

1. Excessive blood loss
2. Increased demand for RBCs
3. Decreased intake of iron
4. Decreased absorption of iron

It is estimated up to 11% of women of childbearing age in the United States are iron deficient as a result of the chronic blood loss associated with excessive menstrual flow **(menorrhagia).** Similarly, 1%–2% of adult men are iron deficient because of chronic blood loss, usually associated with gastrointestinal disease, such as peptic ulcer disease, diverticulosis, hiatal hernia, or malignancy.

An increased demand for erythrocyte production occurs during childhood growth spurts and during pregnancy. A decreased intake of iron may be seen during infancy when the diet consists of relatively iron-poor foods, such as cereals and milk. Likewise, the diets of older people may be deficient if their dental condition prohibits them from eating the proper foods or if they cannot afford iron-rich foods, such as meats and vegetables. In the developing world, intestinal parasites (especially hookworms) are a common cause of iron deficiency in children and pregnant women.

Decreased absorption is a much less common problem; however, it can be seen in patients who have had a complete gastrectomy or who have **celiac sprue,** a condition that results in severe chronic diarrhea because of sensitivity to the plant protein, gluten. Inflammatory bowel disease, particularly Crohn disease, may also result in decreased absorption of iron.

Clinical Features

Patients with iron-deficiency anemia that is severe enough to cause symptoms may complain of fatigue, easy tiring, palpitations, lightheadedness, and lack of energy. Some patients may develop cravings for nonfood substances, such as clay or ice, a condition known as *pica*. Oral manifestations include angular cheilitis and atrophic glossitis or generalized oral mucosal atrophy. The glossitis has been described as a diffuse or patchy atrophy of the dorsal tongue papillae, often accompanied by tenderness or a burning sensation. Such findings are also evident in oral candidiasis, and some investigators have suggested that iron deficiency predisposes the patient to candidal infection, which results in the changes seen at the corners of the mouth and on the tongue. Such lesions are rarely seen in the United States, perhaps because the anemia is usually detected relatively early before the oral mucosal changes have had a chance to develop.

Laboratory Findings

The diagnosis should be established by means of a complete blood count with RBC indices because many other conditions, such as hypothyroidism, other anemias, or chronic depression, may elicit similar systemic clinical complaints. The laboratory evaluation characteristically shows hypochromic microcytic RBCs, which may be reduced in numbers. Additional supporting evidence for iron deficiency includes the findings of low serum iron levels and ferritin concentration together with elevated total iron-binding capacity.

Treatment and Prognosis

Therapy for most cases of iron-deficiency anemia consists of dietary iron supplementation by means of oral ferrous sulfate. For patients with malabsorption problems or severe anemia, parenteral iron may be given periodically. The response to therapy is usually prompt, with red cell parameters returning to normal within 1–2 months. The underlying cause of the anemia should be identified so that it may be addressed, if feasible.

◆ PLUMMER-VINSON SYNDROME (PATERSON-KELLY SYNDROME; SIDEROPENIC DYSPHAGIA)

Plummer-Vinson syndrome is a rare condition characterized by iron-deficiency anemia, seen in conjunction with glossitis and dysphagia. Its prevalence in developed countries has been declining, probably as a result of the improved nutritional status of the populations. The condition is significant in that it has been associated with a high frequency of both oral and esophageal squamous cell carcinoma; therefore, it is considered a premalignant process.

Clinical and Radiographic Features

Most reported patients with Plummer-Vinson syndrome have been women of Scandinavian or Northern European background, between 30 and 50 years of age. Patients typically complain of a burning sensation associated with the tongue and oral mucosa. Sometimes this discomfort is so severe that dentures cannot be worn. Angular cheilitis is often present and may be severe (Fig. 17.15). Marked atrophy of the lingual papillae, which produces a smooth, red appearance of the dorsal tongue, is seen clinically (Fig. 17.16).

Patients also frequently complain of difficulty in swallowing **(dysphagia)** or pain on swallowing. An evaluation with endoscopy or esophageal barium contrast radiographic studies usually shows the presence of abnormal bands of tissue in the esophagus, called **esophageal webs.** Another sign is an alteration of the growth pattern of the nails, which results in a spoon-shaped configuration **(koilonychia)** (Fig. 17.17). The nails also may be brittle.

dentlearn.ir

• **Fig. 17.15 Plummer-Vinson Syndrome.** Patients often show angular cheilitis.

• **Fig. 17.16 Plummer-Vinson Syndrome.** The diffuse papillary atrophy of the dorsal tongue is characteristic of the oral changes. (From Neville BW, Damm DD, White DK: *Color atlas of clinical oral pathology,* ed. 2, Philadelphia, 1999, Lippincott Williams & Wilkins.)

• **Fig. 17.17 Plummer-Vinson Syndrome.** The concave, "spoon-shaped" appearance of this patient's fingernails is a characteristic feature of chronic iron deficiency. (Courtesy of Dr. Ashleigh Briody.)

Symptoms of anemia may prompt patients with Plummer-Vinson syndrome to seek medical care. Fatigue, shortness of breath, and weakness are characteristic symptoms.

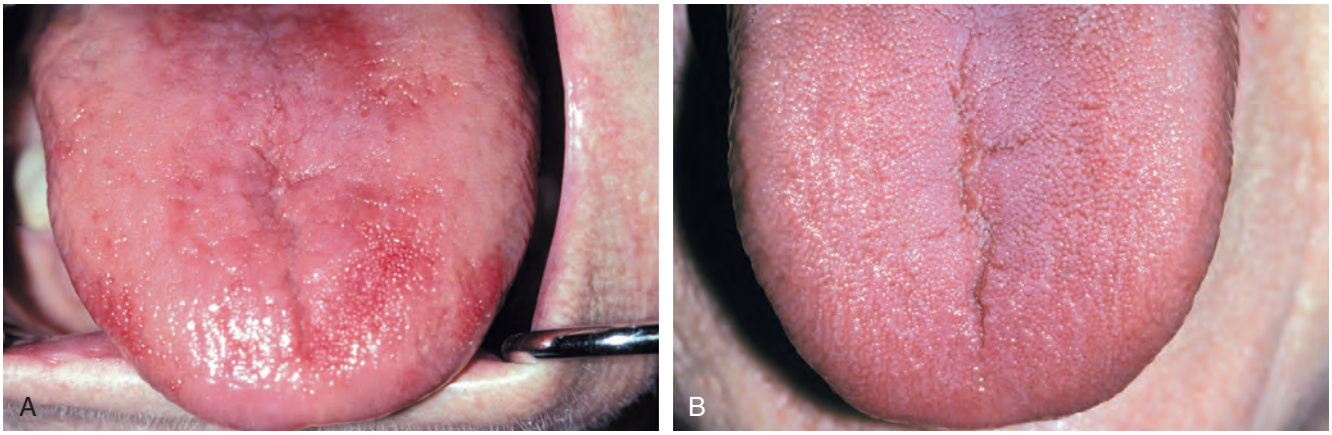
Laboratory Findings

Hematologic studies show a hypochromic microcytic anemia that is consistent with an iron-deficiency anemia.

Histopathologic Features

A biopsy specimen of involved mucosa from a patient with Plummer-Vinson syndrome typically shows epithelial atrophy with varying degrees of submucosal chronic inflammation. In advanced cases, evidence of epithelial atypia or dysplasia may be seen.

Treatment and Prognosis



Treatment of Plummer-Vinson syndrome is primarily directed at correcting the iron-deficiency anemia by means of dietary iron supplementation. This therapy usually resolves the anemia, relieves the glossodynia, and may reduce the severity of the esophageal symptoms. Occasionally, esophageal dilation is necessary to help improve the symptoms of dysphagia. Patients with Plummer-Vinson syndrome should be evaluated periodically for oral, hypopharyngeal, and esophageal cancer because a 5%–50% prevalence of upper aerodigestive tract malignancy has been reported in affected persons.

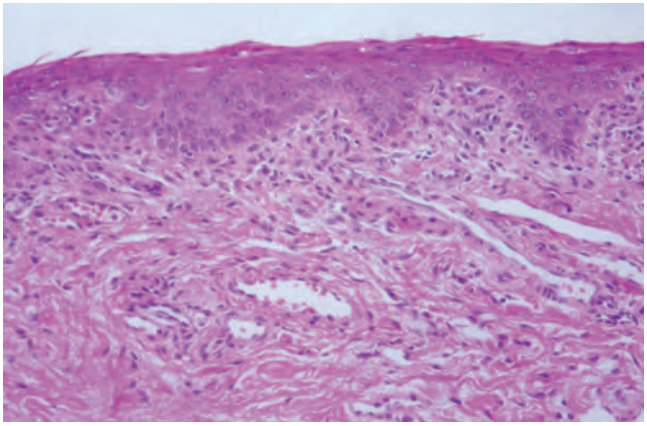
◆ PERNICIOUS ANEMIA

Pernicious anemia is an uncommon condition that occurs with greatest frequency among older patients of Northern European heritage, although recent studies have identified the disease in black and Hispanic populations as well. Asian populations seem to be affected much less frequently. The disease is a megaloblastic anemia caused by poor absorption of cobalamin (vitamin B_{12}, extrinsic factor). Intrinsic factor, which is produced by the parietal cells of the stomach lining, is needed for vitamin B_{12} absorption. Normally, when cobalamin is ingested, it binds to intrinsic factor in the duodenum. Because the lining cells of the intestine preferentially take up the cobalamin-intrinsic factor complex, significant amounts of the vitamin cannot be absorbed unless both components are present.

In the case of pernicious anemia, most patients lack intrinsic factor because of an autoimmune destruction of the parietal cells of the stomach; this results in decreased absorption of cobalamin. Antibodies directed against intrinsic factor are also found in the serum of these patients. Vitamin B_{12} deficiency may occur for other reasons, and although the resulting signs and symptoms may be identical to those of pernicious anemia, these should be considered as

dentlearn.ir

• **Fig. 17.18 Pernicious Anemia. A,** The dorsal tongue shows erythema and atrophy. **B,** After therapy with vitamin B_{12}, the mucosal alteration resolved.



distinctly different deficiency disorders. For example, a decreased ability to absorb cobalamin may also occur after gastrointestinal bypass operations. In addition, because cobalamin is primarily derived from animal sources, some strict vegetarians (vegans) may develop vitamin B_{12} deficiency.

Because cobalamin is necessary for normal nucleic acid synthesis, anything that disrupts the absorption of the vitamin causes problems, especially for cells that are multiplying rapidly and, therefore, synthesizing large amounts of nucleic acids. The cells that are the most mitotically active are affected to the greatest degree, especially the hematopoietic cells and the gastrointestinal lining epithelial cells.

Clinical Features

With respect to systemic complaints, patients with pernicious anemia often report fatigue, weakness, shortness of breath, headache, and feeling faint. Such symptoms are associated with most anemias and probably reflect the reduced oxygen-carrying capacity of the blood. Vitamin B_{12} also functions to maintain myelin throughout the nervous system; therefore, with reduced levels of the vitamin, many patients report paresthesia, tingling, or numbness of the extremities. Difficulty in walking and diminished vibratory and positional sense may be present. Psychiatric symptoms of memory loss, irritability, depression, and dementia have also been described.

Oral symptoms often consist of a burning sensation of the tongue, lips, buccal mucosa, or other mucosal sites. Clinical examination may show focal patchy areas of oral mucosal erythema and atrophy (Fig. 17.18), or the process may be more diffuse, depending on the severity and duration of the condition. The tongue may be affected in as many as 50%–60% of patients with pernicious anemia, but it may not show as much involvement as other areas of the oral mucosa in some instances. The atrophy and erythema may be easier to appreciate on the dorsal tongue than at other sites, however.

• **Fig. 17.19 Pernicious Anemia.** This medium-power photomicrograph shows epithelial atrophy and atypia with chronic inflammation of the underlying connective tissue. These features are characteristic of a megaloblastic anemia, such as pernicious anemia.

Histopathologic Features

Histopathologic examination of an erythematous portion of the oral mucosa shows marked epithelial atrophy with loss of rete ridges, an increased nuclear-to-cytoplasmic ratio of the surface epithelial cells, and prominent nucleoli (Fig. 17.19). This pattern can be misinterpreted as epithelial dysplasia at times, although the nuclei in pernicious anemia typically are pale staining and show peripheral chromatin clumping. A patchy diffuse chronic inflammatory cell infiltrate is usually noted in the underlying connective tissue.

Laboratory Findings

Hematologic evaluation of vitamin B_{12} deficiency shows a macrocytic anemia and reduced serum cobalamin levels. The Schilling test for pernicious anemia has been used to determine the pathogenesis of the cobalamin deficiency by comparing absorption and excretion rates of radiolabeled cobalamin. However, this study is rather complicated to perform, and is now considered to be obsolete. The presence of

dentlearn.ir

serum antibodies directed against intrinsic factor is quite specific for pernicious anemia.

Treatment and Prognosis

Once the diagnosis of pernicious anemia is established, treatment traditionally has consisted of monthly intramuscular injections of cyanocobalamin. The condition responds rapidly once therapy is initiated, with reports of clearing of oral lesions within 5 days. High-dose oral cobalamin therapy has also been shown to be an equally effective treatment, however, with advantages being its cost-effectiveness and the elimination of painful injections. One systematic literature review has identified what appears to be an increased risk of gastric carcinoma, with pernicious anemia patients being seven times more likely to develop this tumor compared to the general population. Both vitamin B_{12} deficiency and folate deficiency will cause megaloblastic anemia. Folate deficiency is much less common today because many foods are enriched with folate. Nevertheless, it is important to distinguish between the two conditions. Treatment of vitamin B_{12} deficiency with folate will resolve the anemia and the oral mucosal atrophy, but reduced myelin production will continue, resulting in further CNS damage.

◆ PITUITARY DWARFISM

Pituitary dwarfism is a relatively rare condition that results from either the diminished production of growth hormone by the anterior pituitary gland, abnormalities of the growth hormone molecule, or a reduced capacity of the tissues to respond to growth hormone. Affected patients are typically much shorter than normal, although their body proportions are generally appropriate.

Several conditions may cause short stature, and a careful evaluation of the patient must be performed to rule out other possible causes, such as the following:

1. Intrinsic defects in the patient's tissues (e.g., certain skeletal dysplasias, chromosomal abnormalities, and idiopathic short stature)
2. Alterations in the environment of the growing tissues (e.g., malnutrition, hypothyroidism, and diabetes mellitus)

If a lack of growth hormone is detected, the cause should be determined. Sometimes the fault lies with the pituitary gland itself (e.g., aplasia or hypoplasia). In other instances, the problem may be related to destruction of the pituitary or hypothalamus by tumors, therapeutic radiation, or infection.

If the hypothalamus is affected, a deficiency in growth hormone–releasing hormone, which is produced by the hypothalamus, results in a deficiency of growth hormone. Often deficiencies in other hormones, such as thyroid hormone and cortisol, are also detected in patients with primary pituitary or hypothalamic disorders.

Some patients exhibit normal or even elevated levels of growth hormone, yet still show little evidence of growth. These individuals usually have inherited an autosomal recessive trait, resulting in abnormal and reduced growth hormone receptors on the patients' cells. Thus normal growth cannot proceed.

Clinical Features

Perhaps the most striking feature of pituitary dwarfism is the remarkably short stature of the affected patient. Sometimes this is not noticed until the early years of childhood, but a review of the patient's growth history should show a consistent pattern of failure to achieve the minimal height on the standard growth chart. Often the patient's height may be as much as three standard deviations below normal for a given age. Unlike the body proportions in many of the dysmorphic syndromes and skeletal dysplasias, the body proportions of patients affected by a lack of growth hormone are usually normal. One possible exception is the size of the skull, which is usually within normal limits. Because the facial skeleton does not keep pace with the skull, however, the face of an affected patient may appear smaller than it should be. Mental status is generally within normal limits.

The maxilla and mandible of affected patients are smaller than normal, and the teeth show a delayed pattern of eruption. The delay ranges from 1 to 3 years for teeth that normally erupt during the first decade of life and from 3 to 10 years for teeth that normally erupt in the second decade of life. Often the shedding of deciduous teeth is delayed by several years, and the development of the roots of the permanent teeth also appears to be delayed. A lack of development of the third molars seems to be a common finding. The size of the teeth is usually reduced in proportion to the other anatomic structures. One recent study suggested that growth hormone-deficient patients may exhibit more severe periodontal disease compared to a matched control population.

Laboratory Findings

Radioimmunoassay for human growth hormone shows levels that are markedly below normal.

Treatment and Prognosis

Replacement therapy with human growth hormone is the treatment of choice for patients with pituitary dwarfism if the disorder is detected before closure of the epiphyseal growth plates. In the past, growth hormone was extracted from cadaveric pituitary glands, which carried the very serious potential of prion-related Creutzfeldt-Jakob disease; since 1985, genetically engineered human growth hormone has been produced with recombinant DNA technology. For patients with a growth hormone deficiency caused by a hypothalamic defect, treatment with growth hormone–releasing hormone is appropriate. If patients are identified and treated at an early age, they can be expected to achieve a relatively normal height. The craniofacial bone structure also assumes a less childlike pattern. Evaluation of a series of patients who had been treated for long periods with growth hormone determined that up to half

dentlearn.ir

developed acromegalic features, including larger feet and a larger mandible. For patients who lack growth hormone receptors, no treatment is available.

◆ GIGANTISM

Gigantism is a rare condition caused by an increased production of growth hormone, usually related to a functional pituitary adenoma. Approximately 3 persons per million population are diagnosed each year. The increased production of growth hormone takes place before closure of the epiphyseal plates, and the affected person grows at a much more rapid pace, becoming abnormally tall. Although the average height of the population of the United States has been gradually increasing during the past several decades, individuals who exceed the mean height by more than three standard deviations may be considered candidates for endocrinologic evaluation. Familial examples of gigantism have also been described.

Clinical and Radiographic Features

Patients with gigantism usually show markedly accelerated growth during childhood, irrespective of normal growth spurts. Radiographic evaluation of the skull often shows an enlarged sella as a result of the presence of a pituitary adenoma. The adenoma may result in hormonal deficiencies, such as hypothyroidism and hypoadrenocorticism, if the remaining normal pituitary gland tissue is compressed and destroyed. **McCune-Albright syndrome** (polyostotic fibrous dysplasia and *café au lait* pigmentation with associated endocrinologic disturbances) (see page 663) may account for as many as 20% of the cases of gigantism.

If the condition remains uncorrected for a prolonged period, extreme height (more than 7 feet tall) will be achieved, and enlargement of the facial soft tissues, the mandible, and the hands and feet will become apparent. These changes often resemble those seen in **acromegaly** (discussed later). Another oral finding is true generalized macrodontia.

Treatment and Prognosis

Appropriate management of gigantism involves the surgical removal of the functioning pituitary adenoma, usually by a transsphenoidal approach. Radiation therapy may also be used, as well as one of the somatostatin analogues and a growth hormone receptor antagonist (discussed in the next topic, **acromegaly**).

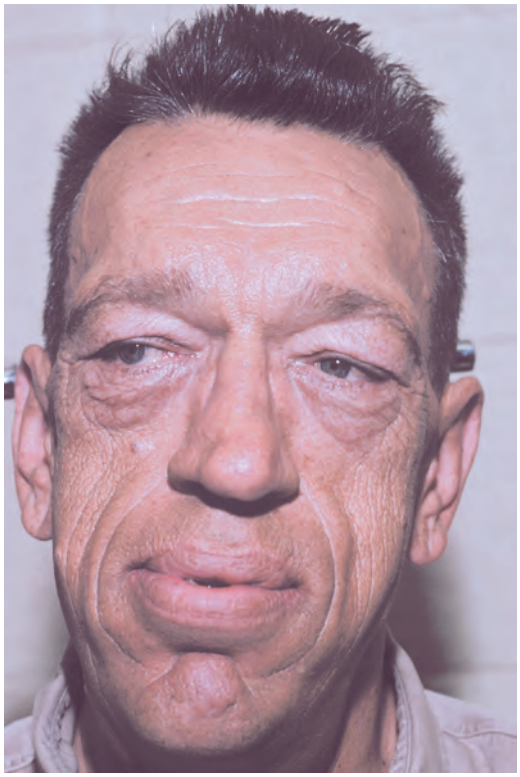
The life span of patients with gigantism is usually markedly reduced. Complications associated with hypertension, peripheral neuropathy, osteoporosis, and pulmonary disease contribute to increased morbidity and mortality.

◆ ACROMEGALY

Acromegaly is an uncommon condition characterized by the excess production of growth hormone after closure of the epiphyseal plates in the affected patient. Usually, this increase in growth hormone is due to a functional pituitary adenoma. The incidence is estimated to be approximately two to eleven new cases diagnosed per million population per year, based on recent European data. The prevalence is now believed to be between 30 and 140 affected patients per million.

Clinical and Radiographic Features

Because most patients with acromegaly have a pituitary adenoma, symptoms related directly to the space-occupying mass of the tumor may be present. These symptoms include headaches, visual disturbances, and other signs of a brain tumor. Sometimes pressure atrophy of the residual normal pituitary by the adenoma results in diminished production of other pituitary hormones and causes other indirect endocrine problems. The direct effects of increased levels of growth hormone include a variety of problems, such as hypertension, heart disease, hyperhidrosis, arthritis, and peripheral neuropathy.



Renewed growth in the small bones of the hands and feet (Fig. 17.20) and in the membranous bones of the skull and jaws is typically observed. Patients may complain of gloves, rings, or hats becoming "too small." The soft tissue is also often affected, producing a coarse facial appearance (Fig. 17.21). Hypertrophy of the soft palatal tissues may cause or accentuate sleep apnea. Because these signs and symptoms are slow to develop and are vague at the onset, an average time of 6–10 years elapses from the onset of symptoms to the diagnosis of disease. The average age at diagnosis is 42 years, and no sex predilection is seen.

From a dental perspective, these patients have mandibular prognathism as a result of the increased growth of the mandible (Fig. 17.22), which may cause apertognathia (anterior open bite). Growth of the jaws also may cause spacing of the teeth, resulting in diastema formation. Soft tissue growth often produces uniform macroglossia in affected patients.

• **Fig. 17.22 Acromegaly.** This lateral skull film shows the dramatic degree of mandibular enlargement that may occur.

Laboratory Findings and Diagnosis

If acromegaly is suspected, measurement of serum growth hormone levels is done after giving the patient a measured quantity of glucose orally. Normally, this glucose challenge will reduce the production of growth hormone, but if the patient has acromegaly, growth hormone will not be suppressed. Usually magnetic resonance imaging (MRI) will identify the pituitary adenoma that is responsible for inappropriate growth hormone secretion.

Treatment and Prognosis

The treatment of a patient with acromegaly is typically directed at the removal of the pituitary tumor mass and the return of the growth hormone levels to normal. The most effective treatment with the least associated morbidity is surgical excision by a transsphenoidal approach. The prognosis for such a procedure is good, although a mortality rate of approximately 1% is still expected. The condition is usually controlled with this procedure, but patients with larger tumors and markedly elevated growth hormone levels are less likely to be controlled.

Radiation therapy may be used in some instances, but the return of the growth hormone levels to normal is not as rapid or as predictable as with surgery. Because some patients also experience hypopituitarism caused by radiation effects on the rest of the gland, some centers may offer radiation therapy as treatment only when surgery fails or is too risky. Pharmacotherapy with one of the somatostatin analogues (e.g., octreotide, lanreotide, and pasireotide) helps to control acromegaly if surgical treatment is unsuccessful or if surgery is contraindicated. A growth hormone receptor–blocking agent, pegvisomant, has also been developed and may be used in conjunction with one of the somatostatin analogues or by itself if the patient cannot tolerate the somatostatin analogue. Pegvisomant is injected daily and acts in the peripheral tissues to inhibit the action of growth hormone. These drugs are also used as an adjunct to radiation therapy during the prolonged period that is sometimes necessary for that treatment to take effect.

The prognosis for untreated patients is guarded, with an increased mortality rate compared with that of the general population. Hypertension, diabetes mellitus, coronary artery disease, congestive heart failure, respiratory disease, and colon cancer are seen with increased frequency in acromegalic patients, and each of these contributes to the increased mortality rate. Although treatment of the patient with acromegaly helps to control many of the other complicating problems and improves the prognosis, the life span of these patients still is shortened, particularly for those with persistent elevated growth hormone levels, cardiomyopathy, or hypertension.

◆ HYPOTHYROIDISM (CRETINISM; MYXEDEMA)

Hypothyroidism is a condition that is characterized by decreased levels of thyroid hormone. When this decrease occurs during infancy, the resulting clinical problem is known as **cretinism.** If an adult has markedly decreased thyroid hormone levels for a prolonged period, then deposition of a glycosaminoglycan ground substance is seen in the

dentlearn.ir

subcutaneous tissues, producing a nonpitting edema. Some call this severe form of hypothyroidism **myxedema;** others use the terms *myxedema* and *hypothyroidism* interchangeably.

Hypothyroidism may be classified as either **primary** or **secondary.** In primary hypothyroidism, the thyroid gland itself is in some way abnormal; in secondary hypothyroidism, the pituitary gland does not produce an adequate amount of thyroid-stimulating hormone (TSH), which is necessary for the appropriate release of thyroid hormone. Secondary hypothyroidism, for example, often develops after radiation therapy for brain tumors, resulting in unavoidable radiation damage to the pituitary gland. Most cases, however, represent the primary form of the disease.

Screening for this disorder is routinely carried out at birth, and the prevalence of congenital hypothyroidism in North America is approximately 1 in 4000 births. Usually, this is due to hypoplasia or agenesis of the thyroid gland. In other areas of the world, hypothyroidism in infancy is usually due to a lack of dietary iodine. In adults, hypothyroidism is often caused by autoimmune destruction of the thyroid gland (known as **Hashimoto thyroiditis**) or iatrogenic factors, such as radioactive iodine therapy or surgery for the treatment of hyperthyroidism. Because thyroid hormone is necessary for normal cellular metabolism, many of the clinical signs and symptoms of hypothyroidism can be related to the decreased metabolic rate in these patients.

Clinical Features

The most common features of hypothyroidism include such signs and symptoms as lethargy, dry and coarse skin, swelling of the face (Fig. 17.23) and extremities, huskiness of the voice, constipation, weakness, and fatigue. The heart rate is usually slowed **(bradycardia).** Reduced body temperature **(hypothermia)** may be present, and the skin often feels cool and dry to the touch. In the infant, these signs may not be readily apparent, and the failure to grow normally may be the first indication of the disease.

With respect to the oral findings, the lips may appear thickened because of the accumulation of glycosaminoglycans. Diffuse enlargement of the tongue occurs for the same reason (Fig. 17.24). If the condition develops during childhood, the teeth may fail to erupt, although tooth formation may not be impaired (Figs. 17.25 and 17.26).

Laboratory Findings

The diagnosis is made by assaying the free thyroxine (T_4) levels. If these levels are low, then TSH levels are measured to determine whether primary or secondary hypothyroidism is present. With primary thyroid disease, TSH levels are elevated. With secondary disease caused by pituitary dysfunction, TSH levels are normal or borderline.

Treatment and Prognosis

Thyroid replacement therapy, usually with levothyroxine, is indicated for confirmed cases of hypothyroidism. The prognosis is generally good for adult patients. If the condition is recognized within a reasonable time, the prognosis is also good for children. If the condition is not identified in a timely manner, however, permanent damage to the CNS may occur, resulting in intellectual disability. For affected children, thyroid hormone replacement therapy often results in a dramatic resolution of the condition (see Fig. 17.23).

• **Fig. 17.23 Hypothyroidism. A,** The facial appearance of this 9-year-old child is due to the accumulation of tissue edema secondary to severe hypothyroidism. **B,** Same patient after 1 year of thyroid hormone replacement therapy. Note the eruption of the maxillary permanent teeth.

◆ HYPERTHYROIDISM (THYROTOXICOSIS; GRAVES DISEASE)

Hyperthyroidism is a condition caused by excess production of thyroid hormone. This excess production results in a state of markedly increased metabolism in the affected patient. Most cases (60%–90%) are due to **Graves disease**, a condition that was initially described in the early nineteenth century. It is thought to be triggered by autoantibodies that are directed against receptors for thyroid-stimulating hormone (TSH) on the surface of the thyroid cells. When the autoantibodies bind to these receptors, they seem to stimulate the thyroid cells to release inappropriate thyroid hormone.

Other causes of hyperthyroidism include hyperplastic thyroid tissue and thyroid tumors, both benign and malignant, which secrete inappropriate thyroid hormone. Similarly, a pituitary adenoma may produce TSH, which can then stimulate the thyroid to secrete excess thyroid hormone.

Clinical Features

Graves disease is five to ten times more common in women than in men and is seen with some frequency. The overall prevalence of this condition is 1.2% in the population of the United States, with almost 2% of the adult female population affected. Graves disease is most commonly diagnosed in patients during the third and fourth decades of life.

Most patients with Graves disease exhibit diffuse thyroid enlargement. Many of the signs and symptoms of hyperthyroidism can be attributed to an increased metabolic rate caused by the excess thyroid hormone. Patients usually complain about nervousness, heart palpitations, heat intolerance, emotional lability, and muscle weakness. The following are often noted during the clinical evaluation:

- Weight loss despite increased appetite
- Tachycardia
- Excessive perspiration
- Widened pulse pressure (increased systolic and decreased diastolic pressures)
- Warm, smooth skin
- Tremor

Ocular involvement (also known as Graves' orbitopathy or thyroid eye disease), which develops in 20%–40% of affected patients, is perhaps the most striking feature of this disease. In the early stages of hyperthyroidism, patients have a characteristic stare with eyelid retraction and lid lag. With some forms of Graves disease, protrusion of the eyes (**exophthalmos** or **proptosis**) develops (Fig. 17.27). This bulging of the eyes is due to an accumulation of glycosaminoglycans in the retro-orbital connective tissues, and patients who smoke cigarettes are more frequently affected. Diplopia (double vision), dry eyes, and compression of the optic nerve may result in significant visual impairment.

Laboratory Findings

The diagnosis of hyperthyroidism is made by assaying free T_4 (thyroxine) and TSH levels in the serum. In affected patients, the T_4 levels should be elevated and the TSH concentration is typically depressed.

dentlearn.ir

• **Fig. 17.27 Hyperthyroidism.** The prominent eyes are characteristic of the exophthalmos associated with Graves disease.

Histopathologic Features

Diffuse enlargement and hypercellularity of the thyroid gland are seen in patients with Graves disease, typically with hyperplastic thyroid epithelium and little apparent colloid production. Lymphocytic infiltration of the glandular parenchyma is also often noted.

Treatment and Prognosis

Initial treatment of hyperthyroidism often consists of one of the beta-blocking drugs, either atenolol or propranolol, which will reduce such uncomfortable symptoms as anxiety, nervousness, excessive sweating, heart palpitations, and tachycardia. The underlying cause of the excess circulating thyroid hormone then must be addressed.

In the United States, radioactive iodine (^{131}I) is the most commonly used form of therapy for adult patients with Graves disease, although it cannot be given if the patient is pregnant. The thyroid gland normally takes up iodine from the bloodstream because this element is a critical component of thyroid hormone. When radioactive iodine is given to a patient with Graves disease, the thyroid gland quickly removes it from the bloodstream and sequesters the radioactive material within the glandular tissue. The radioactivity then destroys the hyperactive thyroid tissue, bringing the thyroid hormone levels back to normal. Most of the radiation is received during the first few weeks because the half-life of ^{131}I is short.

Other techniques include drug therapy with agents that block the normal use of iodine by the thyroid gland, and this form of therapy is initially favored in most European centers. The two drugs that have been widely prescribed in the United States are propylthiouracil (PTU) and methimazole. PTU has been associated with liver toxicity in some patients, and the US Food and Drug Administration has recommended that its use should be limited to specific circumstances, such as methimazole allergy or during the first trimester of pregnancy. Methimazole should not be given to a patient who is in the first trimester of pregnancy because it can cause fetal abnormalities. Sometimes methimazole may be administered chronically in the hope that a remission may be induced. In addition, the thyroid gland, or a significant portion of it, may be removed surgically, thereby reducing thyroid hormone production. Methimazole is often given prior to either surgical removal of the thyroid or treatment with radioactive iodine in order to bring thyroid hormone levels into the normal range.

Drug therapy alone is often unsuccessful in controlling hyperthyroidism, and approximately half of patients treated in this way will relapse. Unfortunately, with radioactive iodine and surgery, the risk of hypothyroidism is relatively great, and thyroid hormone replacement therapy is often needed.

Treatment of thyroid eye disease has been a challenge, with systemic corticosteroid therapy often used to reduce inflammation, and surgical intervention employed to decompress the orbit and restore eyelid function. Neither of these approaches was of significant benefit for patients with severe ocular disease. In 2020, a human monoclonal antibody, teprotumumab, was approved by the U.S. Food and Drug Administration to treat thyroid eye disease. This medication blocks the interaction of thyrotropin receptors and insulin-like growth factor I receptors, which are implicated in causing thyroid eye disease. The treatment results are impressive, although currently a 6-month course of treatment is estimated to cost $200,000.

In a patient with uncontrolled hyperthyroidism, a definite risk exists with respect to an inappropriate release of large amounts of thyroid hormone at one time, resulting in a relatively rare, but very serious, condition called a **thyroid storm.** A thyroid storm may be precipitated by infection, psychologic trauma, or stress. Clinically, patients may have delirium, convulsions, an elevated temperature (up to 106 °F), and tachycardia (sometimes more than 140 beats/minute). Such individuals should be hospitalized immediately because the mortality rate associated with thyroid storm is reported to range from 8% to 25%. The clinician should be aware of the potential for this problem, and patients with hyperthyroidism should ideally have the condition under control before dental treatment.

◆ HYPOPARATHYROIDISM

Calcium levels in extracellular tissues are normally regulated by parathyroid hormone (PTH) (parathormone) in conjunction with vitamin D. If calcium levels drop below a certain point, then the release of PTH is stimulated. The hormone then acts directly on the kidney and the osteoblasts of the bone to restore the calcium to normal levels. In the kidney, calcium reabsorption is promoted, phosphate excretion is enhanced, and the production of vitamin D is stimulated, which increases the absorption of calcium from the gut. Osteoblasts are stimulated to produce a variety of cytokines that subsequently increase osteoclastic differentiation and metabolically activate the osteoclasts to resorb bone, thus liberating calcium.

dentlearn.ir

If a reduced amount of PTH is produced, the relatively rare condition known as **hypoparathyroidism** results. In the United States and Europe, approximately 75% of hypoparathyroidism cases are due to inadvertent surgical removal of the parathyroid glands when the thyroid gland is excised for other reasons, but sometimes it is the result of autoimmune destruction of the parathyroid tissue. Rare syndromes, such as **DiGeorge syndrome** and the **autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome (endocrine-candidiasis syndrome, autoimmune polyglandular syndrome, type 1)** (see page 207), also may be associated with hypoparathyroidism.

Clinical Features

With the loss of parathyroid function, the serum levels of calcium drop, resulting in hypocalcemia. Often the patient with chronic hypoparathyroidism adapts to the presence of hypocalcemia and is asymptomatic unless situations that further reduce the calcium levels are encountered. Such situations include metabolic alkalosis, as seen during hyperventilation, when a state of tetany may become evident.

Chvostek sign is an oral finding of significance, characterized by a twitching of the upper lip when the facial nerve is tapped just below the zygomatic process. A positive response suggests a latent degree of tetany. If the hypoparathyroidism develops early in life during odontogenesis, then a pitting enamel hypoplasia and failure of tooth eruption may occur (Fig. 17.28). The presence of persistent oral candidiasis in a young patient may signal the onset of autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome. Hypoparathyroidism may be only one of several endocrine deficiencies associated with this condition.

Laboratory Findings

PTH can be measured by means of a radioimmunoassay. If serum PTH levels are decreased in conjunction with a decreased serum calcium concentration, elevated serum phosphate level, and normal renal function, then a diagnosis of hypoparathyroidism can be made.

• **Fig. 17.28 Hypoparathyroidism.** Enamel hypoplasia has affected the dentition of this patient, who had hypoparathyroidism while the teeth were forming.

Treatment and Prognosis

Patients with hypoparathyroidism are usually treated with oral doses of an active form of vitamin D, calcitriol (1,25-dihydroxycholecalciferol, vitamin D_3). Additional supplements of dietary calcium are also typically necessary to maintain the proper serum calcium levels. With this regimen, patients can often live a fairly normal life, however problems with renal calculi and soft tissue calcifications frequently develop.

The search has continued for better treatment options for this disorder, focusing on molecular solutions. PTH is a linear protein that is composed of a chain of 84 amino acids, and recently a recombinant PTH composed of all 84 amino acids has been developed. This recombinant PTH has been approved by the FDA for daily subcutaneous injection to treat patients with hypoparathyroidism who have failed standard therapy.

◆ PSEUDOHYPOPARATHYROIDISM (ALBRIGHT HEREDITARY OSTEODYSTROPHY; ACRODYSOSTOSIS)

The rare condition known as **pseudohypoparathyroidism** represents at least two broad disorders in which normal parathyroid hormone (PTH) is present in adequate amounts but the biochemical pathways responsible for activating the target cells are not functioning properly. The clinical result is a patient who appears to have hypoparathyroidism.

In the case of pseudohypoparathyroidism type I, two subcategories have been defined. For type Ia, a molecular defect of a specific intracellular binding protein known as $G_s\alpha$ seems to prevent the formation of cyclic adenosine monophosphate (cAMP), a critical component in the activation of cell metabolism. Because other hormones also require binding with $G_s\alpha$ to carry out their functions, patients have multiple problems with other endocrine organs and functions. This condition is usually inherited as an autosomal dominant trait.

With respect to pseudohypoparathyroidism type Ib, the problem is thought to be caused by defective receptors for the PTH on the surface of the target cells (the proximal renal tubules). For this reason, no other endocrine tissues or functions are affected. An autosomal dominant mode of inheritance has been suggested for a few families affected by type Ib pseudohypoparathyroidism, but most cases are apparently sporadic.

Pseudohypoparathyroidism type II is characterized by the induction of cAMP by PTH in the target cells; however, a functional response by the cells is not invoked. All of the reported cases of this form of the disease appear to be sporadic.

dentlearn.ir

Clinical Features

Pseudohypoparathyroidism most commonly appears as type Ia disease. Patients affected by pseudohypoparathyroidism, type Ia, have a characteristic array of features that includes mild intellectual disability, early-onset obesity, round face, short neck, and markedly short stature. Midfacial hypoplasia is also commonly observed. The metacarpals and metatarsals are usually shortened, and the fingers appear short and thick. Subcutaneous calcifications (**osteoma cutis**) may be identified in some patients. Other endocrine abnormalities that are typically encountered include hypogonadism and hypothyroidism.

Patients with type Ib and II disease clinically appear normal, aside from their symptoms of hypocalcemia.

Dental manifestations of pseudohypoparathyroidism include generalized enamel hypoplasia, widened pulp chambers with intrapulpal calcifications, oligodontia, delayed eruption, shortened roots, and blunting of the apices of the teeth. The pulpal calcifications are often described as "dagger" shaped. A Class III occlusal relation is frequently identified in these patients, possibly related to maxillary hypoplasia.

The diagnosis of pseudohypoparathyroidism is made based on elevated serum levels of PTH seen concurrently with hypocalcemia, hyperphosphatemia, and otherwise normal renal function. More sophisticated studies are necessary to delineate the various subtypes.

Treatment and Prognosis

Pseudohypoparathyroidism is managed by the administration of vitamin D and calcium. The serum calcium levels and urinary calcium excretion are carefully monitored. Because of individual patient differences, the medication may need to be carefully adjusted; however, the prognosis is considered to be good. Annual or semiannual routine dental examinations, particularly during childhood, are usually advised for these patients.

◆ HYPERPARATHYROIDISM

Excess production of parathyroid hormone (PTH) results in the condition known as **hyperparathyroidism.** PTH normally is produced by the parathyroid glands in response to a decrease in serum calcium levels.

Primary hyperparathyroidism is the uncontrolled production of PTH, usually as a result of a parathyroid adenoma (80%–90% of cases) or parathyroid hyperplasia (10%–15% of cases). Rarely (approximately 1% of cases), a parathyroid carcinoma may be the cause of primary hyperparathyroidism. Infrequently this endocrine disturbance is caused by any one of several inherited syndromes, including **multiple endocrine neoplasia type 1** or **type 2a,** or **hyperparathyroidism–jaw tumor syndrome.** In the latter condition, affected patients develop multiple jaw lesions that histopathologically are consistent with central ossifying fibroma (see page 652). In most cases, affected patients develop a single parathyroid adenoma that produces excess parathyroid hormone. There also appears to be an increased risk for these patients to develop parathyroid carcinoma.

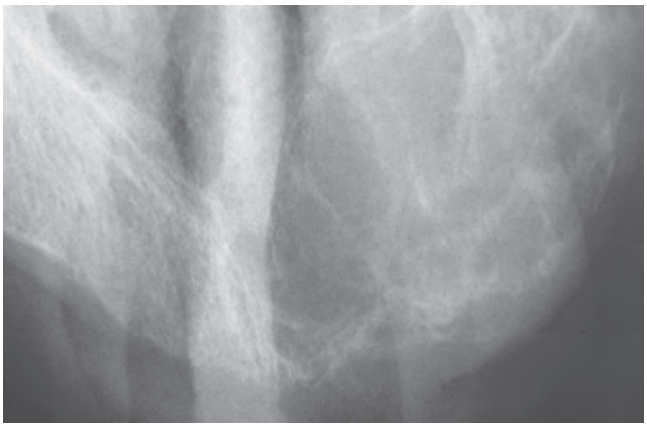
Secondary hyperparathyroidism develops when PTH is continuously produced in response to chronic low levels of serum calcium, a situation usually associated with chronic renal disease. The kidney processes vitamin D, which is necessary for calcium absorption from the gut. Therefore, in a patient with chronic renal disease, active vitamin D is not produced and less calcium is absorbed from the gut, resulting in lowered serum calcium levels.

Clinical and Radiographic Features

Most patients with primary hyperparathyroidism are older than 60 years of age. Women have this condition two to four times more often than men do. In developed countries, the condition typically is identified on routine serologic testing, and the majority of patients are relatively asymptomatic.

Patients with the classic triad of signs and symptoms of hyperparathyroidism are described as having "stones, bones, and abdominal groans." Affected individuals are more likely to present with these signs and symptoms in economically less developed countries where serologic evaluation is not done on a routine basis.

"Stones" refers to the fact that these patients, particularly those with primary hyperparathyroidism, have a marked tendency to develop renal calculi (kidney stones, nephrolithiasis) because of the elevated serum calcium levels. Metastatic calcifications are also seen, frequently involving other soft tissues, such as blood vessel walls, subcutaneous soft tissues, the sclera, the dura, and the regions around the joints.



"Bones" refers to a variety of osseous changes that may occur in conjunction with hyperparathyroidism. One of the first clinical signs of this disease is seen radiographically as subperiosteal resorption of the phalanges of the index and middle fingers. Generalized loss of the lamina dura surrounding the roots of the teeth is also seen as an early manifestation of the condition (Fig. 17.29). Alterations in trabecular pattern characteristically develop next. A decrease in trabecular density and blurring of the normal trabecular pattern occur; often a "ground glass" appearance results.

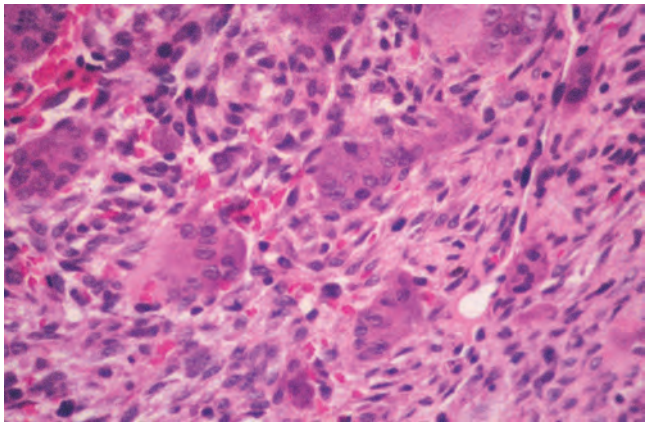
With persistent disease, other osseous lesions develop, such as the so-called **brown tumor** of hyperparathyroidism. This lesion derives its name from the color of the tissue specimen, which is usually a dark red-brown because of the abundant hemorrhage and hemosiderin deposition within the tumor. These lesions appear radiographically as well-demarcated unilocular or multilocular radiolucencies (Fig. 17.30). They commonly affect the mandible, clavicles, ribs, and pelvis. They may be solitary but are often multiple, and long-standing lesions may produce significant cortical expansion. Typically, the other osseous changes are observable if brown tumors are present. The most severe skeletal manifestation of chronic hyperparathyroidism has been called **osteitis fibrosa cystica,** a condition that

dentlearn.ir

• **Fig. 17.29 Hyperparathyroidism.** This periapical radiograph reveals the "ground glass" appearance of the trabeculae and loss of lamina dura in a patient with secondary hyperparathyroidism. (Courtesy of Dr. Randy Anderson.)

• **Fig. 17.30 Hyperparathyroidism.** This occlusal radiograph of the edentulous maxillary anterior region shows a multilocular radiolucency characteristic of a brown tumor of primary hyperparathyroidism. (Courtesy of Dr. Brian Blocher.)

develops from the central degeneration and fibrosis of long-standing brown tumors. In patients with secondary hyperparathyroidism caused by end-stage renal disease (**renal osteodystrophy; chronic kidney disease—mineral and bone disorder**), striking enlargement of the jaws has been known to occur (Fig. 17.31) and produce a "ground-glass" radiographic pattern (see Fig. 17.29).

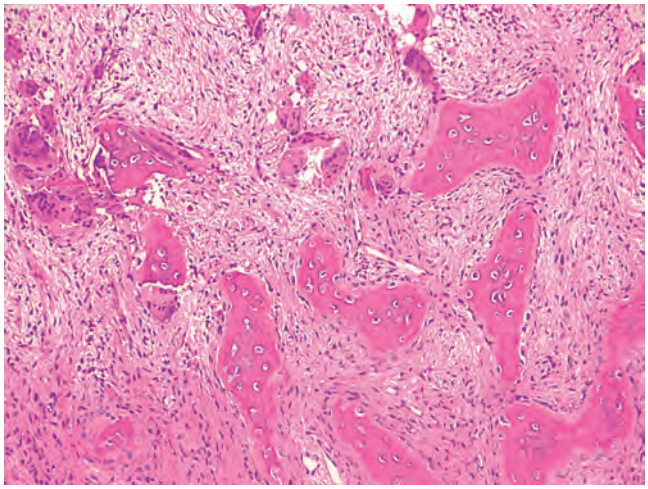


"Abdominal groans" refers to the tendency for the development of duodenal ulcers. In addition, changes in mental status are often seen, ranging from lethargy and weakness to confusion or dementia.

Histopathologic Features

The brown tumor of hyperparathyroidism is histopathologically identical to the **central giant cell granuloma** of the jaws, a benign tumorlike lesion that usually affects teenagers and young adults (see page 631). Both lesions are characterized by a proliferation of exceedingly vascular granulation

• **Fig. 17.31 Hyperparathyroidism.** Palatal enlargement is characteristic of the renal osteodystrophy associated with secondary hyperparathyroidism.



• **Fig. 17.32 Hyperparathyroidism.** This high-power photomicrograph of a brown tumor of hyperparathyroidism shows scattered multinucleated giant cells within a vascular and proliferative fibroblastic background.

tissue, which serves as a background for numerous multinucleated osteoclast-type giant cells (Fig. 17.32). Some lesions may also show a proliferative response characterized by a parallel arrangement of spicules of woven bone set in a cellular fibroblastic background with variable numbers of multinucleated giant cells (Fig. 17.33). This pattern is often associated with secondary hyperparathyroidism related to chronic renal disease (renal osteodystrophy).

Treatment and Prognosis

In **primary hyperparathyroidism,** the hyperplastic parathyroid tissue or the functional tumor must be removed surgically to reduce PTH levels to normal. Localization of the parathyroid adenoma is often facilitated by a sestamibi scan, which is a nuclear medicine technique using a technetium 99-labeled small protein that is preferentially taken up by the tumor. Ultrasonography is another technique that is often used to identify hyperplastic parathyroid glands or parathyroid adenomas. Such lesions are frequently removed

dentlearn.ir

• **Fig. 17.33 Hyperparathyroidism.** This medium-power photomicrograph shows trabeculae of cellular woven bone and clusters of multinucleated giant cells within a background of cellular fibrous connective tissue. These features are characteristic of tissue changes seen in renal osteodystrophy.

by a minimally invasive surgical technique, and intraoperative assessment of the adequacy of excision can be determined by noting a drop in parathormone levels within 10 minutes of removing the adenoma.

Secondary hyperparathyroidism may evolve to produce signs and symptoms related to renal calculi or renal osteodystrophy. Restriction of dietary phosphate, use of phosphate-binding agents, and pharmacologic treatment with an active vitamin D metabolite (e.g., calcitriol) and a calcimimetic agent, such as cinacalcet, may avert problems. Cinacalcet sensitizes the calcium receptors of the parathyroid cells to extracellular calcium, causing the cells to reduce their output of parathormone. Exposure to aluminum salts, which inhibit bone mineralization, should be eliminated also. Patients who do not respond to medical therapy may require parathyroidectomy. Renal transplantation may restore the normal physiologic processing of vitamin D, as well as phosphorus and calcium reabsorption and excretion; however, this does not occur in every case.

◆ HYPERCORTISOLISM (CUSHING SYNDROME)

Hypercortisolism is a clinical condition that results from a sustained increase in glucocorticoid levels. In most cases this increase is due to corticosteroid therapy that is prescribed for other medical purposes. The increase is less commonly caused by an endogenous source, such as production of adrenocorticotropic hormone (ACTH) by an adrenal tumor or pituitary adenoma. If a pituitary adenoma is responsible, then the term **Cushing disease** is applied. This condition is rather rare and usually affects young adult women.

• **Fig. 17.34 Cushing Syndrome.** The rounded facial features ("moon facies") of this patient are due to the abnormal deposition of fat, which is induced by excess corticosteroid hormone. (Courtesy of Dr. George Blozis.)

Clinical Features

The signs of Cushing syndrome usually develop slowly. The most consistent clinical observation is weight gain, particularly in the central areas of the body. The accumulation of fat in the dorsocervical spine region results in a "buffalo hump" appearance; fatty tissue deposition in the facial area results in the characteristic rounded facial appearance known as *moon facies* (Fig. 17.34). Other common findings include the following:

- Red-purple abdominal striae
- Hirsutism
- Poor healing
- Osteoporosis
- Hypertension
- Mood changes (particularly depression)
- Hyperglycemia with thirst and polyuria
- Muscle wasting with weakness

Diagnosis

If the patient has been receiving large amounts of corticosteroids (greater than the equivalent of 20 mg of prednisone) on a daily basis for several months, then the diagnosis is rather obvious, given the classic signs and symptoms described earlier. The diagnosis may be more difficult to establish in

dentlearn.ir

patients with a functioning adrenal cortical tumor or an ACTH-secreting pituitary adenoma. Evaluation of these patients should include the measurement of free cortisol in the urine and an assay of the effect of dexamethasone (a potent artificial corticosteroid) on the serum ACTH and cortisol levels. In an unaffected patient, the levels of free cortisol should be within normal limits, and the administration of an exogenous corticosteroid, such as dexamethasone, should suppress the normal level of ACTH, with a concomitant decrease in the cortisol levels. Because functioning tumors do not respond to normal feedback mechanisms, the anticipated decreases in ACTH and cortisol would not be seen in a patient with such a tumor.

Treatment and Prognosis

The clinician should be aware of the signs and symptoms of hypercortisolism to refer affected patients for appropriate endocrinologic evaluation and diagnosis. Once the diagnosis is established and the cause is determined to be an adrenal or pituitary tumor, surgical removal of the lesion is the treatment of choice. Radiation therapy also may be effective, particularly in younger patients, however the reduction in ACTH production by the tumor may require several months to reach normal levels. For patients who are treated with radiation therapy or who have unresectable tumors, drugs that inhibit cortisol synthesis (such as, ketoconazole or metyrapone) may be used to help control the excess production of cortisol.

Most cases of hypercortisolism, however, are caused by systemic corticosteroid therapy that is given for a variety of immunologic reasons, including treatment of autoimmune diseases and allogeneic transplant recipients. Certain strategies, such as the use of corticosteroid-sparing agents or alternate-day therapy, may minimize the corticosteroid dose needed. The goal should be for patients to use the lowest dose possible to manage immunologic disease.

In normal situations, cortisol is critical to the function of the body, particularly in dealing with stress. As the hormone is metabolized and serum levels drop, feedback to the pituitary gland signals it to produce ACTH, which stimulates the adrenal gland to produce additional cortisol. Unfortunately, therapeutic corticosteroids suppress the production of ACTH by the pituitary gland to the extent that the pituitary gland may not be able to produce ACTH in response to stress, and an acute episode of hypoadrenocorticism *(addisonian crisis)* may be precipitated. Therefore, the clinician must be aware of the potential side effects of chronic high-dose corticosteroid use and must be able to adapt the treatment of the patient accordingly. For stressful dental and surgical procedures especially, it is often necessary to increase the corticosteroid dose because of the greater need of the body for cortisol. Consultation with the physician who is managing the corticosteroid therapy is advised to determine to what extent the dose should be adjusted.

◆ ADDISON DISEASE (HYPOADRENOCORTICISM)

Insufficient production of adrenal corticosteroid hormones caused by the destruction of the adrenal cortex results in the condition known as **Addison disease**, or **primary hypoadrenocorticism.** The incidence of new cases diagnosed in the Western hemisphere is approximately 6 per million population per year, while the prevalence is about 140 cases per million people. The causes are diverse and include the following:

- Autoimmune destruction (most common cause in Western societies)
- Infections (e.g., tuberculosis and deep fungal diseases, particularly in patients with acquired immunodeficiency syndrome [AIDS])
- Rarely, metastatic tumors, sarcoidosis, hemochromatosis, or amyloidosis

If the pituitary gland is not functioning properly, **secondary hypoadrenocorticism** may develop because of decreased production of ACTH, the hormone responsible for maintaining normal levels of serum cortisol.

Clinical Features

The clinical features of hypoadrenocorticism do not actually begin to appear until at least 90% of the glandular tissue has been destroyed. With gradual destruction of the adrenal cortex, an insidious onset of fatigue, irritability, depression, weakness, and hypotension is noted over a period of months. A generalized hyperpigmentation of the skin occurs, classically described as *bronzing*. The hyperpigmentation is generally more prominent on sun-exposed skin and over pressure points, such as the elbows and knees; it is caused by increased levels of beta-lipotropin or ACTH, each of which can stimulate melanocytes. The patient usually complains of gastrointestinal upset with anorexia, nausea, vomiting, diarrhea, weight loss, and a peculiar craving for salt, due to hyponatremia caused by lack of the mineralocorticoid, aldosterone. When hypoadrenocorticism is accompanied by hypoparathyroidism and mucocutaneous candidiasis, the possibility of autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome should be considered (see page 207).

The oral manifestations include diffuse or patchy, brown, macular pigmentation of the oral mucosa (particularly the lips, tongue, palate, and attached gingiva) caused by excess melanin production (Fig. 17.35). Often the oral mucosal changes are the first manifestation of the disease, with the skin hyperpigmentation occurring afterward. Sometimes the oral hypermelanosis may be difficult to distinguish from physiologic racial pigmentation, but a history of a recent onset of oral pigmentation should suggest the possibility of Addison disease.

dentlearn.ir

• **Fig. 17.35 Addison Disease.** Diffuse pigmentation of the maxillary facial gingiva in a patient with Addison disease. (Courtesy of Dr. John Kalmar.)

Laboratory Findings

The diagnosis of hypoadrenocorticism is confirmed by a rapid ACTH stimulation test and measurement of serum cortisol levels and plasma ACTH levels. If serum cortisol levels are below 16–18 μg/dL, then the patient has adrenal insufficiency. In primary hypoadrenocorticism, the plasma ACTH levels are high (>100 ng/L). In secondary hypoadrenocorticism, the levels are normal (9–52 ng/L) or low, as would be expected because the condition results from decreased ACTH production by the pituitary gland.

Treatment and Prognosis

Addison disease is managed with replacement therapy, including both a glucocorticoid (such as, hydrocortisone) and mineralocorticoid (such as, fludrocortisone). The physiologic dose of glucocorticoid is considered to be approximately 15–25 mg of hydrocortisone or its equivalent per day, usually given in divided doses. Because the body's need for corticosteroid hormones increases during stressful events, the patient must take this into account and increase the dose accordingly. This adjustment is generally not required for dental procedures performed using local anesthesia and lasting less than 1 hour, but an increased dose may be necessary for certain dental and oral surgical procedures that are more lengthy or are done under general anesthesia.

Before the availability of corticosteroids, the prognosis for patients with hypoadrenocorticism was poor, with most patients surviving less than 2 years. Even today, if the condition is not recognized promptly, death may result in a relatively short period of time. With proper diagnosis and management, most patients with hypoadrenocorticism can expect to have a normal life span, although a recent population-based study suggested an increased mortality rate related to malignancy and cardiovascular disease.

◆ DIABETES MELLITUS

Diabetes mellitus is a common disorder of carbohydrate metabolism that is thought to have several causes, although the basic problem is one of either decreased production of insulin or tissue resistance to the effects of insulin. The net result of this abnormal state is an increase in the blood glucose level **(hyperglycemia).**

Diabetes mellitus is usually divided into two presentations:

1. Type I—characterized by complete, or nearly complete, lack of insulin production
2. Type II—characterized by inadequate insulin production or resistance of target tissues to the effects of insulin

Type I diabetes mellitus was formerly known as insulin-dependent diabetes mellitus or juvenile-onset diabetes, but these terms are not considered to be accurate. Type II diabetics often require insulin injections in order to manage their disease, and from 5% to 10% of type 1 diabetics develop their disease after 30 years of age. Patients with type 1 diabetes mellitus usually exhibit severe hyperglycemia and ketoacidosis without treatment, and they require exogenous insulin injections to survive.

Type II diabetes mellitus is sometimes more difficult to diagnose. It usually occurs in older, obese adults, but it may be seen in obese adolescents as well. For this reason, the term "adult-onset diabetes" was abandoned. Although hyperglycemia is present, ketoacidosis rarely develops. Furthermore, patients can produce some endogenous insulin. Certain patients may require insulin to help control their disease; the insulin injections, however, are usually not necessary for the patient's survival.

With respect to epidemiology, in the United States diabetes mellitus affects approximately 7%–11% of the population, or slightly more than 30 million people, although approximately 8 million of these cases remain undiagnosed. More than 1.5 million new cases are identified each year in the United States. Of these affected patients, most have type II diabetes; only 5%–10% have type I.

Diabetes is an important disease when we consider the many complications associated with it and the economic effect it has on society. One of the main complications of diabetes is **peripheral vascular disease,** a problem that results in kidney failure, as well as ischemia and gangrenous involvement of the limbs. By some estimates, 25% of all new cases of kidney failure occur in diabetic patients. Thus diabetes is the leading cause of kidney failure in the United States. Each year more than 50,000 amputations are performed for the gangrenous complications of diabetes. This disease is the leading cause of lower limb amputations in the United States. Retinal involvement often results in blindness; thus the leading cause of new cases of blindness in working-age adults in the United States is diabetes, with more than 12,000 people affected annually. Complications because of diabetes are estimated to contribute to the deaths of more than 200,000 Americans each year.

The cause of diabetes mellitus is essentially unknown, although most cases of type I diabetes appear to be caused by autoimmune destruction of the pancreatic islet cells, and this immunologic attack may be precipitated by a viral infection in a genetically susceptible individual. Type II diabetes does not appear to have an autoimmune cause,

dentlearn.ir

however, because no destruction of the islet cells is seen microscopically. Instead, genetic abnormalities have been detected in patients with certain types of type II diabetes, which may explain why the condition occurs so often in families. If one parent is affected by type II diabetes, then the chances of a child having the disorder is about 40%. Similarly, if one identical twin has type II diabetes, then the chances are 90% that the disease will also develop in the other twin.

Clinical Features

Although a complete review of the pathophysiology of diabetes mellitus is beyond the scope of this text, the clinical signs and symptoms of a patient with this disease are easier to understand with some basic knowledge of the process. The hormone insulin, produced by the beta cells of the pancreatic islets of Langerhans, is necessary for the uptake of glucose by the cells of the body. When insulin binds to its specific cell surface receptor, a resulting cascade of intracellular molecular events causes the recruitment of intracellular glucose-binding proteins, which facilitate the uptake of glucose by each cell.

Type I Diabetes Mellitus

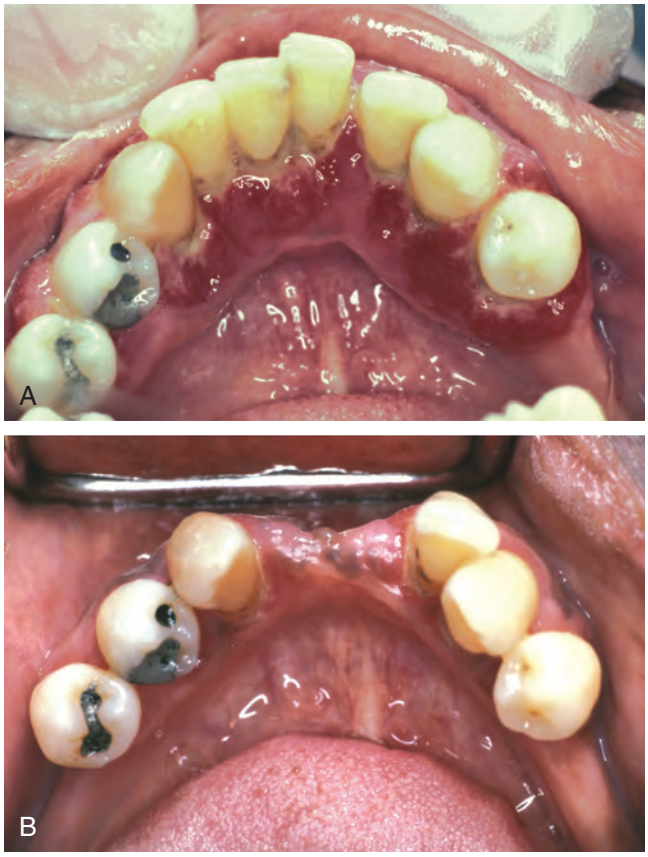
Because patients with type I diabetes have a deficiency in the amount of insulin, the body's cells cannot absorb glucose and it remains in the blood. Normal blood glucose levels are between 70 and 120 mg/dL; in diabetic patients, these levels are often between 200 and 400 mg/dL. Above 300 mg/dL, the kidneys can no longer reabsorb the glucose; therefore, it spills over into the urine. Because glucose is the main source of energy for the body, and because none of this energy can be used because glucose cannot be absorbed, the patient feels tired and lethargic. The body begins to use other energy sources, such as fat and protein, resulting in the production of ketones as a by-product of those energy consumption pathways. The patient often loses weight, despite increased food intake **(polyphagia).** With the hyperglycemia, the osmolarity of the blood and urine increases. The increased osmolarity results in frequent urination **(polyuria)** and thirst, which leads to increased water intake **(polydipsia).** Clinically, most patients with type I diabetes are younger (average age at diagnosis being 14 years), and they have a thin body habitus.

Type II Diabetes Mellitus

By contrast, patients with type II diabetes are usually older than 40 years of age at diagnosis, and 80%–90% of them are obese. In this situation, it is thought that a decrease in the number of insulin receptors or abnormal post-binding molecular events related to glucose uptake results in glucose not being absorbed by the body's cells. Thus patients are said to show "insulin resistance" because serum insulin levels are usually within normal limits or even elevated. If the hyperglycemia is taken into account, however, the amount of circulating insulin is typically not as much as would be present in a normal person with a similar level of blood glucose. Therefore, many of these patients are described as having a relative lack of insulin.

The symptoms associated with type II diabetes are much more subtle in comparison to those seen with type I. The first sign of type II diabetes is often detected with routine hematologic examination rather than any specific patient complaint. Ketoacidosis is rarely seen in patients with type II diabetes. Nevertheless, many of the other complications of diabetes are still associated with this form of the disease.

Monitoring of either type of diabetes includes not only blood glucose measurement (showing the immediate levels of blood glucose), but also assessment of the percentage of glycated hemoglobin, which is a reflection of the overall control of blood glucose levels over the past 2–3 months. Glycated hemoglobin, commonly known as HbA_{1c}, develops with continuous exposure to blood glucose. Because erythrocytes (which contain hemoglobin) survive for about 120 days in the bloodstream, nonenzymatic glycation that occurs during the 2–3-month period immediately prior to the blood draw correlates with the average concentration of blood glucose during that time. For example, an HbA_{1c} reading of 6% would be consistent with an average blood glucose level of 126 mg/dL for the preceding 2–3 months.



Complications

Many complications of diabetes mellitus are directly related to the **microangiopathy** caused by the disease. The microangiopathy results in occlusion of the small blood vessels, producing peripheral vascular disease. The resultant decrease in tissue perfusion results in ischemia. The ischemia predisposes the patient to infection, particularly severe infections such as gangrene. Another contributing factor is the impairment of neutrophil function, particularly neutrophil chemotaxis.

Amputation of the lower extremity often is necessary because of the lack of tissue perfusion and the patient's inability to cope with infection. Similar vascular occlusion may affect the coronary arteries (which places the patient at risk for myocardial infarction) or the carotid arteries and their branches (predisposing the patient to cerebrovascular accident, or stroke). When microvascular occlusion affects the retinal vessels, blindness typically results. Kidney failure is the outcome of renal blood vessel involvement. If the ketoacidosis is not corrected in type I diabetes, the patient may lapse into a diabetic coma.

The oral manifestations of diabetes mellitus are generally limited to patients with type I diabetes. Problems include periodontal disease, which occurs more frequently and progresses more rapidly than in normal patients. Healing after surgery may be delayed, and the likelihood of infection is probably increased. Diffuse, nontender, bilateral enlargement of the parotid glands, called **diabetic sialadenosis** (see page 476), may be seen in patients with either form of diabetes. In uncontrolled or poorly controlled diabetic patients, a striking enlargement and erythema of the attached gingiva has been described (Fig. 17.36). In addition, these patients appear to be more susceptible to **oral candidiasis** in its various clinical forms (see page 201). Erythematous

dentlearn.ir

• **Fig. 17.36 Diabetes Mellitus. A,** This diffuse, erythematous enlargement of the gingival tissues developed in a diabetic patient who discontinued taking her insulin. **B,** The gingival tissues have greatly improved after reinstitution of regular insulin injections. Several incisors were extracted because of severe periodontal bone loss.

candidiasis, which appears as central papillary atrophy of the dorsal tongue papillae, is reported in up to 30% of these patients. **Mucormycosis** (see page 219) may occur in patients with poorly controlled type I diabetes. Some investigators have identified an increased prevalence of **benign migratory glossitis** (see page 784) in patients with type I diabetes; however, others have not been able to confirm this finding. **Xerostomia,** a subjective feeling of dryness of the oral mucosa, has been reported as a complaint in one-third of diabetic patients. Unfortunately, studies that attempt to confirm an actual decrease in salivary flow rate in diabetic patients have produced conflicting results. Some studies show a decrease in salivary flow; some, no difference from normal; and some, an increased salivary flow rate.

Treatment and Prognosis

For patients with type II diabetes, dietary modification coupled with exercise may be the only treatment necessary, with the goal being weight loss. The dietary and lifestyle changes may need to be coupled with one or more oral hypoglycemic agents. These drugs are designed to affect different pathophysiologic aspects of the disease. For example, secretagogues increase the insulin supply. These include the second-generation sulfonylurea medications, such as glipizide or glyburide, and nonsulfonylureas, such as mitiglinide and nateglinide. Metformin is a biguanide that increases glucose utilization and decreases insulin resistance and hepatic glucose production. Thiazolidinediones, such as rosiglitazone and pioglitazone, also reduce insulin resistance. Acarbose and miglitol are α-glucosidase inhibitors that reduce the absorption of glucose from the gastrointestinal tract by inhibiting enzymatic degradation of more complex sugars. Sodium-glucose cotransporter 2 inhibitors, including canagliflozin and dapagliflozin, increase glucose excretion from the kidneys. Newer agents also include the glucagon-like peptide 1 (GLP-1) receptor agonists, such as dulaglutide, semaglutide, and liraglutide, which are given parenterally and may contribute to weight loss. If these modalities do not control the blood glucose levels, then treatment with insulin is necessary.

For patients with type I diabetes, injections of insulin are required to control blood glucose levels. Different types of insulin are marketed, each type having different degrees of duration and times of peak activity. Insulin was previously extracted primarily from beef and pork pancreata. In some patients, however, antibodies developed to this foreign protein and rendered the insulin useless. To overcome this problem, pharmaceutical companies have developed brands of insulin that have the molecular structure of human insulin. Laboratories produce this human insulin with genetically engineered bacteria using recombinant DNA technology.

The patient's schedule of insulin injections must be carefully structured and monitored to provide optimal control of blood glucose levels. This schedule is carefully formulated by the patient's physician and takes into account such factors as the patient's activity level and the severity of the insulin deficiency. It is imperative that adequate dietary carbohydrates be ingested after the administration of the insulin; otherwise, a condition known as **insulin shock** may occur. If carbohydrates are not consumed after an insulin injection, then the blood glucose levels may fall to dangerously low levels. The brain is virtually dependent on blood glucose as its energy source. If the blood glucose level drops below 40 mg/dL, the patient may go into shock. This condition can be treated by administration of sublingual dextrose paste, IV infusion of a dextrose solution, or injection of glucagon.

In summary, diabetes mellitus is a common, complex medical problem with many complications. The prognosis is guarded. Studies suggest that strict control of blood glucose levels results in a slowing of the development of the late complications of type I diabetes (e.g., blindness, kidney damage, and neuropathy) and reduces the frequency of these complications. Health care practitioners should be aware of the problems these patients may have and should be prepared to deal with them. Consultation with the patient's physician may be necessary, particularly for patients with type I diabetes that show poor blood glucose control, have active infections, or require extensive oral surgical procedures.

dentlearn.ir

◆ HYPOPHOSPHATASIA

Hypophosphatasia is a rare metabolic bone disease that is characterized by a deficiency of tissue-nonspecific alkaline phosphatase. Approximately 300 distinct mutations of the gene responsible for alkaline phosphatase production have been described. One of the first presenting signs of hypophosphatasia may be the premature loss of the primary teeth, presumably caused by a lack of cementum on the root surfaces. In the homozygous autosomal recessive form, there are rather severe manifestations, and many of these patients are identified in infancy. The milder forms of the disease are inherited in an autosomal dominant or recessive fashion, appearing in childhood or even adulthood, with variable degrees of expression. Generally, the younger the age of onset, the more severe the expression of the disease. The common factors in all types include the following:

- Reduced levels of the bone, liver, and kidney isozyme of alkaline phosphatase
- Increased levels of blood and urinary phosphoethanolamine
- Bone abnormalities that resemble rickets

Most authorities believe that the decreased alkaline phosphatase levels probably are responsible for the clinically observed abnormalities. Alkaline phosphatase is thought to play a role in the production of bone, but its precise mechanism of action is unknown.

Clinical and Radiographic Features

Six types of hypophosphatasia are now recognized, depending on the severity and the age of onset of the symptoms:

1. Perinatal lethal
2. Perinatal benign
3. Infantile
4. Childhood
5. Adult
6. Odontohypophosphatasia

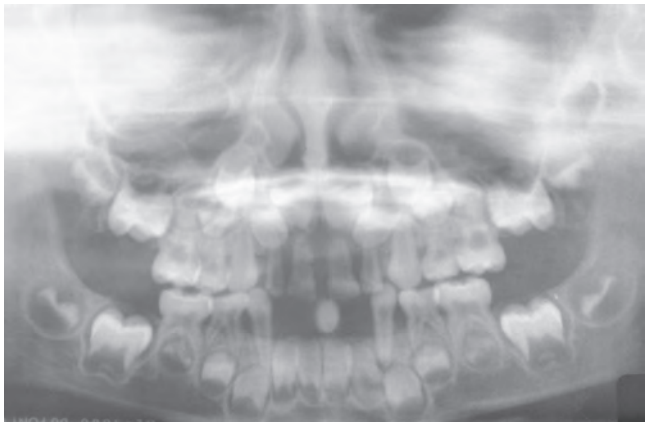
Perinatal Lethal Hypophosphatasia

The **perinatal lethal** form has the most severe manifestations. It is usually diagnosed at birth, and the infant rarely survives for more than a few hours. Death is due to respiratory failure. Marked hypocalcification of the skeletal structures is observed.

Perinatal Benign Hypophosphatasia

The **perinatal benign** form of hypophosphatasia appears similar to the lethal form, but these infants have a clinical course similar to infantile hypophosphatasia. Some investigators have noted that skeletal calcification may be detected in some of these fetuses during the third trimester of pregnancy, in contrast to the lethal form.

Infantile Hypophosphatasia



Babies affected by **infantile** hypophosphatasia may appear normal up to 6 months of age; after this time, they begin to show a failure to grow. Vomiting and hypotonia may develop as well. Skeletal malformations that suggest rickets are typically observed; these malformations include shortened, bowed limbs. Deformities of the ribs predispose these patients to pneumonia, and skull deformities cause increased intracranial pressure. Nephrocalcinosis and nephrolithiasis also produce problems for these infants. Radiographs show a markedly reduced degree of ossification with a preponderance of hypomineralized osteoid. If these infants survive, premature shedding of the deciduous teeth is often seen.

Childhood Hypophosphatasia

The **childhood** form is usually detected at a later age and has a wide range of clinical expression. One of the more consistent features is the premature loss of the primary teeth without evidence of a significant inflammatory response (Figs. 17.37 and 17.38). The deciduous incisor teeth are usually affected first and may be the only teeth involved. In some patients, this may be the only expression of the disease. The teeth may show enlarged pulp chambers in some instances, and a significant degree of alveolar bone loss may be seen. More severely affected patients may have open fontanelles with premature fusion of cranial sutures. This

• **Fig. 17.37 Hypophosphatasia.** Premature loss of the mandibular anterior teeth. (Courtesy of Dr. Jackie Banahan.)

• **Fig. 17.38 Hypophosphatasia.** This panoramic radiograph shows the loss of the mandibular anterior teeth. (Courtesy of Dr. Jackie Banahan.)

dentlearn.ir

early fusion occasionally leads to increased intracranial pressure and subsequent brain damage. Affected patients typically have a short stature, bowed legs, and a waddling gait. The development of motor skills is often delayed.

Radiographically, the skull of more severely affected individuals may show uniformly spaced, poorly defined, small radiolucencies, a pattern that has been described as resembling "beaten copper." This appearance may be the result of areas of thinning of the inner cortical plate produced by the cerebral gyri.

Adult Hypophosphatasia

The **adult** form is typically mild. Patients often have a history of premature loss of their primary or permanent dentition, and many of these patients are edentulous. Stress fractures that involve the metatarsal bones of the feet may be a presenting sign of the condition, or an increased number of fractures associated with relatively minor trauma may alert the clinician to this disorder.

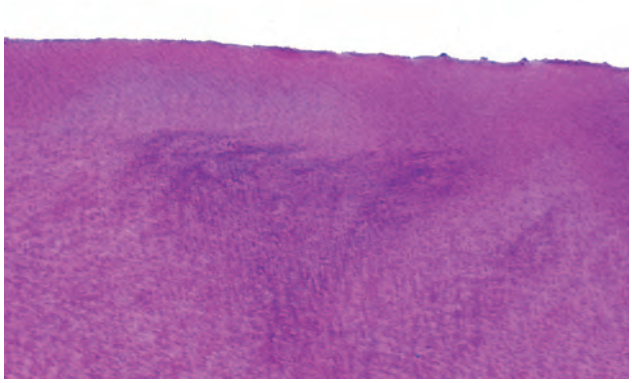
Odontohypophosphatasia

This form of hypophosphatasia is perhaps the most controversial. Affected patients present with premature loss of the incisor teeth as the only clinical sign of disease, although serologic studies will be consistent with hypophosphatasia. Some investigators have suggested that this may simply represent a mild expression of the disorder.

Diagnosis

The diagnosis of hypophosphatasia is based on the clinical manifestations and the finding of decreased levels of serum alkaline phosphatase and increased amounts of phosphoethanolamine in both the urine and the blood. Interestingly, as some patients grow older, serum alkaline phosphatase levels may approach normal.

Histopathologic Features



The histopathologic evaluation of bone sampled from a patient affected with the **infantile** form of hypophosphatasia shows abundant production of poorly mineralized osteoid. In the **childhood** or **adult** form, the bone may appear relatively normal or it may show an increased amount of woven bone, which is a less mature form of osseous tissue.

The histopathologic examination of either a primary or permanent tooth that has been exfoliated from an affected patient often shows an absence or a marked reduction of cementum that covers the root's surface (Fig. 17.39). This reduced amount of cementum is thought to predispose to tooth loss because of the inability of periodontal ligament fibers to attach to the tooth and to maintain it in its normal position.

Treatment and Prognosis

In the past, the treatment of hypophosphatasia essentially consisted of symptomatic care because the lack of alkaline phosphatase could not be corrected. Attempts to treat this condition by infusing alkaline phosphatase were unsuccessful, presumably because the enzyme functions within the cell rather than in the extracellular environment. In 2015, however, the U.S. Food and Drug Administration approved a recombinant enzyme known as asfotase alfa for treatment of perinatal, infantile, and childhood hypophosphatasia. The medication is comprised of three components: the catalytic portion of tissue nonspecific alkaline phosphatase; the Fc portion of IgG; and a molecular configuration that increases binding to hydroxyapatite, an important calcium-containing component of bone. The results of this treatment are impressive, either halting or reversing most of the manifestations of hypophosphatasia; nevertheless, the treatment is quite expensive.

For those patients without access to asfotase alfa, the traditional treatment approaches remain an option. Basically, fractures are treated with orthopedic surgery, followed by rehabilitation. Prosthetic appliances are indicated to replace missing teeth, but satisfactory results are not always possible because the alveolar bone is hypoplastic. In patients who are skeletally mature, dental implants have also been used successfully in managing the edentulous spaces. Because mutational analysis of DNA can identify carriers of the defective gene, patients and their parents should be provided with genetic counseling. As stated earlier, the prognosis varies with the onset of symptoms; the perinatal and infantile types are associated with a rather poor outcome. The childhood and adult forms are usually compatible with a normal life span.

• **Fig. 17.39 Hypophosphatasia.** This medium-power photomicrograph of an exfoliated tooth shows no cementum associated with the root surface.

◆ VITAMIN D–RESISTANT RICKETS (HEREDITARY HYPOPHOSPHATEMIA; FAMILIAL HYPOPHOSPHATEMIC RICKETS)

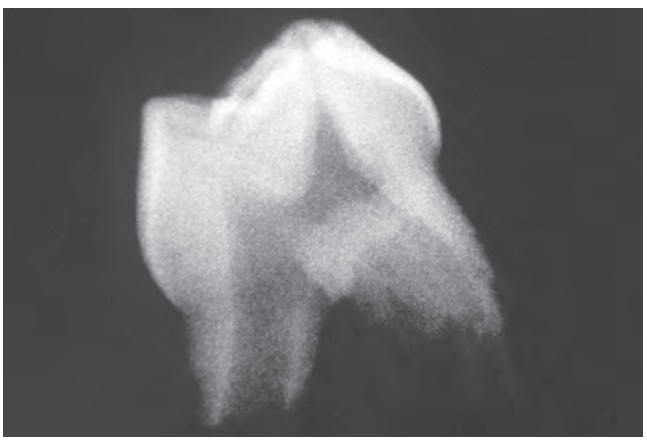
After the use of vitamin D to treat rickets became widespread, it was recognized that some individuals with clinical features characteristic of rickets did not seem to respond to therapeutic doses of the vitamin. For this reason, this condition in these patients was called **vitamin D–resistant rickets**. Most cases of this rare condition appear to be inherited as

dentlearn.ir

an X-linked dominant trait; therefore, males are usually affected more severely than females, who presumably have attenuated features because of lyonization. In the United States, this condition occurs at a frequency of 1 in 20,000 births. In addition to the rachitic changes, these patients are also hypophosphatemic and show a decreased capacity for reabsorption of phosphate from the renal tubules. The disorder is caused by mutations in a zinc metalloproteinase gene known as *phosphate-regulating gene with endopeptidase activity on the X chromosome (PHEX).* Although the precise mechanisms of action of this gene are unclear, it appears to play a role in vitamin D metabolism.

In contrast, patients affected by the rare autosomal recessive condition known as **vitamin D–dependent rickets** exhibit hypocalcification of the teeth, unlike those with vitamin D–resistant rickets. Otherwise, the two disorders have similar clinical features. Vitamin D–dependent rickets is caused by a lack of 1α-hydroxylase, the enzyme responsible for converting the relatively inactive vitamin D precursor, 25-hydroxycholecalciferol (calcifediol) to the active metabolite 1,25-dihydroxycholecalciferol (calcitriol) in the kidney. Therefore, these patients respond to replacement therapy with active vitamin D (calcitriol).

Clinical Features



Patients with vitamin D–resistant rickets have a short stature. The upper body segment appears more normal, but the lower body segment is shortened. The lower limbs are generally shortened and bowed.

Laboratory investigation reveals hypophosphatemia with diminished renal reabsorption of phosphate and decreased intestinal absorption of calcium. This typically results in rachitic changes that are unresponsive to vitamin D (calciferol). With aging, ankylosis of the spine frequently develops.

From a dental standpoint, the teeth have large pulp chambers, with pulp horns extending almost to the dentinoenamel junction (Figs. 17.40 and 17.41). In some cases the cuspal enamel may be worn down by attrition to the level of the pulp horn, causing pulpal exposure and pulp death. The exposure may be so small that the resulting periapical abscesses and gingival sinus tracts seem to affect what appear to be otherwise normal teeth (Fig. 17.42). Studies have also shown that microclefts may develop in the enamel, giving the oral microflora access to the dentinal tubules and subsequently to the pulp. One study examined a series of affected children and found that 25% of these patients had multiple abscesses involving the primary dentition. Another report described 24 affected children with a mean age of 6 years, and 67% had a history of periapical abscess formation. Affected adults also have an increased frequency of endodontic problems, with an average of approximately seven endodontically treated teeth per person in people over 40 years of age, compared to two endodontically treated teeth per person in a matched control group. In addition, vitamin D-resistant rickets patients have been shown to have an increased risk of periodontal disease.

• **Fig. 17.41 Vitamin D–Resistant Rickets.** Ground section of the same tooth depicted in Fig. 17.39. A pulp horn extends to the dentinoenamel junction. (Courtesy of Dr. Carl Witkop.)

• **Fig. 17.40 Vitamin D–Resistant Rickets.** This radiograph of an extracted tooth shows a prominent pulp chamber with pulp horns extending out toward the dentinoenamel junction.

• **Fig. 17.42 Vitamin D–Resistant Rickets.** This patient exhibits multiple nonvital teeth with associated parulides. This arose in the absence of caries or trauma.

dentlearn.ir

Histopathologic Features

Microscopic examination of an erupted tooth from a patient with vitamin D–resistant rickets usually shows markedly enlarged pulp horns. The dentin appears abnormal and is characterized by the deposition of globular dentin, which often exhibits clefting. The clefts may extend from the pulp chamber to the dentinoenamel junction. Microclefts are also seen within the enamel. The pulp frequently is nonvital, presumably because of the bacterial contamination associated with both the enamel and the dentinal clefts.

Treatment and Prognosis

For a normal stature to develop, patients with vitamin D–resistant rickets usually need early treatment with calcitriol and multiple daily doses of phosphate. In 2018, however, a monoclonal antibody, burosumab, was approved for treatment of this condition. This antibody targets a fibroblast growth factor 23 (FGF23), a cytokine that normally is regulated by PHEX. FGF23 helps regulate the degree to which phosphate is reabsorbed by the kidney, and excess levels of FGF23 decrease the reabsorption of phosphate, allowing it to be eliminated in the urine, therefore decreasing the amount in the blood. In addition, FGF23 appears to inactivate enzymes that normally convert vitamin D precursors to active vitamin D, thus reducing calcium absorption from the intestine.

With respect to the dental aspects of vitamin D-resistant rickets, endodontic therapy is necessary for the pulpally involved teeth. Initiating therapy in early childhood with a synthetic vitamin D compound (1α-hydroxycholecalciferol) appears to reduce dental problems in affected patients when compared with untreated historic controls. Interestingly, the radiographic dental abnormalities do not seem to be improved. Some investigators have suggested that application of the newer dental sealants may reduce the frequency of pulpal necrosis, but long-term follow-up studies will be necessary to confirm this. Standard systemic treatment with oral vitamin D and phosphate supplementation appears to reduce the severity of periodontitis.

Although serum and urine calcium levels must be monitored carefully to prevent nephrocalcinosis with its potential for kidney damage, patients generally have a normal life span.

◆ CROHN DISEASE (REGIONAL ILEITIS; REGIONAL ENTERITIS)

Crohn disease is an inflammatory and probably an immunologically mediated condition of unknown cause that primarily affects the distal portion of the small bowel and the proximal colon. It is now well established that the manifestations of Crohn disease may be seen anywhere in the gastrointestinal tract, from the mouth to the anus. In addition, other extraintestinal sites of disease involvement (such as, the skin, eyes, and joints) have also been identified. The oral lesions are significant because they may precede the gastrointestinal lesions in as many as 30% of the cases that have both oral and gastrointestinal involvement. It is interesting that the prevalence of Crohn disease appears to be increasing, but the reasons for this increase have not been determined. The prevalence of Crohn disease in the United States is estimated to be 214 cases per 100,000 people. Familial clustering of cases has suggested that genetic factors play a role in the pathogenesis of this disease.

Clinical Features

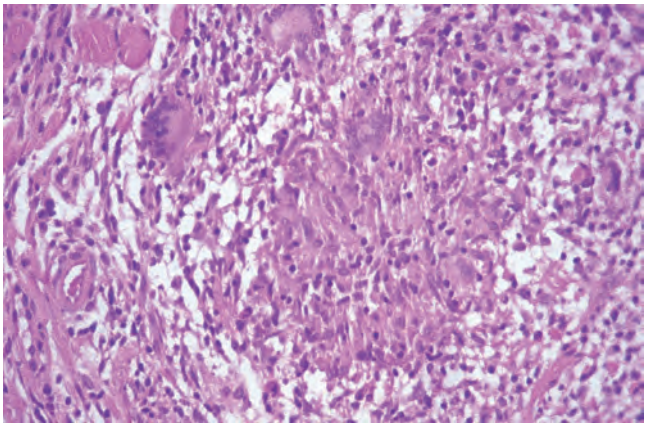
Most patients with Crohn disease are teenagers when the disease first becomes evident, although another diagnostic peak of disease activity occurs in patients more than 60 years of age. Gastrointestinal signs and symptoms usually include abdominal cramping and pain, nausea, and diarrhea, occasionally accompanied by fever. Weight loss and malnutrition may develop, which can lead to anemia, decreased growth, and short stature.

A wide range of oral lesions has been clinically reported in Crohn disease; however, many of the abnormalities described are relatively nonspecific and may be associated with other conditions that cause **orofacial granulomatosis** (see page 330). The more prominent findings include diffuse or nodular swelling of the oral and perioral tissues, a cobblestone appearance of the mucosa, and deep, granulomatous-appearing ulcers. The ulcers are often linear and develop in the buccal vestibule (Fig. 17.43). Patchy erythematous macules and plaques involving the attached and unattached gingivae have been termed *mucogingivitis* and may represent one of the more common lesions related to Crohn disease. Soft tissue swellings that resemble denture-related fibrous hyperplasia may be seen, as well as smaller mucosal tags. Acquired lymphangiectasias of the buccal mucosa, buccal vestibule, and labial mucosa have been described, appearing similar to lymphangiomas, which typically are seen in early childhood. Another manifestation that

• **Fig. 17.43 Crohn Disease.** This patient has a linear ulceration of the mandibular vestibule. An adhesion between the alveolar and labial mucosae was caused by repeated ulceration and healing of the mucosa at this site.

dentlearn.ir

has been reported is aphthous-like oral ulcerations, although the significance of this finding is uncertain because aphthous ulcerations are found rather frequently in the general population, including the same age group that is affected by Crohn disease. One large study showed no difference in the prevalence of aphthous ulcers in patients with Crohn disease compared with a control population. Less than 1% of patients with Crohn disease may develop diffuse stomatitis, with some cases apparently caused by *Staphylococcus aureus,* and others being nonspecific. In at least one instance, recurrent severe buccal space infections resulted in cutaneous salivary fistula formation. Infrequently, pyostomatitis vegetans (see next topic) has been associated with Crohn disease.



Histopathologic Features

Microscopic examination of lesional tissue obtained from the intestine or from the oral mucosa should show nonnecrotizing granulomatous inflammation within the submucosal connective tissue (Fig. 17.44). The severity of the granulomatous inflammation may vary tremendously from patient to patient and from various sites in the same patient. Therefore, a negative biopsy result at any one site and time may not necessarily rule out a diagnosis of Crohn disease. As with the clinical lesions, the histopathologic pattern is relatively nonspecific, resembling orofacial granulomatosis. Special stains should be performed to rule out the possibility of deep fungal infection, syphilis, or mycobacterial infection.

Treatment and Prognosis

Most patients with mild Crohn disease are initially treated medically with mesalamine (5-aminosalicylic acid) or sulfasalazine, a drug that is enzymatically broken down by bacteria in the colon to form sulfapyridine and 5-aminosalicylic acid. Some patients respond well to this medication, typically when it is combined with an antibiotic such as metronidazole. With moderate to severe involvement, systemic prednisone may be used and is often effective, particularly when combined with an immunomodulating drug, such as azathioprine, methotrexate, or 6-mercaptopurine. For more severe or refractory cases of Crohn disease, one of the tumor necrosis factor-α inhibitors (such as, infliximab, adalimumab, golimumab, or certolizumab pegol) may be used. Ustekinumab, a monoclonal antibody that inbibits IL12/IL23, has also been shown to be an effective medication for managing Crohn disease. If these medications fail to control the condition, an anti-adhesion monoclonal antibody known as vedolizumab can be used to help block the migration of inflammatory cells specifically into the lesional areas of the intestinal lining. Sometimes the disease cannot be maintained in remission by medical therapy, and complications develop that require surgical intervention. Complications may include bowel obstruction or fistula or abscess formation. If a significant segment of the terminal ileum has been removed surgically or is involved with the disease, then periodic injections of vitamin B_{12} may be necessary to prevent megaloblastic anemia secondary to the lack of ability to absorb the vitamin. Similar supplementation of magnesium, iron, the fat-soluble vitamins, and folate may also be required because of malabsorption. Cigarette smoking is known to exacerbate Crohn disease, and patients should be advised to stop this habit.

Oral lesions have been reported to clear with treatment of the gastrointestinal process in many cases. Occasionally persistent oral ulcerations will develop, and these may have to be treated with topical or intralesional corticosteroids. Systemic thalidomide and infliximab have been used successfully to manage refractory oral ulcers of Crohn disease.

• **Fig. 17.44 Crohn Disease.** This medium-power photomicrograph of an oral lesion shows a nonnecrotizing granuloma in the submucosal connective tissue.

◆ PYOSTOMATITIS VEGETANS

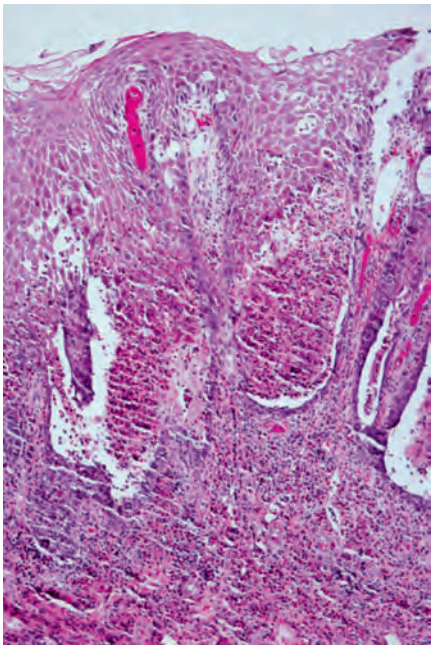
Pyostomatitis vegetans is a relatively rare condition that has a controversial history. It has been associated in the past with diseases such as pemphigus or pyodermatitis vegetans. Most investigators today, however, believe that pyostomatitis vegetans is an unusual oral expression of inflammatory bowel disease, particularly **ulcerative colitis** or **Crohn disease.** The pathogenesis of the condition, like that of inflammatory bowel disease, is poorly understood. A few patients with pyostomatitis vegetans have also been noted to have one of several concurrent liver abnormalities.

Clinical Features

Patients with pyostomatitis vegetans exhibit characteristic yellowish, slightly elevated, linear, serpentine pustules set on an erythematous oral mucosa. The lesions primarily affect the buccal and labial mucosa, soft palate, and ventral tongue (Figs. 17.45 and 17.46). These lesions have been called "snail track" ulcerations, although in most instances the lesions are probably not truly ulcerated. Oral discomfort is variable but can be surprisingly minimal in some patients. This variation in symptoms may be related to the number of pustules that have ruptured to form ulcerations. The oral lesions may

dentlearn.ir

• **Fig. 17.45 Pyostomatitis Vegetans.** The characteristic lesions are seen on the buccal mucosa, appearing as yellow-white pustules.



• **Fig. 17.46 Pyostomatitis Vegetans. A,** Characteristic "snail track" lesions involve the soft palate. **B,** Same patient after 5 days of prednisone therapy. (From Neville BW, Laden SA, Smith SE, et al: Pyostomatitis vegetans, *Am J Dermatopathol* 7:69–77, 1985.)

appear concurrently with the bowel symptoms, or they may precede the intestinal involvement.

Histopathologic Features

A biopsy specimen of an oral lesion of pyostomatitis vegetans usually shows marked edema, causing an acantholytic appearance of the involved epithelium. This may be the result of the accumulation of numerous eosinophils within the spinous layer, often forming intraepithelial abscesses (Fig. 17.47). Subepithelial eosinophilic abscesses have been reported in some instances. The underlying connective tissue usually supports a dense mixed infiltrate of inflammatory cells that consists of eosinophils, neutrophils, and lymphocytes. Perivascular inflammation may also be present.

• **Fig. 17.47 Pyostomatitis Vegetans.** Medium-power photomicrograph showing intraepithelial abscesses composed of eosinophils.

Treatment and Prognosis

Usually, the intestinal signs and symptoms of inflammatory bowel disease are of most concern for patients with pyostomatitis vegetans. Medical management of the bowel disease with sulfasalazine or systemic corticosteroids also produces clearing of the oral lesions (see Fig. 17.46). Often the oral lesions clear within days after systemic corticosteroid therapy has begun, and they may recur if the medication is withdrawn. If the bowel symptoms are relatively mild, then the oral lesions have been reported to respond to topical therapy with some of the more potent corticosteroid preparations.

◆ UREMIC STOMATITIS

Patients who have either acute or chronic renal failure typically show markedly elevated levels of urea and other nitrogenous wastes in the bloodstream. **Uremic stomatitis** represents a relatively uncommon complication of renal failure. In two series that included 562 patients with renal failure, only eight examples of this oral mucosal condition were documented. Nevertheless, for the patients in whom uremic stomatitis develops, this can be a painful disorder. The cause

dentlearn.ir

• **Fig. 17.48 Uremic Stomatitis. A,** Ragged white plaques affect the ventral tongue and floor of the mouth. **B,** Same patient after renal dialysis. (From Ross WF, Salisbury PL: Uremic stomatitis associated with undiagnosed renal failure, *Gen Dent* 42:410–412, 1994.)

of the oral lesions is unclear, but some investigators suggest that urease, an enzyme produced by the oral microflora, may degrade urea secreted in the saliva. This degradation results in the liberation of free ammonia, which presumably damages the oral mucosa.

Clinical Features

Most cases of uremic stomatitis have been reported in patients with acute renal failure. The onset may be abrupt, with white plaques distributed predominantly on the buccal mucosa, tongue, and floor of the mouth (Fig. 17.48). Patients may complain of unpleasant taste, oral pain, or a burning sensation with the lesions, and the clinician may detect an odor of ammonia or urine on the patient's breath. The clinical appearance occasionally has been known to mimic oral hairy leukoplakia.

Treatment and Prognosis

In some instances, uremic stomatitis may clear within a few days after renal dialysis, although such resolution may take place over 2–3 weeks. In other instances, treatment with a mildly acidic mouth rinse, such as diluted hydrogen peroxide, seems to clear the oral lesions. For control of pain while the lesions heal, patients may be given palliative therapy with ice chips or a topical anesthetic, such as viscous lidocaine or dyclonine hydrochloride. Although renal failure itself is life threatening, at least one example of a uremic plaque that presumably caused a patient's death has been recorded. This event was thought to have been caused by the dislodging of the plaque with subsequent obstruction of the patient's airway.

Facial Pain and Neuromuscular Diseases

REVISED BY N. LYN WILSON WESTMARK

◆ BELL PALSY (IDIOPATHIC SEVENTH NERVE PARALYSIS; IDIOPATHIC FACIAL PARALYSIS)

Bell palsy is an acute weakness or paralysis of the facial nerve without an identifiable cause. It is the most common cause of facial paralysis or paresis, but is a clinical diagnosis of exclusion limited to idiopathic cases with acute onset. Although the etiology is uncertain, evidence suggests that the condition may be related to either a viral infection (herpes simplex, varicella-zoster, or Epstein Barr virus) or cell-mediated autoimmune reaction resulting in demyelination of the nerve. Other proposed etiologies include anatomical factors, ischemia, and cold stimulation. Coronavirus infection (SARS-CoV-2) also has been suggested to increase prevalence of Bell palsy, but limited and conflicting epidemiological data are available. Ultimately, the mechanism is related to inflammation or compression of the facial nerve resulting in weakness or paralysis. According to Baugh et al., a variety of factors may increase the risk for developing Bell palsy, including:

- Pregnancy (especially third trimester)
- Preeclampsia
- Diabetes
- Hypertension
- Obesity
- Upper respiratory infections

Bell palsy can occur at any age, but it develops most frequently in individuals 15–45 years of age. Depending on the population studied, the annual incidence of Bell palsy ranges from 11.5 to 53.3 per 100,000 persons. The lifetime risk for developing this condition is 1 in 60. Other specific conditions may cause facial nerve paralysis which should be excluded by history or physical exam, including neoplasms, sarcoidosis, orofacial granulomatosis (Melkersson-Rosenthal syndrome), Lyme disease, congenital malformations, inappropriate administration of local anesthesia, trauma, and postsurgical damage.

Clinical Features

Bell palsy presents with an abrupt unilateral loss of facial muscle control resulting in inability to smile, close the eye, or raise the eyebrow (Fig. 18.1). Drooling, slurred speech, and abnormal taste also may occur. Full severity often is reached within 72 hours, and patients frequently may wake in the morning with a full-fledged case. In patients where the eye cannot close, conjunctival dryness or ulceration may cause permanent ocular damage. Some patients experience a prodromal sensation of pain or fullness on the affected side prior to onset of paralysis.

Infrequently, bilateral involvement is seen. However, rapid onset of bilateral facial weakness should alert the clinician to the possibility of other diseases, such as **Guillain-Barré syndrome** or a form of sarcoidosis known as *uveoparotid fever* (see Heerfordt syndrome, page 329). If multiple cranial nerve deficits accompany facial nerve paralysis, then central nervous system (CNS) infectious diseases and basilar skull tumors must be considered in the differential diagnosis. If the patient has symptoms of vertigo, tinnitus, or rash on the auricle, then a diagnosis of Ramsay Hunt syndrome must be suspected (see page 240).

Treatment and Prognosis

Bell palsy is a self-limiting condition, and most patients will recover over a 3–4 month period. Without treatment, complete facial nerve function will be restored in nearly three-quarters of patients with complete paralysis and in over 90% of patients with partial paralysis. However, as many as 20%–30% of patients will not recover completely. The most consistently effective treatment is systemic corticosteroid therapy, which has been shown to improve recovery rates and should be started within 72 hours of symptom onset. A 10-day tapering course of prednisone often is prescribed, beginning at a dosage of 60 mg per day. Antiviral therapy (acyclovir, famciclovir, or valacyclovir) may be associated with a modest improvement in recovery and potential

dentlearn.ir

• **Fig. 18.1 Bell Palsy.** Paralysis of the facial muscles on the patient's left side. **A,** Patient is trying to raise the eyebrows. **B,** Patient is attempting to close the eyes and smile. (Courtesy of Dr. Bruce B. Brehm.)

avoidance of some long-term sequelae (abnormal lacrimation, muscle contracture), when given in combination with corticosteroids. However, antiviral therapy alone is not recommended. Surgical decompression of the facial nerve has been attempted, but evidence for the effectiveness of this approach is lacking. Electrodiagnostic testing may be helpful to assess the likelihood of recovery for patients with complete paralysis. Eye protection is critical for patients with impaired eye closure. Topical ocular antibiotics and artificial tears may be required to prevent corneal ulceration, and the eyelid may have to be taped shut. Patients without improvement or with worsening symptoms despite conventional therapy should undergo further workup for other causes of facial paralysis.

◆ FREY SYNDROME (AURICULOTEMPORAL SYNDROME; GUSTATORY SWEATING AND FLUSHING)

Named for Polish neurologist Łucja Frey, **Frey syndrome** typically is unilateral and characterized by facial flushing and sweating along the distribution of the auriculotemporal nerve in response to gustatory stimuli. This syndrome occurs after injury to the nerve, and signs begin to develop after nerve regeneration. The most widely accepted mechanism of Frey syndrome is aberrant neuronal regeneration.

The auriculotemporal nerve, in addition to supplying sensory fibers to the preauricular and temporal regions, carries parasympathetic fibers to the parotid gland and sympathetic vasomotor and sudomotor (sweat stimulating) fibers to the preauricular skin. After parotid abscess, trauma, facial surgery, neck dissection, or parotidectomy, the parasympathetic nerve fibers may be severed. In their attempt to reestablish innervation, these fibers occasionally become misdirected and regenerate along the sympathetic nerve pathways, establishing communication with the sympathetic nerve fibers of sweat glands and blood vessels of the facial skin. Subsequent to these aberrant neural connections, when salivation is stimulated, local sweat glands are activated inadvertently and the patient's cheek becomes flushed and moist.

Parotidectomies are the most common preceding cause, with 30%–60% of patients reporting subjective development of Frey syndrome 6–18 months after surgery, although a much higher frequency (70%–100%) can be documented if objective testing is performed (Minor starch-iodine test or infrared thermography). The condition is rare in infancy but has been seen after forceps delivery. Neonatal cases typically do not occur until the child begins to eat solid foods, at which time it may be interpreted as an allergy. Interestingly, bilateral gustatory sweating of the face and neck can be seen in diabetic patients, especially those with neuropathy or nephropathy.

Similar phenomena include sweating and flushing of the chin after submandibular gland surgery or injury (chorda tympani syndrome) or gustatory lacrimation (crocodile tears) after injury of the facial nerve proximal to the geniculate ganglion.

dentlearn.ir

Clinical Features

The presenting signs and symptoms of Frey syndrome include sweating, flushing, warmth, and occasionally pain or itching in the preauricular and temporal regions during chewing or exposure to gustatory stimuli. Sweating and flushing become evident 2 months to 2 years (average 9 months) post nerve injury and may intensify over the course of several months before stabilizing. In children, Frey syndrome may be distinguished from allergy by repeated pattern of flushing, often unilateral, which resolves quickly after eating without intervention. When flushing occurs, the local skin temperature may be raised as much as 2°C. This may occur without sweating, especially in females. Pain, when present, is usually mild, and hypoesthesia or hyperesthesia are common features.

To detect sweating, a Minor starch-iodine test may be used. A 1% iodine solution is painted on the affected area of the skin. This solution is allowed to dry, and the area is then coated with a layer of starch. When the patient is given something to eat, the moisture of the sweat that is produced will mix with the iodine on the skin. This allows the iodine to react with the starch and produce a blue color (Fig. 18.2). Iodine-sublimated paper, which changes color when wet, also can be used, and thermography or surface thermometers will document the temperature changes of the skin.

Treatment and Prognosis

The initial risk for developing Frey syndrome is diminished greatly by positioning a musculofascial flap or allograft between the gland and the overlying skin of the cheek at the time of surgery, especially during parotidectomy. Use of temporoparietal fascia and acellular dermal matrix has been shown to reduce subjective and objective Frey syndrome, respectively. Most cases are mild enough that the patient may decide treatment is not required, although some patients may report a diminished quality of life. Additionally, some adult patients may report spontaneous resolution, but this is much more common in infant Frey syndrome, which has an observed resolution rate of 69%.

If treatment is desired, intracutaneous injections of botulinum toxin A can provide long-term relief, although injections may need to be repeated. Topically applied medications, such as aluminum chloride or anticholinergics (e.g., scopolamine and glycopyrrolate), also have been used for short-term control. Surgical management may include insertion of various tissue barriers or tympanic neurectomy, but this rarely is indicated due to risk of injury to the facial nerve or a cosmetic defect. Therefore, surgery should be reserved for severe cases refractory to medical treatment.

• **Fig. 18.2 Frey Syndrome.** This patient received an injury to her auriculotemporal nerve during orthognathic surgery 3 years earlier. Notice the region of sweating detected during mastication by a color change of the starch in the Minor starch-iodine test.

HEAD AND NECK PAIN

Pain is a universal experience and is often a protective mechanism which alerts organisms to the possibility of harm. As pain is the primary motivation for the majority of health care encounters in our culture, it is prudent to consider pain in a wider context prior to discussing specific pain entities common to the head and neck region.

Pain can be characterized broadly as acute or chronic. Typically, acute pain is associated with a tissue injury of sudden onset and has a more predictable outcome. Chronic pain is ongoing and may become a disease entity by itself, requiring continued management, and it may affect an individual's physical, social, and psychological states. Estimates suggest that between 17% to 26% of the general population experience orofacial pain, and for 7%–12% that pain presentation will become chronic. The majority of acute pain presentations in dental practice are associated with the teeth and their supporting structures, and dentists usually diagnose and treat these conditions with relative ease. However, the diagnosis and management of non-odontogenic head and neck pain often presents a challenge to even the most skilled diagnosticians due to the complexity of the neural and vascular networks of the orofacial region.

Pain fibers from the orofacial region travel to the spinal nucleus caudalis of the trigeminal nerve in a process known as *trigeminal convergence.* Of note, nociceptive fibers from the cervical region also converge in this area, adding further complexity. This convergence often makes it virtually impossible for patients to distinguish the site of their pain from the source of their pain in a reliable fashion. For this reason, it is important that health care providers have a working knowledge of the myriad of diagnostic possibilities for those patients presenting with chronic orofacial pain. Although it is well beyond the scope of this chapter to discuss each of these entities, differential considerations related to chronic orofacial pain are summarized in Box 18.1. In general, if the pain is thought to be of nondental origin, then a comprehensive pain evaluation, complete with diagnostic anesthesia and appropriate laboratory testing, is warranted.

• BOX 18.1 Disorders Associated With Chronic Orofacial Pain

Temporomandibular Joint Disorders

Joint pain
- Arthralgia
- Arthritis

Joint disorders
- Disc-condyle complex disorders
  - Disc displacement with reduction
  - Disc displacement without reduction
- Hypomobility disorders
  - Adhesions
  - Ankylosis
- Hypermobility disorders
  - Subluxation
  - Luxation

Joint diseases
- Degenerative joint disease (osteoarthritis/osteoarthrosis)
- Condylysis (idiopathic condylar resorption)
- Osteochondritis dissecans
- Osteonecrosis
- Synovial chondromatosis

Congenital/developmental disorders of the condyle
- Aplasia
- Hypoplasia
- Hyperplasia

Masticatory Muscle Disorders

Muscle pain limited to the orofacial region
- Myalgia
- Myositis
- Spasm

Masticatory muscle pain attributed to systemic/central disorders
- Fibromyalgia
- Centrally mediated myalgia

Movement disorders affecting masticatory muscles
- Orofacial dyskinesia
- Oromandibular dystonia

Primary Headache Disorders

Migraine headache
Tension-type headache (TTH)
Trigeminal autonomic cephalalgias (TACS)
- Cluster headache
- Paroxysmal hemicrania
- Short-lasting unilateral neuralgia headache attacks with conjunctival injection and tearing (SUNCT)
- Short-lasting unilateral neuralgia headache attacks with cranial autonomic symptoms (SUNA)
- Hemicrania continua

Other primary headaches
- Primary exertional headache
- Primary thunderclap headache
- Hypnic headache

Neuropathic Pain Disorders

Trigeminal neuralgia
Pretrigeminal neuralgia
Glossopharyngeal neuralgia
Nervus intermedius neuralgia
Superior laryngeal neuralgia
Occipital neuralgia
Painful ophthalmoplegia
Idiopathic (trigeminal) neuropathic pain
Post traumatic (trigeminal) neuropathy
Postherpetic (trigeminal) neuropathy
Anesthesia dolorosa
Persistent idiopathic facial pain
Complex regional pain syndrome
Burning mouth syndrome
Occlusal dysesthesia
Central neuropathic pain
- Central neuropathic pain due to multiple sclerosis
- Central poststroke pain

Cervical Pain Disorders

Cervicalgia
Sprain and strain of cervical spine
Cervical osteoarthritis
Radiculopathy
Cervical dystonia (Spasmodic torticollis)
Cervicogenic headache
Neck-tongue syndrome
Pain secondary to inflammation of the stylohyoid ligament (Eagle syndrome)

Systemic Causes of Orofacial Pain

Diabetes mellitus
Lyme disease
Multiple sclerosis
Neurodegenerative diseases
- Parkinson disease

Connective tissue diseases
- Systemic lupus erythematosus
- Rheumatoid arthritis (RA)
- Sjögren syndrome
- Systemic sclerosis

Giant cell arteritis
Primary malignancies

Modified from de Leeuw R, Klasser GD, editors: *Orofacial pain—guidelines for assessment, diagnosis and management,* ed 6, Chicago, 2018, Quintessence Publishing.

◆ TRIGEMINAL NEURALGIA (TIC DOULOUREUX; TIC)

The head and neck region is a common site for neuralgias (pain extending along the course of a nerve). Because facial neuralgias produce pain that often mimics pain of dental origin, the dental profession is frequently called on to rule out odontogenic or inflammatory causes. **Trigeminal neuralgia,** the most serious and the most common of the facial neuralgias, is characterized by a paroxysmal, extremely severe, electric shock-like or sharp, stabbing pain limited to one or more branches of the trigeminal nerve. The significance of this disorder is underscored by the fact that it has one of the highest suicide rates of any disease and

dentlearn.ir

is regarded as one of the most painful afflictions known. The pathogenesis of *classical* trigeminal neuralgia is not well understood but is thought to be secondary to vascular compression of the trigeminal nerve root, resulting in demyelination. *Secondary* trigeminal neuralgia occurs subsequent to a separate disease process such as multiple sclerosis or compression of the nerve by tumors or arteriovenous malformations. The condition may be termed *idiopathic* if no identifying disease process is found. Advanced imaging techniques such as magnetic resonance imaging have made subclassification of clinically diagnosed trigeminal neuralgia possible.

The incidence of trigeminal neuralgia in the general population is 4–29 per 100,000 person years annually. The condition is approximately 20 times more prevalent in patients with multiple sclerosis.

Clinical Features

Trigeminal neuralgia characteristically affects individuals older than 50 years of age (average onset 53–57 years), although it can develop at any age, including young children. Women are affected more often than men by a ratio of 3:1. One or more branches of the trigeminal nerve may be involved, with the majority of cases affecting the maxillary (V2) or mandibular (V3) distributions of the nerve. The ophthalmic division is reported to be affected in approximately 1%–4% of cases. The right side is affected more commonly, and bilateral involvement is unusual (3%–5% of cases). This may suggest the possibility of underlying multiple sclerosis. Trigeminal neuralgia associated with multiple sclerosis also tends to develop at a younger age and may be a presenting symptom. Multiple sclerosis should be ruled out when a diagnosis of trigeminal neuralgia is made in a person under the age of 40.

In the early stages, the pain of trigeminal neuralgia may be rather mild and is often described by the patient as a twinge, dull ache, or burning sensation. This clinical presentation may be attributed erroneously to disorders of the teeth, jaws, and paranasal sinuses, leading to inappropriate treatment. With time, the attacks occur at more frequent intervals and the pain becomes increasingly intense, sometimes being described as feeling like "an electric shock," "a bolt of lightning," or "being stabbed by an ice pick." Patients often clutch at the face and experience spasmodic contractions of the facial muscles during attacks, a feature that long ago led to the use of the term *tic douloureux* (i.e., painful jerking) for this disease.

For most patients, the pain will be provoked by stimulation of a specific trigger zone along the distribution of the trigeminal nerve, although spontaneous episodes of pain may occur. Continuous aching, burning, or throbbing pain in between episodes is reported by 24%–49% of patients. Extraoral and intraoral trigger zones are common, and the most frequently reported areas are the gingiva, chin, cheek, lips, and nasolabial fold. Stimulation of trigger areas, even by light sensation, may trigger an attack. Commonly reported trigger actions include toothbrushing, face washing, shaving, eating, or even exposure to a breeze.

• BOX 18.2 Clinical Features of Trigeminal Neuralgia

- Abrupt onset of pain often initiated by light touch to a consistent and specific trigger point.
- Pain is described as paroxysmal, severe, and shooting or shocking in nature
- Single episode duration is less than 2 minutes, but overall attack may consist of repeating episodes of short duration
- Pain is limited to the distribution of one or more branches of the trigeminal nerve and no motor deficits are present.
- A refractory period is present after an attack during which another episode generally cannot be triggered
- Severe episodes may be accompanied by ipsilateral muscle contraction
- Less common features
  - Continuous dull, aching pain between episodes may be present
  - Mild hypoesthesia may be present

Each painful episode typically lasts for no longer than 2 minutes, followed by a refractory period in which stimulation of the trigger zone will not elicit another attack. This refractory period can be clinically useful in distinguishing trigeminal neuralgia from stimulus-provoked odontogenic pain. Rarely autonomic signs may be present. If motor deficits, sensory loss, or ataxia are present, then a CNS tumor should be ruled out.

Variations in diagnostic criteria exist, with some experts including clinical criteria and others incorporating imaging findings, to distinguish between classical, secondary, and idiopathic trigeminal neuralgia. A summary of distinguishing clinical features of trigeminal neuralgia can be found in Box 18.2. If the pain pattern does not meet these criteria, then a different diagnosis should be considered, such as persistent idiopathic facial pain or one of the trigeminal autonomic cephalalgias.

Treatment and Prognosis

There have been rare reports of spontaneous permanent and intermittent remissions of trigeminal neuralgia. However, more often than not, this disease is characterized by a protracted clinical course with increasing frequency and severity of exacerbations. The initial treatment for trigeminal neuralgia is pharmacological, with carbamazepine (an anticonvulsant) being the first drug of choice, followed by oxcarbazepine. Over 80% of patients experience significant pain control on this regimen, but side effects are frequent and may be intolerable. Additionally, treatment response may wane over time, necessitating combination therapy. Other medications (phenytoin, gabapentin, lamotrigine, pregabalin, duloxetine, valproic acid, topiramate, and baclofen) also may be used in addition to first-line therapy, in combination, or as monotherapy. Side effects may still occur, and treatment may need to be modified. Botulinum toxin

dentlearn.ir

• BOX 18.3 Neurosurgical Therapies for Trigeminal Neuralgia

- Repositioning of blood vessels impinging on trigeminal nerve (microvascular decompression)
- Injection of caustic material near nerves leaving or entering the gasserian ganglion (glycerol rhizotomy)
- Removal of skull base bony irregularities impinging on trigeminal nerve (decompression)
- Balloon microcompression of the gasserian ganglion
- Selective destruction of the sensory fibers of the nerve by crushing or by the application of heat (percutaneous radiofrequency rhizotomy)
- Severing the trigeminal sensory roots (neurectomy)

type A injections into trigger zones can be used as an adjunctive therapy and may lead to lasting (>1 year) symptom relief in some patients. Opioid medications are typically ineffective in managing the pain of trigeminal neuralgia.

If medical management fails, a variety of surgical treatments may be considered (Box 18.3). Microvascular decompression is an invasive, but nondestructive, surgical technique, which aims to address compression of the nerve by adjacent blood vessels. The mortality rate from this procedure is approximately 0.3%, but this approach is favored in cases with proven vascular compression as pain relief is achieved in 62%–89% of patients at long term follow up (3–11 years). Potential long-term complications include facial numbness and ipsilateral hearing loss.

A noninvasive but destructive technique is stereotactic radiosurgery (Gamma Knife) in which a portion of the trigeminal nerve is treated with a focused beam of radiation. Other ablative procedures that are less invasive but also involve destruction of affected portions of the trigeminal nerve by mechanical, thermal, and chemical means include balloon microcompression, radiofrequency thermocoagulation, and glycerol rhizotomy, respectively. Ablative therapies are recommended when vascular compression is not detected and, depending on the technique used, many patients may experience long-term (4–11 years) relief. As these procedures are ablative in nature, repeated procedures may be necessary, and there is a higher chance of sensory complications such as distorted sensations of the facial skin **(facial dysesthesia)** or a combination of anesthesia and spontaneous pain **(anesthesia dolorosa).** Anesthesia dolorosa is a dreaded form of central pain that can occur after any neurosurgical procedure that causes a variable amount of sensory loss, but this complication occurs more commonly with procedures that totally denervate a region.

◆ GLOSSOPHARYNGEAL NEURALGIA (VAGOGLOSSOPHARYNGEAL NEURALGIA)

Neuralgia of the ninth cranial nerve, **glossopharyngeal neuralgia,** is similar to trigeminal neuralgia (see previous topic) except in the anatomic location of the pain. In glossopharyngeal neuralgia the pain is centered on the tonsil and the ear. The pain often radiates from the throat to the ear because of the involvement of the tympanic branch of the glossopharyngeal nerve. Some unfortunate individuals have a combination of glossopharyngeal neuralgia and trigeminal neuralgia (approximately 10%–12%).

Glossopharyngeal neuralgia is rare, representing only 0.2%–1.3% of facial pain syndromes, with an incidence of about 0.7 per 100,000 per year. The pain also may affect sensory areas supplied by the pharyngeal and auricular branches of the vagus nerve. As with trigeminal neuralgia, subtypes of glossopharyngeal neuralgia are recognized: *classical*, *secondary*, and *idiopathic*. Classical glossopharyngeal neuralgia is attributed to arterial compression of the nerve, usually the posterior inferior cerebellar artery. Secondary glossopharyngeal neuralgia occurs due to compression of the nerve by a specific lesion, such as intracranial or cranial base tumors, oropharyngeal tumors, pagetic bone, or calcified stylohyoid ligament (Eagle syndrome; see page 23). Idiopathic glossopharyngeal neuralgia is unassociated with any identifiable underlying disorder. Unlike trigeminal neuralgia, it is uncommon for glossopharyngeal neuralgia to be associated with multiple sclerosis.

Clinical Features

Glossopharyngeal neuralgia usually occurs in middle-aged and older adults. There is no sex predilection, and only rarely is there bilateral involvement. The paroxysmal pain may be felt in the ear **(tympanic plexus neuralgia),** infra-auricular area, tonsil, base of the tongue, posterior mandible, or lateral wall of the pharynx; however, the patient often has difficulty localizing the pain in the oropharynx.

The episodic pain in this unilateral neuralgia is sharp, lancinating (jabbing), and extremely intense. Attacks have an abrupt onset and a short duration (seconds to minutes). The pain typically radiates upward from the oropharynx to the ipsilateral ear, but pain referring to the nose, eye, chin, and shoulder also have been reported. Talking, chewing, swallowing, yawning, or touching a blunt instrument to the tonsil on the affected side may precipitate the pain, but a definite trigger zone is not easily identified. Because the pain is related to jaw movement, it may be confused with the pain of **temporomandibular joint dysfunction.**

Patients frequently point to the neck immediately below the angle of the mandible as the site of greatest pain, but trigger points are not found on the external skin, except within the ear canal. Excessive vagal effects will occur in approximately 10% of patients, resulting in cough, syncope, hypotension, seizures, bradycardia, or cardiac arrest **(vagoglossopharyngeal neuralgia).**

Treatment and Prognosis

As in trigeminal neuralgia, glossopharyngeal neuralgia is subject to unpredictable remissions and recurrences. It is not unusual during the early stages for remissions to last 6 months or more. Painful episodes are of varying severity

dentlearn.ir

but generally become more severe and more frequent with time. Some patients may report nearly continuous pain, but this is rare.

Many patients will experience pain relief when a topical anesthetic agent is applied to the tonsil and pharynx on the side of the pain. Because this relief lasts only 60–90 minutes, it is used more as a diagnostic tool and emergency measure than a long-term treatment. Repeated applications to a trigger point for 2 or 3 days may extend the pain-free episode enough to allow the patient to obtain much needed rest and nutrition.

For most patients with classical or idiopathic glossopharyngeal neuralgia, the first line of therapy is pharmacological, similar to trigeminal neuralgia (discussed above). For individuals with vagoglossopharyngeal neuralgia, atropine can be used to prevent the related cardiac phenomena. If a patient with glossopharyngeal neuralgia fails drug therapy, then surgical options should be considered. The preferred neurosurgical treatments are microvascular decompression or surgical sectioning of the glossopharyngeal nerve and the upper two rootlets of the vagus nerve, both of which have been shown to provide long term relief. Other possible procedures include radiofrequency nerve ablation, balloon compression, and stereotactic radiosurgery (Gamma Knife ablation). If the pain is secondary to another condition (e.g., tumor or Eagle syndrome), then management of the underlying lesion must be addressed.

◆ GIANT CELL ARTERITIS (TEMPORAL ARTERITIS; GRANULOMATOUS ARTERITIS)

Giant cell arteritis is an immune-mediated vasculitis that affects medium-sized and larger arteries, leading to vascular occlusion and ischemia. The condition also is termed **temporal arteritis** because the superficial temporal artery is the most commonly affected site. Although giant cell arteritis most often affects head and neck vessels, it is considered to be a systemic condition that can involve multiple vessels, including the aorta and its proximal branches. Although the exact cause is uncertain, there appears to be a strong genetic predisposition, with a higher frequency of disease in patients who express certain human leukocyte antigen (HLA) types, specifically the HLA-DRB1*0 allele. Because geographic and seasonal variations have been observed, an infectious etiology or trigger also has been suggested.

Giant cell arteritis occurs primarily in older individuals (average age = 70 years); the condition demonstrates an annual incidence rate of 20 per 100,000 population over the age of 50 years. There is an increased incidence associated with advancing age, with the highest rate observed in the eighth decade (average age, 70 years). The disease shows a predilection for individuals of Scandinavian and northern European descent. Women are affected more often than men (2:1 to 3:1 ratio).

Clinical Features

The disease most frequently involves the temporal artery, presenting with symptoms of new, severe headache and scalp tenderness. The superficial temporal artery often is exquisitely sensitive to palpation and eventually appears erythematous, swollen, tortuous, or sometimes ulcerated. A highly characteristic feature is jaw claudication, which is described as cramping pain due to ischemia of the masseter and temporalis muscles, which increases with usage (chewing or talking) but is relieved by rest. Jaw claudication and ocular involvement frequently coexist.

The most significant complication in the head and neck region is vision loss, which usually is due to vasculitis of the posterior ciliary artery and ischemic optic neuropathy. Permanent loss of vision occurs in 15% of patients. Visual disturbances (blurred vision with exercise, diplopia, transient vision loss) often are an early manifestation of giant cell arteritis, sometimes occurring before the onset of other symptoms.

Systemic signs and symptoms include fever, malaise, fatigue, anorexia, and weight loss. Many patients (40%) develop **polymyalgia rheumatica,** which is characterized by aching pain and morning stiffness in the neck, shoulders, and pelvic girdle. Giant cell arteritis may affect the aorta and other large vessels 30%–70% of cases, although such involvement often is asymptomatic. On occasion, however, undetected aortic inflammation may be associated with aortic aneurysm and rupture. Patients have an increased risk of cerebrovascular accidents, cardiac infarction, and limb claudication and vasculitis.

Histopathologic and Laboratory Features

Microscopic changes tend to be segmental and can be missed if the specimen is too small. At least 1 cm of the affected vessel must, therefore, be examined for proper evaluation.

The disease is characterized by chronic inflammation of the tunica intima and tunica media of the involved artery, with narrowing of the lumen from edema and proliferation of the tunica intima. Necrosis of the smooth muscle and elastic lamina is frequent. A variable number of multinucleated giant cells are mixed with macrophages and lymphocytes. Thrombosis or complete occlusion of the lumen is not unusual.

Clinical laboratory features often include an elevated erythrocyte sedimentation rate, increased C-reactive protein levels, and an elevated platelet count.

Diagnosis

Due the lower cost and less invasive procedure, ultrasound of the temporal artery is demonstrating a greater role in the early diagnosis of temporal arteritis, but this modality is highly operator sensitive. Imaging features include vessel wall thickening, occlusion, stenosis, and non-compressible arteries. Other imaging (MRI) may be recommended to evaluate

dentlearn.ir

for large vessel involvement. Despite imaging advances, temporal artery biopsy remains the preferred confirmatory test in the United States.

Treatment and Prognosis

Because of the risk for sudden and permanent loss of vision, prompt treatment of giant cell arteritis is critical. If diagnostic imaging or biopsy cannot be completed in a timely manner, treatment may need to be initiated. Initial treatment with high dose systemic corticosteroids and tocilizumab (monoclonal antibody against interleukin 6) is recommended. The disease typically responds well to high-dose systemic corticosteroid therapy, and symptoms often subside within a few days. However, many cases are chronic and require treatment for years. Additional steroid corticosteroid-sparing medications may include methotrexate or azathioprine.

◆ BURNING MOUTH DISORDER (BURNING MOUTH SYNDROME; ORAL DYSESTHESIA; ORAL SENSORY NEUROPATHY; STOMATOPYROSIS; STOMATODYNIA; GLOSSOPYROSIS; GLOSSODYNIA; BURNING TONGUE SYNDROME; BURNING MOUTH SYNDROME)

Burning mouth disorder (BMD) is one of the most common nondental orofacial pains encountered in the clinical practice, and it likely represents neuropathic pain, potentially with both peripheral and central nervous system components. Because taste disturbances (reduced ability to taste; altered taste; taste "phantoms") and altered perception of oral mucosal texture (xerostomia; swelling; gritty; slimy sensation) frequently accompany the onset of burning sensation, this condition has been referred to as *burning mouth syndrome.* Whether the presence of these additional clinical findings actually constitute a syndrome is a matter of much debate. Terms that are more inclusive of the various presenting symptoms are "*oral sensory neuropathy*" or "*oral dysesthesia.*"

Oral burning may be attributed to various local or systemic factors (Box 18.4), and if a local or systemic cause is found, the diagnosis of secondary BMD is applied. Primary BMD is limited to the presence of oral burning in the absence of both abnormal clinical and laboratory findings, meaning that the patient will have a clinically normal oral appearance.

The etiology and pathogenesis of primary BMD are not well established and are likely complex. Despite numerous investigations, no clear causative agent has been identified. Proposed theories include nerve damage, hormonal changes, psychological factors, and alteration of the peripheral and central nervous system. Specific proposed mechanisms include chorda tympani damage resulting in loss of central inhibition or dysregulation of the gustatory and sensory systems. Although patients with oral dysesthesias often present with psychological dysfunction such as depression, anxiety, or irritability, these findings are common in patients with chronic pain conditions, and there is no correlation between duration and intensity of the burning sensation and the amount of psychologic dysfunction. Potentially, the development of psychologic distress in some affected individuals may be caused by, or exacerbated by, the presence of chronic oral discomfort that is experienced by the patient.

Although BMD often is reported to affect women much more often than men, most of those reports are based on the gender of the patients who present to a particular center for treatment. However, this discrepancy in gender predilection may be explained by the increased tendency of women to seek medical care. The 1989 National Health Interview Survey, which interviewed thousands of adults over the age of 35, found no significant difference in the number men vs women with a complaint of burning mouth. This finding was replicated in a survey of elderly adults in Florida, with approximately 1.7% of both men and women affected. There seems to be increasing prevalence with advancing age, especially after age 55. The syndrome is rare before the age of 30 years.

• BOX 18.4 Local and Systemic Factors Associated With Oral Burning

Local Factors

- Clinically observable hyposalivation
- Chronic mechanical trauma
- Oral fungal, bacterial, or viral infection
- Contact stomatitis
- Geographic tongue
- Local manifestation of immune-mediated or autoimmune disease

Systemic Factors

- Vitamin B deficiency
  - Vitamin B_1 or B_2 deficiency
  - Pernicious anemia (B_{12})
  - Pellagra (niacin deficiency)
  - Folic acid deficiency
- Iron deficiency
- Diabetes mellitus
- Chronic gastritis or regurgitation

Clinical Features

Burning mouth disorder (BMD) usually is described by the patient as a burning sensation of the oral mucosa. When asked, patients often will say that their mouth "feels like I scalded it with a hot cup of coffee." Although the anterior dorsal tongue is the most commonly affected site **(glossopyrosis),** other mucosal surfaces also may be symptomatic **(stomatopyrosis).** The anterior hard palate, as well as the maxillary and mandibular labial mucosa, frequently are involved, and the pain generally is bilateral and symmetric. Very infrequently unilateral involvement may occur.

dentlearn.ir

Approximately 70% of patients also report taste disturbances, which can include an obtunded taste sensation, a distorted sense of taste, termed *dysgeusia*, or the development of taste "phantoms," in which a metallic, salty, sweet, "rotten," or bitter taste may be present. Patients have been known to seek dental care for removal of their amalgam restorations in an attempt (unsuccessfully) to relieve the metallic taste phantom.

At least 25% of these patients report having an altered texture of their oral mucosa, typically a dry mouth, although other textures (sandpaper, sliminess, swelling) also have been reported. The sensation of dry mouth mimics true *xerostomia* (see page 470); however, a normal degree of moisture will be present. None of the typical signs of decreased saliva will be evident. In other words, clear, copious saliva can be milked from the major salivary gland ducts. No significant plaque accumulation will be seen, and no Class V dental caries will be present. Actual reduction of salivary flow, as seen in patients with Sjögren syndrome (see page 472) or patients whose major salivary glands were located in the field of therapeutic radiation used to treat a head and neck/oral malignancy (see page 282) would result in extreme dental plaque accumulation and diffuse cervical dental caries.

Typically, this disorder has an abrupt onset, although much less frequently the onset is quite gradual. There are no proven etiologic triggers, but it is human nature to want to find a "cause and effect." For this reason, many patients may want to attribute their symptoms to anything new or different that occurred at the onset of the burning sensation, but no unifying precipitating event has been identified. The various "causative" factors actually are coincidental and unrelated to the BMD.

The report of irritation with foods is variable, with some patients reporting symptom relief when eating or drinking, whereas others report exacerbation, especially with hot or spicy foods. Mucosal changes are seldom visible, although some patients will show erythema of their anterior tongue because the abnormal sensation of BMD makes them want to rub the tongue against the teeth, resulting in removal of the keratin (which is white) associated with the filiform papillae. If the dorsum is diffusely erythematous and smooth, an underlying systemic or local infectious process, such as anemia or erythematous candidiasis, should be suspected.

The symptoms of BMD often fluctuate in intensity. One frequently described pattern is that of minimal discomfort on awakening, with increasing intensity throughout the day. Other affected patients describe a waxing and waning pattern that occurs over several days or weeks, and the symptoms of oral burning, taste or texture alterations, and xerostomia may change in prominence independently of one another over time. A minority describe a constant degree of discomfort. Some individuals with BMD report that their symptoms flare in the presence of increased personal stressors as is typical with many chronic pain conditions. Usually, the condition does not interfere with sleep.

Treatment and Prognosis

If an underlying systemic or local cause for the burning sensation can be identified and corrected, the burning symptoms should predictably disappear. Almost two-thirds of patients with idiopathic disease show at least some improvement of their symptoms with pharmacologic therapies including: anxiolytics, antioxidants, antidepressants, and/or anticonvulsants alone or in combination. Some of this apparent response may be attributed to the placebo effect. Because most patients see their health care provider when symptoms are at their peak, it is realistic to assume that any treatment provided at that point will appear to be effective because the symptoms will diminish following the peak. This scenario easily could explain the wide array of purported "treatments," which often have similar reported effectiveness, but totally unrelated mechanisms of action. In addition, a significant number of patients will undergo spontaneous resolution of their symptoms, and it may appear that a particular treatment was "effective," when in fact, the BMD would have resolved on its own. For these reasons, randomized double-blind, placebo-controlled trials are required in order to identify treatments that actually are effective in treating this condition. Many of the purported treatments have significant side effects or are expensive, which are not good features for a placebo.

Systematic reviews have shown the most evidence for use of systemic or topical benzodiazepines, specifically clonazepam, for both short- and long-term relief. Alpha-lipoic acid may convey some benefit when used in conjunction with other therapies, especially gabapentin, but the effectiveness of alpha-lipoic acid alone over placebo has not been confirmed. Capsaicin topical rinse may offer some benefit, but side effects (transient increased oral burning, gastric irritation) may be intolerable.

Non-pharmacologic approaches include cognitive behavioral therapy alone or in combination with the evidence-based pharmacologic management described above, and stress management, which may be useful in those patients with existing psychological factors affecting their pain experience.

The long-term prognosis for BMD is variable. It is reported that one-third to one-half of patients experience a spontaneous or gradual remission months or years after the onset of symptoms. However, other patients may be refractory to therapeutic interventions and continue to experience symptoms throughout the rest of their lives. Even though the condition is chronic and may not always respond to therapy, patients should be reassured that BMD is benign and not indicative of a more ominous disease.

◆ DYSGEUSIA AND HYPOGEUSIA (PHANTOM TASTE; DISTORTED TASTE)

Dysgeusia is defined as a persistent abnormal taste and this condition was mentioned briefly in the previous section on burning mouth disorder. However, dysgeusia occurs independently of this association and merits additional discussion

dentlearn.ir

• BOX 18.5 Local and Systemic Factors Associated With Altered Taste Sensations (Dysgeusia) or Diminished Taste Sensations (Hypogeusia)

Local Factors

Oral candidiasis
Oral galvanism
Periodontitis or gingivitis
Chlorhexidine rinse
Xerostomia

Systemic Factors

Vitamin A deficiency
Vitamin B_{12} deficiency
Zinc deficiency
Iron deficiency
Nutritional overdose (zinc, vitamin A, or pyridoxine)
Food sensitivity or allergy
Sjögren syndrome
Chorda tympani nerve damage
Anorexia, cachexia, or bulimia
Severe vomiting during pregnancy
Liver dysfunction
Crohn disease
Cystic fibrosis
Familial dysautonomia
Addison disease
Turner syndrome
Alcoholism
Medications (200 types)
Psychosis or depression
Pesticide ingestion
Lead, copper, or mercury poisoning
Temporal arteritis
Brainstem ischemia or infarction
Migraine headaches
Temporal lobe central nervous system (CNS) tumor
Nerve trauma, gustatory nerves
Herpes zoster, geniculate ganglion
Upper respiratory tract infection
Chronic gastritis or regurgitation
Bell palsy
COVID-19 infection
Radiation therapy to head and neck

here. Interestingly, the majority of purported taste disorders are in fact disorders of smell, and deficiencies in one or both of these senses has a potentially significant impact on the patient's quality of life. Altered or phantom gustatory and olfactory function are less tolerated than hyposmia or hypogeusia, and these symptoms can be quite distressing. The COVID-19 pandemic brought new attention to the experience of alterations in taste and smell, as many infected individuals report chemosensory changes ranging from a decrease in sensation (hyposmia, anosmia, hypogeusia, ageusia) to altered perception (parosmia, phantosmia, dysgeusia.) Prior to this, estimated prevalence of taste disorders was 5%–20% and olfactory disorders was approximately 20%–30% in the general population. Higher rates of dysfunction are reported in individuals over the age of 70. In general, both taste and smell discriminatory capability decreases with advancing age.

Although dysgeusia can be associated with medications, local factors, an underlying systemic disorder, or after radiation therapy to the head and neck region (Box 18.5), many cases are idiopathic. Trauma, tumors, or inflammation of the peripheral nerves of the gustatory system usually produce transient hypogeusia rather than dysgeusia. In contrast, relatively common upper respiratory tract infections produce a temporary and mild dysgeusia in almost one-third of cases, although they seldom produce hypogeusia. Various mechanisms have been proposed in COVID-19 including both peripheral neurotropism and infection with inflammation of associated non-neuronal cells, but no clear etiology has been identified. CNS neoplasms predominantly produce dysgeusia, not hypogeusia or ageusia, and taste hallucinations are fairly common during migraine headaches, Bell palsy, or herpes zoster of the geniculate ganglion. Ischemia and infarction of the brainstem can lead to ageusia of only half of the tongue **(hemiageusia)** on the same side as the brainstem lesion.

The perception of a particular taste depends on its concentration in a liquid environment; hence, persons with severe dry mouth may suffer from both hypogeusia and dysgeusia. In addition, more than 200 drugs are known to produce taste disturbances (Table 18.1), and more than 500 are associated with salivary hypofunction or xerostomia. Dysgeusia is also a common complaint in patients undergoing chemotherapy with standard chemotherapeutic regimens, which can affect not only quality of life but also treatment outcomes due to food aversion and weight loss. The clinician should be especially diligent in assessing local, intraoral causes of dysgeusia, such as periodontal or dental abscess, oral candidiasis, and routine gingivitis or periodontitis.

Clinical Features

In contrast to hypogeusia, dysgeusia is discerned promptly and distressingly by affected individuals. The clinician must be certain that the patient's alteration is, in fact, a taste disorder rather than an olfactory one, because 75% of "flavor" information (e.g., taste, aroma, texture, temperature, and irritating properties) is derived from smell. Abnormal taste function should be verified through formal taste testing by using standard tastants that are representative of each of the four primary taste qualities (i.e., sweet, sour, salty, and bitter) in a nonodorous solution. Taste testing is more technique sensitive than olfactory testing, and additional electrical and chemical analysis of taste bud function is frequently required. Because this is outside the scope of most general practices, patients are typically referred to a *taste and smell center.*

dentlearn.ir

TABLE 18.1 Examples of Pharmaceutical Agents That May Be Associated With Altered Taste

Pharmaceutical Action	Examples
Anticoagulant	Phenindione
Antihistamine	Chlorpheniramine maleate
Antihypertensive or diuretic	Captopril, diazoxide, and ethacrynic acid
Antimicrobial	Amphotericin B, ampicillin, griseofulvin, idoxuridine, lincomycin, metronidazole, streptomycin, tetracycline, and tyrothricin
Antineoplastic or immunosuppressant	Doxorubicin, methotrexate, vincristine, azathioprine, and carmustine
Antiparkinsonian agent	Baclofen, chlormezanone, and levodopa
Antipsychotic or anticonvulsant	Carbamazepine, lithium, and phenytoin
Anti-rheumatic	Allopurinol, colchicine, gold, levamisole, penicillamine, and phenylbutazone
Antiseptic	Hexetidine and chlorhexidine
Antithyroid agent	Carbimazole, methimazole, and thiouracil
Hypoglycemic	Glipizide and phenformin
Opiate	Codeine and morphine
Sympathomimetic	Amphetamines and phenmetrazine
Vasodilator	Oxyfedrine and bamifylline

Affected patients may describe their altered taste as one of the primary tastes, but many describe the new taste as metallic, rotten, foul, or rancid. The latter two are more likely to be associated with aberrant odor perception **(parosmia)** than with dysgeusia, and this presentation is more common in COVID-19. The altered taste may require a stimulus, such as certain foods or liquids, in which case the taste is said to be distorted. If no stimulus is required, then the dysgeusia is classified as a *phantom taste*, as described in the discussion of burning mouth disorder above.

Treatment and Prognosis

If an underlying disease or process is identified and treated successfully, the taste function should return to normal. In cases related to COVID-19, two thirds of those affected will report complete recovery, approximately 20% report partial recovery, and most improvement occurs within 2 weeks after onset. For idiopathic cases there is no effective pharmacologic therapy. Dysgeusia in particular tends to affect lifestyles and interpersonal relationships significantly, perhaps leading to depression, anxiety, or nutritional deficiencies from altered eating habits. Fortunately, two-thirds of dysgeusia patients experience spontaneous resolution (average duration, 10 months). Idiopathic hypogeusia is less of a problem for the patient, but slowly tends to become worse over time. Fortunately, spontaneous resolution is still a possibility for idiopathic hypogeusia.

◆ OSTEOARTHRITIS (DEGENERATIVE ARTHRITIS; DEGENERATIVE JOINT DISEASE)

Osteoarthritis is a common degenerative and destructive alteration of the joints that traditionally was considered to be the inevitable result of simple wear and tear on aging anatomic structures, because almost every person older than 50 years is affected to some extent. This condition involves loss of articular cartilage, deterioration of subchondral bone, and also involves affiliated structures such as ligaments, muscles, synovium, and the joint capsule. Disease initiation and progression is influenced by mechanical, inflammatory, and metabolic processes. Articular cartilage becomes weakened with overload or overuse, metabolic alteration, or over time due to senescence of chondroblasts and chondrocytes. As the articular tissue is damaged, underlying bone can become exposed. Attempts at repair of both cartilage and bone also produce pro-inflammatory factors that contribute to abnormal remodeling, resulting in a dual process of degenerative destruction and proliferation.

The knee, hip, and hand are the most common sites of osteoarthritis, but this condition also affects the temporomandibular joint (TMJ). Patients with osteoarthritis of the TMJ tend to be younger than those with disease affecting the large weight-bearing joints. Prevalence of TMJ osteoarthritis is difficult to assess due to variability in diagnostic criteria and clinical assessment, but approximately 8%–16% of the population exhibit clinical signs.

dentlearn.ir

Clinical and Radiographic Features

Osteoarthritis usually involves multiple joints, typically the large weight-bearing joints mentioned above. Clinical signs and symptoms include pain, restriction of joint movement, and joint sounds. The disease is characterized by a gradually intensifying deep ache and pain, usually worse in the evening than in the morning. Some degree of morning joint stiffness and stiffness after inactivity is present in 80% of cases. The affected joint may become swollen and warm to the touch, rarely with erythema of the overlying skin. Movement restriction can be due to inflammation or deformation of the joint due to degenerative changes. Joint sounds such as crepitation (i.e., crackling noise during motion) are a late sign of the disease and are associated with more pronounced damage.

These changes are seen also when the TMJ is affected, except that patients seldom experience stiffness of the TMJ. In addition, the muscles of mastication frequently exhibit tenderness because of the overactivation and fatigue associated with "muscle guarding" (i.e., attempting to keep the painful joint immobile).

Radiographically, joints affected by osteoarthritis demonstrate mild changes early in the course of the disease. However, as the disease progresses, the radiographic presentation becomes more characteristic of arthritic joints in general with some combination of the following: erosion of the cortical outline, narrowing or obliteration of the joint space, surface irregularities and protuberances **(exostoses, osteophytes)**, flattening of the articular surface, osteosclerosis and osteolysis of bone beneath the cartilage, radiolucent **subchondral cysts,** and ossification within the synovial membrane **(ossicles).** More sensitive diagnostic techniques, such as computed tomography (CT), cone beam computed tomography (CBCT), magnetic resonance imaging (MRI), and arthroscopy, reveal the same features but in much more detail; hence, they are able to identify earlier changes. MRI is particularly useful in assessing joint effusion and the articular disc. Significant osseous imaging findings are often later complications of joint degeneration, and earlier evidence of the disease process often can be detected with arthroscopy before cartilage and bony surface changes are radiographically demonstrable. Of note, the degree of pain experience is not directly correlated with severity of radiographically evident osseous change.

Histopathologic Features

The articular disc of a joint affected by osteoarthritis can exhibit sclerotic change, calcifications, diminished number of chondrocytes, and alteration of the collagen matrix. The surface is proliferative in some areas and degenerative in others. The bone beneath the cartilage shows a loss of osteocytes, minimal osteoblastic or osteoclastic activity, fatty degeneration or necrosis of the marrow, marrow fibrosis, infiltration by chronic inflammatory cells, and perhaps the formation of a large degenerative space beneath the articular cartilage **(subchondral cyst).** Inflammation and thickening of the synovial membrane is seen, sometimes with the formation of metaplastic bone **(ossicles)** or hyaline cartilage granules **(chondral bodies),** which may number in the hundreds within a single joint. The synovial joint fluid typically contains inflammatory and degradation molecules, the levels of which have prognostic significance.

The TMJ is unique because of its fibrocartilage covering and its meniscus. The disk may be centrally destroyed, and there is little vertical clefting of the articular surface. All other features of TMJ osteoarthritis, however, are similar to those noted in other joints and are irreversible.

Treatment and Prognosis

The treatment of osteoarthritis is usually palliative and consists of analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs) to reduce pain and inflammation. Occlusal splints may reduce TMJ symptoms by relieving the pressure on the joint surfaces, and orofacial physiotherapy and hot or cold packs may be helpful to relax involved muscles. Glucosamine and chondroitin sulfate oral supplements, common therapies for large joint arthritis, may offer some benefit.

Aggressive therapy might not be indicated for this disease except in its most severe form. A 30-year follow-up investigation found radiographic evidence of continued joint destruction, but the clinical signs and symptoms were no more severe than they had been initially. In general, surgical management of TMJ osteoarthritis is not recommended unless all conservative, nonsurgical means have failed and the patient's symptoms warrant an escalation of therapy. Surgical interventions are available such as arthrocentesis, arthroscopy, and open joint surgery or total joint replacement. Arthrocentesis is minimally invasive and involves lavage of the affected joint with physiological solution, with or without hyaluronic acid or corticosteroids. Arthroscopy is a more invasive technique which allows for visualization and manipulation of the joint tissues as well as lavage. Open joint surgery and total joint replacement are reserved for patients with significant destruction affecting function.

◆ RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic autoimmune disorder characterized by nonsuppurative inflammatory destruction of synovium and subsequent destruction of the affected joints due to autoantibody formation to immunoglobulin G (IgG). Specific antibodies include anti-citrullinated protein antibodies (APCAs) and rheumatoid factor, although individuals can have RA and be seronegative for these. The presentation and clinical course and presentation are variable, similar to many autoimmune diseases. Prevalence of RA in the United States is estimated to be about 0.6%–1%, or 1.3 million individuals. Higher prevalence (5%–6%) in individuals of Native American descent has been reported.

dentlearn.ir

The etiology is multifactorial, and increased susceptibility is associated with female gender, genetics, and certain environmental factors. Genetic components are associated strongly with RA, specifically the human leukocyte antigen (HLA) locus DRβ1. However, other genetic associations also exist and vary, particularly amongst ACPA seropositive and seronegative individuals, although some variations are found in both groups. Environmental factors, such as smoking and silica exposure, as well as viral infection (Epstein-Barr virus) also have been shown to contribute to the development of RA in susceptible individuals. Of interest to oral health providers, periodontal disease also is associated with risk of developing RA; however current research does not prove causation. The proposed mechanisms are mediated by oral microbiota, specifically the induction of citrullination and formation of ACPAs by *P. gingivalis* and *A. actinomycetemcomitans*.

RA demonstrates both intra-articular and extra-articular features. Systemic manifestations are relatively common in RA and include: vasculitis, interstitial lung diseases, cardiovascular diseases, anemia, osteoporosis, and ocular involvement (scleritis, keratoconjunctivitis, and uveitis).

In contrast to osteoarthritis (see previous topic), RA begins as an attack against the periarticular structures, such as the synovial membrane **(synovitis).** A reactive macrophage-laden fibroblastic proliferation **(pannus)** from the synovium creeps onto the joint surface. This releases collagenases and other proteases, which destroy the cartilage and underlying bone. Attempted remodeling by the damaged bone results in a characteristic deformation of the joint.

Clinical and Radiographic Features

RA affects women two to three times more frequently than men. Women generally become symptomatic in middle age (40–60 years), whereas men often have later disease onset. The onset and course of the disease are extremely variable, and serology sometimes can be detectable up to 10 years before clinical manifestations of the disease. For many patients, only one or two joints become involved and significant pain or limitation of motion never develops. In others, the disease rapidly progresses to debilitating **polyarthralgia.**

Typically, the signs and symptoms become more severe over time and include swelling, stiffness, pain, joint deformity, and disability, with possible late term fibrous or bony fusion of opposing articular surfaces **(ankylosis).** Morning stiffness and joint swelling are particularly common, even in early disease. Periods of remission often are interspersed with periods of exacerbation. Symmetric polyarticular involvement of the small joints of the hands and feet almost always is present, but it is not unusual for the elbows, wrists, and knees to be affected. Involvement of the central (hips, shoulders) and axial joints, is less common, but still may occur. The hands often display a classic ulnar deviation with swan neck deformities of the fingers. **Rheumatoid nodules** are firm, partially moveable, nontender growths which occur beneath the skin near the affected joint. Although they are now less common due to earlier disease intervention, they are considered pathognomonic for the disease.

Ideally, patients are identified and treated prior to developing radiographically evident joint disease, as manifestations can occur within the first 2 years after symptom presentation. Plain films are commonly utilized for routine monitoring and diagnosis, but ultrasound and MRI have utility as well. Initial radiographic findings include tissue edema and periarticular osteopenia, whereas later findings include bony erosion and decreased joint spaces. Up to 86% of RA patients are reported to have some level of TMJ involvement, although this is often subclinical. When present, TMJ involvement is usually bilateral and occurs late in the clinical course of the disease. The signs and symptoms include stiffness, crepitation, pain or ache, tenderness, or limitation of mouth opening. Severity is variable, but swelling is less obvious than with other joints. A joint click on opening frequently is reported.

Frequently, the pain of TMJ RA is not related to motion but rather to pressure on the joint. Clenching the teeth on one side produces pain of the contralateral joint. Subluxation or ankylosis is less frequent in the TMJs than in other joints, but gross destruction of the condylar heads may be so severe that a progressive class II malocclusion and anterior open bite develop. Permanent TMJ subluxation has been reported.

Radiographically, involved TMJs demonstrate a flattened condylar head with irregular surface features, an irregular temporal fossa surface, perhaps with remodeling of the fossa itself, and anterior displacement of the condyle. Several diagnostic techniques are available besides routine TMJ radiographs. CT scans, MRI, and arthroscopy are excellent tools for assessing TMJ damage. Ultrasonography is valuable for larger joints but has been used little in TMJ disease and has few studies to demonstrate its utility and reliability at this time. Nuclear medicine scans that use scintigraphy have been largely replaced by MRI scans due to the ability to image the soft and hard joint structures, as well as associated tissues, such as musculature.

Laboratory Values

Rheumatoid arthritis may be seropositive or seronegative, and laboratory studies may be normal in about 30% of patients. As a result, negative serology does not rule out RA. Studies of particular interest in RA include anti-citrullinated protein antibodies (ACPAs), rheumatoid factor (RF), and acute phase reactants such as C-reactive protein (CRP), and erythrocyte sedimentation rate (ESR). ACPAs have been identified as specific serological markers of RA. The presence of these antibodies leads to the formation of immune complexes and subsequent inflammation of the type seen in RA. Additionally 70%–80% of patients with RA exhibit significant elevations of rheumatoid factor (RF), an autoantibody thought to be directed toward an altered host IgG antibody that is no longer recognized by the body as "self." During active phases of the disease, elevations of ESR and CRP are common. These tests are not specific for

dentlearn.ir

RA, but they are useful for distinguishing between inflammatory and non-inflammatory conditions, as well as monitoring the clinical course of RA. Additionally, antinuclear antibodies (ANAs) can be detected in many patients with RA, but this is not diagnostically specific because it also may be associated with other autoimmune diseases.

Histopathologic Features

Needle biopsy using guided techniques or arthroscopy is the most popular technique for obtaining diagnostic synovial material, and the arthroscopic technique gives the ability to directly visualize tissue being sampled. Aspiration and analysis of synovial fluid from the affected joint frequently are undertaken to rule out other forms of arthritis, but these techniques are used more commonly for large joints.

Microscopically, early cases of RA demonstrate hyperplasia of the synovial lining cells with deeper portions of the membrane showing hyperemia, edema, and infiltration by lymphocytes, macrophages, and occasional neutrophils. Older lesions show continued, often pronounced synovial proliferation and edema, with cholesterol crystals and fewer inflammatory cells. Typically, the membrane protrudes into the joint space as villi or fingerlike projections. These projections occasionally undergo necrosis, producing **rice bodies**—small whitish villi fragments composed of cellular debris admixed with fibrin and collagen. When the TMJ is severely involved, the meniscus is typically perforated or replaced completely by fibrous scar.

The rheumatoid nodule is represented by a moderately well-demarcated area of amorphous, eosinophilic necrosis surrounded by a thick layer of mononuclear cells. The mononuclear cells closest to the amorphous center are typically large and palisaded.

Treatment and Prognosis

No cure exists for RA and treatment is lifelong, focusing on strategies to suppress the disease process and prevent joint degeneration. Patient education, physical therapy, lifestyle modification, and exercise are important adjunct therapies, but the mainstay of treatment for many patients is the use of disease-modifying anti-rheumatic drugs (DMARDs). These medications are now recommended to be started as soon as the diagnosis is made. There are numerous agents available with varying side effect profiles that may necessitate treatment change. The classic and first-line DMARD is methotrexate, a folic acid antagonist. Other DMARDs include sulfasalazine, leflunomide, biologics (specifically tumor necrosis factor inhibitors), and targeted biologics such as janus kinase (JAK) inhibitors. Treatment with glucocorticoids sometimes is necessary to provide symptomatic relief or bridge therapy, but long-term use of corticosteroids is not ideal. Other adjunct therapies include NSAIDs, perhaps aided by occasional corticosteroid injections into the joint. The latter injections are used sparingly, however, because frequent use is associated with additional degenerative changes and fibrous ankylosis.

With the advent of biologic and targeted DMARDs, immunosuppressive drugs (such as azathioprine, cyclosporine, and cyclophosphamide) rarely are recommended today due to the risk of their side effect profile and increased risk for serious infections and potential induction of malignancy. However, immunosuppressive therapy may be indicated for patients who have failed all other efforts at disease modulation.

Severely damaged joints may require surgical replacement, with the goals of therapy being attenuation of pain and reduction of disability. Total joint replacement of the hips, knees, and shoulders are reported to have the highest satisfaction rates associated with surgical management of these patients. Due to the complex nature of temporomandibular joint disorders, as discussed in the next section, replacement of the TMJ may increase function but not necessarily result in resolution of pain.

◆ TEMPOROMANDIBULAR DISORDERS

Temporomandibular disorders (**TMDs**) are a group of musculoskeletal or neuromuscular conditions affecting the temporomandibular joint (TMJ), masticatory muscles, and associated structures. They are the most frequent cause of non-odontogenic orofacial pain. TMDs are generally myogenous (affecting muscle) or arthrogenous (affecting the joint) related, but at least half are considered myogenous in nature.

In the general population, prevalence of painful TMD is reported to be about 9%, and an estimated 3.6%–7% will need intervention for their condition. The OPPERA (Orofacial Pain: Prospective Evaluation and Risk Assessment) study, a large U.S. based multicenter prospective cohort study reported an annual 4% incidence of TMD, but the average descriptors of these cases were "slightly annoying" and "mild," so this number does not necessarily represent the incidence of clinically significant cases seeking treatment. Incidence is highest in the 20–40 year age range. TMDs are seen most commonly in young and middle-aged women, but this may be due to more frequent healthcare utilization among this group. Prevalence is highest in the 20–40 year age range. Of note, however, the OPPERA study has reported an equal distribution of TMD amongst male and female participants.

TMD is not an isolated facial pain, and multicenter studies have shown that there are underlying neurophysiologic mechanisms common to many chronic pain conditions. Additionally, individuals with sleep disordered breathing are reported to have a 40% increased risk of TMD development.

Although the etiology of TMD is not known, it is generally agreed that a variety of conditions may reduce the organic physiologic adaptive capacity of the masticatory system and result in TMDs. Implicated contributing conditions include trauma, systemic disease processes, skeletal morphology, joint laxity, and alterations in the peripheral and central nervous system (sensitization).

dentlearn.ir

• BOX 18.6 Classification of Temporomandibular Disorders

Muscular Disorders

- Hyperactivity, spasm, and trismus
- Inflammation (myositis)
- Trauma
- Myofascial pain and fibromyalgia
- Atrophy or hypertrophy

Joint Disorders

- Disc displacement (internal derangement)
- Hypomobility of the disc (adhesions or scars)
- Dislocation and subluxation
- Arthritis
- Infections
- Metabolic disease (gout, chondrocalcinosis)
- Capsulitis, synovitis
- Ankylosis (fibrous, bony)
- Fracture
- Condylar hyperplasia, hypoplasia, or aplasia
- Neoplasia

The classification of TMDs (Box 18.6) remains a challenge due to our limited understanding of their etiology and the lack of universally accepted diagnostic criteria for the myriad of conditions presenting as TMDs, although various classification systems such as the Research Diagnostic Criteria for Temporomandibular Disorders (DCRDC/TMD) and the International Classification of Orofacial Pain continue to be developed and validated to inform future scientific endeavors and improve patient outcomes. Our understanding of the TMDs has evolved as our understanding of the complex biopsychosocial nature of chronic pain has developed, and development of new diagnostic and treatment algorithms have improved management of chronic pain in general. Multicenter research efforts such as the long-running OPPERA clinical study attest to the idea that TMD is a complex multifactorial disease with genetic, physiological, and psychological implications.

Clinical and Radiographic Features

Pain is primary motivation for seeking treatment, but limitations in jaw movement during functional excursions, and restricted joint movement with or without associated joint noises, are frequent complaints. The pain usually is localized to the preauricular area but may radiate to the temporal, frontal, or occipital areas. The pain may present as a headache **(cephalalgia),** a ringing in the ears **(tinnitus),** an earache **(otalgia),** a toothache **(odontalgia),** or any combination of these symptoms. The pain usually is associated with the surrounding musculature and soft tissue more than the TMJ itself. Muscle splinting, a protective mechanism characterized by shortening and stiffening of muscle fibers meant to protect from further injury, can lead to involuntary CNS-induced muscular contractions **(myospasm),** or the muscle fibers themselves may become inflamed **(myositis).**

Myofascial trigger point pain is common in TMD, but it is seldom noted in other TMJ disorders. It is characterized by circumscribed regions, often referred to as taut bands within the muscle ("trigger points"), that elicit local or referred pain on palpation and may be a source of constant deep pain. In many instances, patients are aware only of the referred pain and not the trigger points themselves. The exact nature of the trigger points is not known, but they seem similar to small areas of myospasm and can, through their chronic nature, induce CNS excitatory effects. This hyperexcitability of the CNS produces the clinical findings of **hyperalgesia** (an exaggerated response to a painful stimulus) and **allodynia** (a painful response to a nonpainful stimulus), which are characteristic of chronic pain conditions.

Non-arthritic inflammatory disorders of the TMJ are characterized by continuous deep pain or ache. The pain is evoked by palpation of the affected joint or by mandibular movement, especially chewing and clenching. Both TMJs may be involved, at the same time or at differing times.

Derangements of the condyle and meniscus complex are more often associated with dysfunction **(arthropathy)** than with joint pain **(arthralgia).** Articular disc displacements can occur in an anterior, posterior, and mediolateral direction and are characterized by a variety of joint noises and limitations in jaw opening. Ligament laxity and elongation are thought to be major contributing factors to disc-condyle displacement disorders, and poor joint lubrication and osteoarthritis are implicated as well. Disc-condyle disorders include both disc displacement without reduction and disc displacement with reduction, of which the latter is more common. MRI of the TMJ complex reveals that up to 35% of asymptomatic individuals appear to have disc displacements.

Many systemic conditions are thought to contribute to the development of TMDs and must be included in the differential diagnosis of chronic orofacial pain. Inflammatory conditions of the musculoskeletal system and autoimmune-mediated connective tissue disorders (such as lupus erythematosus, rheumatoid arthritis, and progressive systemic sclerosis) are frequently co-morbid with TMDs. Similar to other chronic pain conditions, patients with TMD may report increased stress, anxiety, or depression. This is not causative but can be associated with symptom exacerbation.

The selection of imaging technique of the TMJ complex depends largely upon what type of information is needed from this adjunctive examination and how this information will affect patient management. Panoramic radiographs routinely are used as screening films for patients presenting with preauricular pain, and the interpretation of these films will influence the decision for the use of advanced imaging modalities such as CT and MRI. MRI imaging is preferred as it can assess not only bony components but also the disc and other associated structures.

dentlearn.ir

• BOX 18.7 Examples of Medications Used to Treat the Symptoms of Temporomandibular Disorders

- Oral Medications
  - Acetaminophen (with or without codeine)
  - Nonsteroidal anti-inflammatory drugs (NSAIDs)
    - Ibuprofen, Naproxen, Diclofenac* (also available in topical formulation)
  - Muscle relaxants
    - Methocarbamol, cyclobenzaprine, metaxalone
  - Benzodiazepine derivatives
    - Diazepam
  - Glucocorticoids
    - Prednisone
- Injectable
  - Glucocorticoids
    - Triamcinolone
  - Botulinum toxin A
  - Local anesthetics

Treatment and Prognosis

The natural clinical course of the TMDs is poorly understood and we cannot reliably determine which conditions will progress to more significant long-term consequences such as chronic dysfunction and chronic pain. Many TMDs are transient and self-limiting, with resolution reported in a majority of cases in 6–15 months. Cohort studies vary, 51% of patients reporting resolution in 6 months and up to 90% having resolution or sustainable symptom reduction in 12–15 months post treatment. Therefore, reversible and conservative therapies are encouraged. Conservative interventions include patient education, simple rest or immobilization of the joint, soft diet, application of cold (usually reserved for acute injuries) or heat, occlusal splints, physical therapy, and elimination of parafunctional habits, if present. Appropriate management of concurrent psychological and social stressors may be of benefit, similar to other chronic pain conditions. Various medications also have been used for TMD with some success (Box 18.7), and other therapies include dry needling or injection of local anesthetic into muscular trigger points to relieve pain, as well as botulinum-A toxin injection into the temporalis and masseter muscles for pain relief and reduction of muscle activity. However, few TMD treatments have been examined in a blinded, controlled fashion.

Surgical intervention may be required for severely affected joints, especially those with internal meniscal derangements, condylar dislocation or fracture, ankylosis, and degenerative or developmental deformities. Usually, TMD is treated conservatively for several years without improvement before surgery is attempted, although there is emerging, but limited, evidence for minimally invasive arthroscopic procedures in early treatment. Due to the multifactorial influences on TMD and high prevalence of muscular dysfunction, joint surgery may not completely resolve symptomatic TMD.

19 Forensic Dentistry

EDWARD E. HERSCHAFT

Forensic dentistry, which is also referred to as *forensic odontology*, is the area of dentistry concerned with the correct management, examination, evaluation, and presentation of dental evidence in criminal or civil legal proceedings in the interest of justice. Thus, the forensic dentist must be knowledgeable in both dentistry and law.

Classically, forensic dentistry can be considered a subspecialty of oral and maxillofacial pathology. This is analogous to the relationship in medicine between forensic pathology and pathology. The requirements of forensic dental field work, however, often demand an interdisciplinary knowledge of dental science. This has resulted in other dental specialists and general dentists joining oral and maxillofacial pathologists in providing legal authorities with dental expertise.

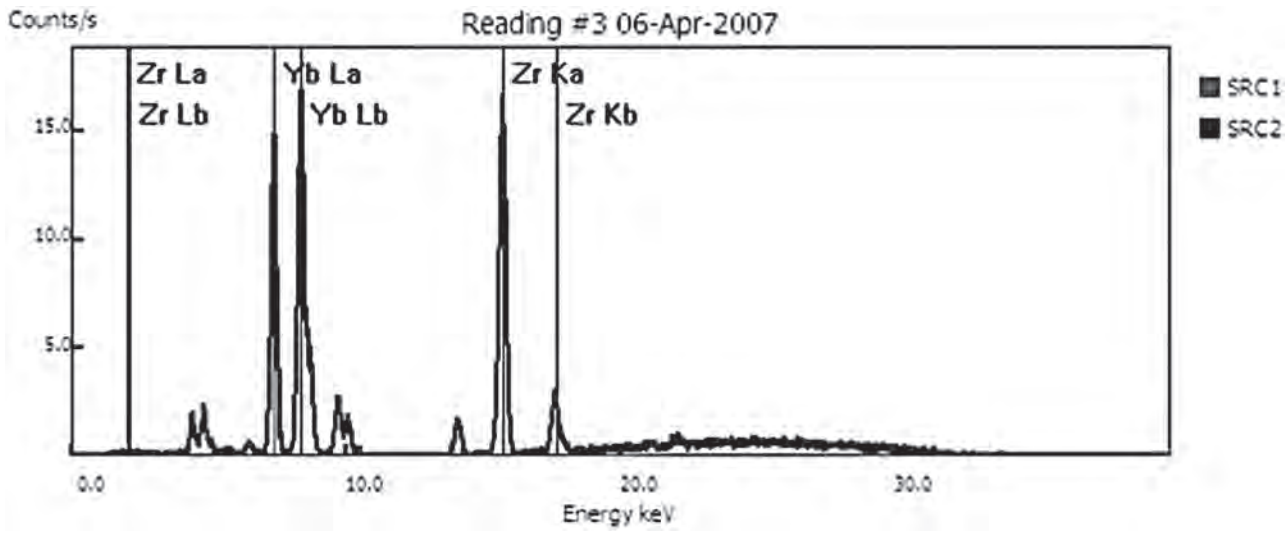
Regardless of background, forensic dentists assist legal authorities by preparing dental evidence in the following situations:

- Management and maintenance of dental records that comply with the US Department of Health and Human Services (HHS) Health Insurance Portability and Accessibility (HIPAA) Act of 1996 and guidelines established by the HHS Occupational Safety and Health Administration (OSHA). The former regulations protect the privacy of an individual's health information obtained from electronic, written, or verbal exchange of records. The latter guidelines delineate legal requirements required to document all unique dental information and ensure that these data are the foundation on which dental identification of the patient is accomplished and potential malpractice litigation is reduced.
- Identification of human remains, through the comparison of antemortem and postmortem dental information, in cases that involve the death of an individual or numerous deaths in multiple fatality incident (MFI) situations. Collection and analysis of patterned marks (bite marks) in inanimate material or injured tissue that can be analyzed and potentially compared with a specific human or animal dentition.
- Recognition of the signs and symptoms of human abuse (including intimate partner violence [IPV], elder abuse, and child abuse) and the rights and responsibilities of the dental health care practitioner when reporting such abuse.
- Presentation of dental evidence as an expert witness in identification, bite mark, human abuse, malpractice, fraud, and personal injury cases.

RECORD MANAGEMENT

The dental record is a legal document, owned by the dentist or an incorporated dental practice, which contains all subjective and objective information about the patient. In the United States, the Privacy Rule governing the use of protected health information (PHI) is regulated under the federal HIPAA act of 1996. Under this legislation the patient has the right to view original documents and obtain copies.

Despite the establishment of the Privacy Rule, the ability and necessity of forensic dentists, law enforcement personnel, medical examiners (MEs), and coroners to obtain released antemortem dental and medical records for forensic purposes without requiring consent of next-of-kin or a guardian was recognized and provided for in the HIPAA legislation—45 Code of Federal Regulations §164.512(g)(1).



Initially, demographic information is secured when the medical and dental history of the patient is obtained. Results of the physical examination of the dentition and supporting oral and para-oral structures are recorded.

In addition, the results of clinical laboratory tests, study casts, photographs, and radiographs become components of the record. With this database, the dentist can develop a thorough assessment of all of the patient's medical and dental problems. Subsequent documentation of this "problem list" facilitates the development of a plan of treatment and prognosis for the patient.

The treatment plan addresses the management of both systemic and oral problems. It can then be periodically revised and updated as problems resolve or as new ones develop. Supplemental material, such as dental laboratory authorizations, referral letters from other practitioners, statements of informed consent, written prescriptions, and insurance and financial statements, also is included and stored in the record.

The progress notes (i.e., daily log of actual treatment rendered) should contain information about restorative and therapeutic procedures provided. This information should include documentation of the specific brand of dental

dentlearn.ir

• **Fig. 19.1** The X-ray fluorescence (XRF) spectrum from a particle recovered from a cremation retort. The spectrum makes this a match for the restorative resin Four Seasons or Tetric Ceram (Ivoclar Vivadent, Amherst, NY). (Courtesy of Dr. Mary A. Bush and Peter J. Bush.)

material used in restorative procedures. This concept has forensic import because each dental restorative product contains inorganic materials, trace elements, and fillers that are unique to that product and can be detected by **X-ray fluorescence (XRF)** technology even after incineration. The XRF trace element and major element analysis of dental remains may be useful as an adjunct to traditional evaluation of dental information in some forensic settings, including cremation and dismemberment cases (Fig. 19.1). The technique was first used in an actual case to identify three victims of the Buffalo, New York Colgan Air flight 3402 accident in 2009.

Unusual physiologic and psychological reactions and the patient's comments concerning therapy are entered in the record. Summaries of telephone conversations with patients, consultants, insurance company representatives, or legal authorities should be noted. All entries should be signed or initialed by recording personnel. Changes in the record should not be erased but corrected by a single line drawn through the incorrect material. This method permits the original entry to remain readable and removes any questions concerning fraudulent intent to alter recorded information.

By 2015, medical and dental records in the United States were required to be maintained in an electronic format and numerous commercial and individually designed computer software programs have been marketed to assist physicians, dentists, health care facilities, hospitals, and insurance companies in collecting and preserving the medical and dental information of patients. The obvious advantage of electronic medical, health, or dental record (EMR, EHR, and EDR) systems is facilitation of networking and exchange of records among the different formats ("interoperability") for routine professional consultation or use in forensic identification cases requiring medical and dental records for comparison.

However, the increased use of EHRs and EDRs has also created legal, financial, and ethical issues concerning patient privacy as noted in the HIPAA regulations. Additionally, there may be a potential for insurance fraud associated with the computer enhancement of dental lesions or restorations on electronically generated dental radiographs.

The potential charge of insurance fraud associated with the enhancement of dental lesions or restorations on computer-generated or scanned **digital radiography (DR)** can be avoided if a clinician stores and maintains unaltered images. This is accomplished using programs with unchangeable, secure tagged block file extensions in their native file formats. When duplicates or copies are required, working images should be generated.

Computer-assisted management technology (e.g., WinID3 dental comparison software bridged with the Dexis DR program) has been an asset in expediting the comparison of antemortem and postmortem dental record information in MFI events, including the World Trade Center terrorist attack, the Indian Ocean tsunami disaster, the Hurricane Katrina recovery effort, and deaths caused by wildfires in the western United States. Additionally, Win ID3 is used to maintain missing person databases and is available as a free download in six different languages. Other software such as Adobe Photoshop and Mideo Systems CASEWORKSeis facilitates the superimposition of digitally scanned radiographs and photographs for comparison.

Whether preserved in written form or by using a computer database, the principles of record management describe a mechanism that ensures that dental information, which may be required to resolve a forensic problem, is properly maintained and retrievable. Additionally, records preserved in this manner are reliable evidentiary material if subpoenaed in peer review or malpractice litigation proceedings.

Time limits concerning how long records must be retained vary among the states. As a rule, states mandate that records be kept for 7–10 years. Federal legislation related to the problem of missing persons in the United States requires

dentlearn.ir

that records of pediatric dental patients be retained until the patient reaches the age of majority (adulthood). Depending on the jurisdiction, this can vary from 18 to 21 years of age.

The maintenance period for EHR and EDR patient data exceeds the duration of paper records and may vary from 20 to 100 years. Provisions for security and integrity of stored archival information in EHRs and EDRs must support ethical and legal principles regarding privacy because the technology used to input information will be unavailable to those who may need to examine this data in the future.

IDENTIFICATION

Legal situations often revolve around the establishment of a person's proper identity. Any death not certified by an individual's own physician must be referred to the medical examiner (ME) or coroner for review. However, cases requiring an **autopsy** to determine the time, cause, and manner of death represent a small percentage of cases. When required, these tasks are the responsibility of a coroner or ME. These officials are charged with the role of establishing identification; determining the cause, mechanism, and mode or manner of death; and issuing a death certificate. Besides identification of the decedent, these key issues of death investigation for the coroner or ME are defined according to the following:

- **Cause of death.** The disease, injury, or chemical or physical agent responsible for initiating the lethal sequence of events (e.g., myocardial infarction, cancer, bullet, knife, poison, ligature, lightning, and infectious agents)
- **Mechanism of death.** The pathologic process that results in death (e.g., congestive heart failure, cardiac arrhythmias, asphyxia, sepsis, exsanguination, renal failure, and hepatic failure)
- **Mode or manner of death.** According to the **NASH** classification, the mode or manner of death is considered to be **N**atural, **A**ccidental, **S**uicide, or **H**omicide. Natural deaths are caused exclusively by disease. Accidental deaths result from an environmental or human tragedy (e.g., lightning strike or vehicular incident).
- **Undetermined death.** Although the cause and mechanism of death may be resolved, the manner or mode may not be established because of decomposition, dismemberment, or postmortem destruction of the remains by insects or feral animals.

The coroner is an elected official and, depending on the laws of each state, does not necessarily have to be a physician or have advanced training in death investigation. An ME is an appointed official who is a pathologist specifically trained in forensic medicine. Many jurisdictions use forensic pathologists, and this trend has contributed to the professionalizing of a position increasingly involved with the interpretation of advanced scientific techniques requiring knowledge of toxicology, ballistics, anthropology, pharmacology, and criminalistics, as well as pathology.

A death certificate, identifying the decedent, is required before probation of a will, release of life insurance claims, or resolution of other affairs associated with the settlement of an estate. Criminal cases involving homicide, suicide, and fraudulent misidentification may also require the expertise of forensic dentists and other forensic scientists trained in identification techniques. These professionals act as consultants to the coroner or ME and assist in this aspect of a death investigation.

Besides analysis of the dentition, the most common methods of identification include personal recognition, fingerprinting (friction ridge analysis—dermatoglyphics), physical anthropologic examination of bones, and serologic and genetic (DNA) comparison techniques.

Additionally, the use of facial superimposition techniques (when the teeth are visible) and facial reconstruction techniques may also permit scientifically supported comparisons for identification. Each method has its advantages and disadvantages. However, all rely on the principle that identification is the positive correlation obtained by comparing known information about a suspect or victim with unique facts retrieved by physical examination of the suspect or victim.

Regardless of the method used to identify a decedent, the results of the antemortem and postmortem data comparison lead to one of the following four situations:

1. **Positive identification.** There is sufficient uniqueness among the comparable items in the antemortem and postmortem databases, and no major differences are observed.
2. **Presumptive (possible) identification.** There are commonalities among the comparable items in the antemortem and postmortem databases; however, enough information may be missing from either source to prevent the establishment of a positive identification.
3. **Insufficient identification evidence.** There is insufficient supportive evidence available to compare and arrive at a conclusion based on scientific principles.
4. **Exclusion of identification evidence.** Either explainable or unexplainable discrepancies exist among comparable items in the antemortem and postmortem databases. This results in inconsistencies that prevent the establishment of any identification. Exclusion may be just as important as a determination of positive identification.

Personal Recognition

Personal recognition is the least reliable method used to identify an individual. It is often based on the visual identification of a decedent by a family member, friend, or acquaintance. This process assesses artifactual material such as clothing, jewelry, keys, wallet contents, luggage, other personal effects, scars, and tattoos to determine identification. Evidence in this type of identification can be accidentally or purposely exchanged between bodies. This can occur in MFI situations or when there is criminal intent to create a misidentification in cases of identity theft or alias associated with criminal activity.

Even when a body is viewed shortly after death, distraught relatives can inadvertently misidentify the decedent. After the occurrence of postmortem changes associated with soft

dentlearn.ir

tissue decomposition, insect and burn artifact, skeletonization, or dismemberment, this method of identification may be precluded (Figs. 19.2–19.5).

Fingerprinting and Other Morphometric Means of Identification

- **Anthropometry** was the first "scientific" system police used to identify criminals. The French law enforcement officer, Alphonse Bertillon, developed this system in the latter part of the 19th century. The method was unreliable and flawed because it relied on biometric physical measurements of the head and body, individual markings including scars and tattoos, and other personal characteristics. Bertillon's anthropometry identification process was eventually replaced by analysis of the epidermal friction ridges of the fingers, palms, and feet unique to koala bears and all primates and commonly referred to as **fingerprinting.** Other evolving nondental morphometric identification techniques include:

• **Fig. 19.2** Unrecognizable partially decomposed human remains with a maxillary removable partial denture in place. Notice that the skin tissue of the neck that has been protected by the windbreaker jacket has not reached the stage of decomposition of the tissues of the exposed face. (Courtesy of Dr. Raymond D. Rawson.)

• **Fig. 19.3** A burn victim requiring identification by dental, DNA, or fingerprint methodology rather than personal recognition. (Courtesy of Dr. Raymond D. Rawson.)

• **Fig. 19.4** Decomposing human remains with infestation of blue bottle fly (*Calliphora vomitoria*) larvae covering the face. These insect maggots are important forensically, and forensic entomology can be used to estimate time of death based on their egg and oviposition timing. Notice the mandibular removable partial denture replacing three incisors.

• **Fig. 19.5** The frontal view of a skeletonized human skull. The shape of the orbits and nasal borders may be helpful in determining into which ethnic group the remains should be assigned.

dentlearn.ir

- Rugoscopy—analysis of the palatal rugae by computer-assisted photographic superimposition
- Cheiloscopy—comparison of lip prints
- Iris pattern evaluation for unique similarities.

These morphometric comparison methods, in addition to comparison of the radiographic outlines of the maxillary and frontal sinuses, are now considered unique and have become additional means of identification. By the beginning of the 20th century, forensic science had recognized that the ridge-like patterns on the fingertips and palms are unique for each person (dermatoglyphia). These friction ridges are genetically determined, and not even homozygous twins have the same patterns of loops, arches, and whorls. A principal variation in the fingerprints of twins is that they appear as mirror images of each other. The morphometric variation in combinations of the loops, arches, and whorls permits a scientific comparison of fingerprint records with the friction ridges of an unidentified decedent.

Because the fingerprint pattern is inherited, it is a static characteristic and remains unchanged throughout life. However, the friction ridges associated with a fingerprint may be missing through application of an acid or other caustic material for criminal intent. Several dermatological diseases may also result in alteration of these identifying morphometric markers. A very rare genetic mutation of the SMARCAD1 gene, which encodes only for a protein found in the skin, results in an absence of fingerprint patterns (adermatoglyphia) as well.

The inheritance of static dermatoglyphs is advantageous when one compares fingerprint identification with fluid characteristics associated with the teeth and their supporting structures. Dental patterns change as teeth erupt, exfoliate, decay, become restored, and, perhaps, are eventually extracted and replaced with implants or other prosthetic devices.

Unlike dental records, which are principally retained in private dental offices in the Americas and Western Europe, fingerprint information is maintained by governmental agencies. Several states retain records of non-criminals who work in sensitive occupations. In this regard, Nevada has a fingerprint database for employees in the gaming industry. The Criminal Justice Information Services (CJIS) Division of the Federal Bureau of Investigation (FBI) contains the largest biometric database in the world with over 130 million fingerprint records included in criminal, civil, and known and suspected terrorist formats.

Currently, these records are retained within the Integrated Automated Fingerprint Identification System (IAFIS). IAFIS permits input, matching, and retrieval of even a single fingerprint image for identification. Next-Generation Identification (NGI) technology is being developed for the FBI to expand the morphometric information contained in IAFIS to include palm print, iris, and facial identification data.

The establishment of the CJIS Division's IAFIS files permits automated computer data entry and search capabilities for matching and retrieval of fingerprint images. This information is available for electronic exchange among law enforcement agencies for identification purposes. Included in the IAFIS database are criminal and civil 10-print fingerprint records, latent fingerprint services, and subject and criminal history search capabilities. Information from this fingerprint repository is shared with international legal agencies, such as Interpol and the Royal Canadian Mounted Police.

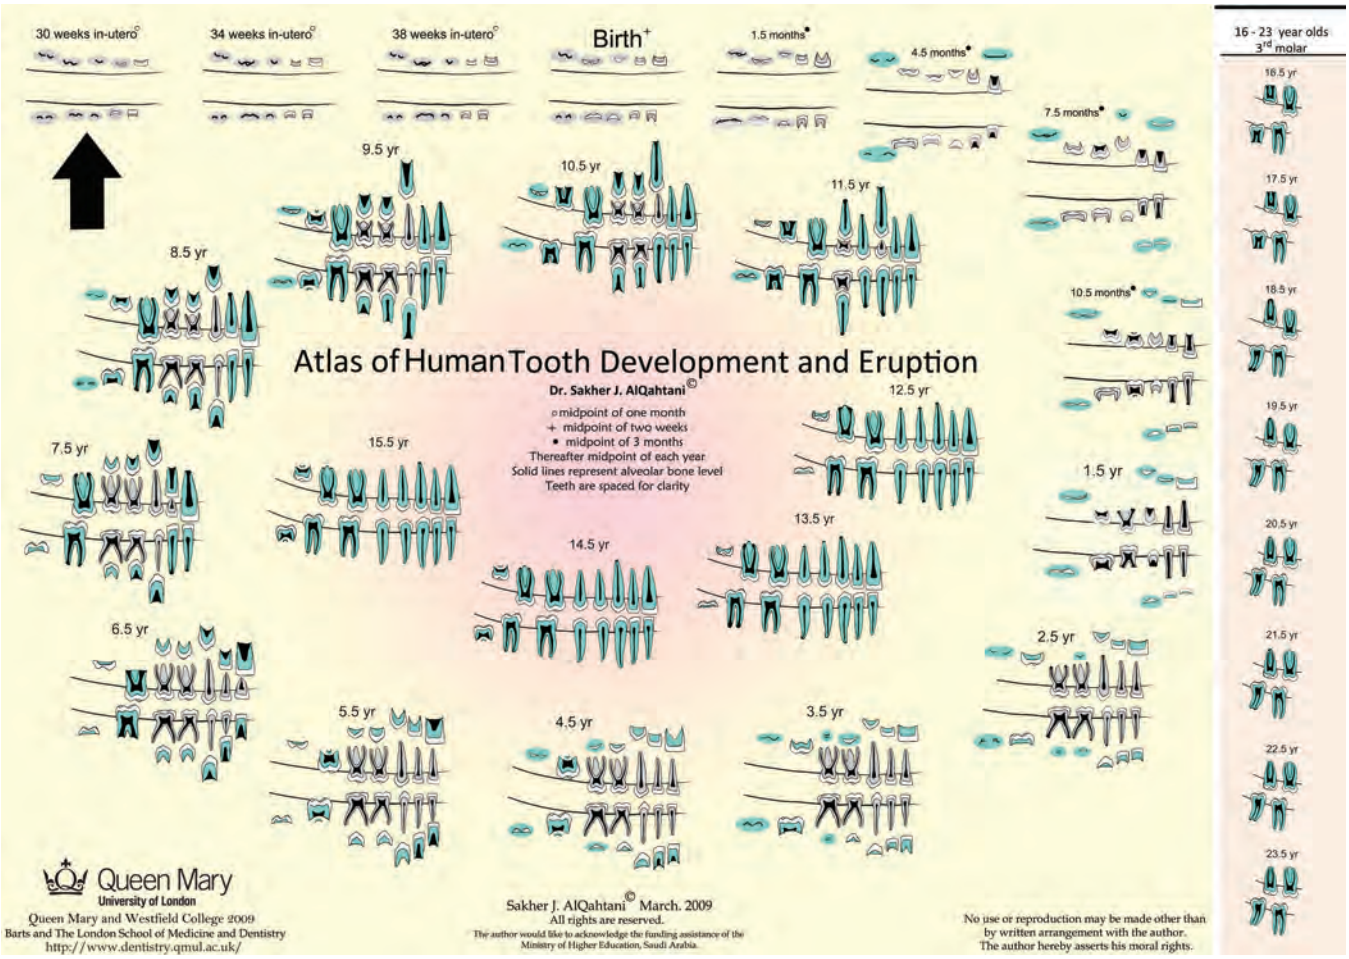
Fingerprint nomenclature is standardized in IAFIS, and all fingerprint experts use the same terminology worldwide. This advantage is not observed in dental identification, in which numerous charting and tooth-numbering systems are used. Because soft tissues decompose shortly after death, the friction ridge patterns within the epidermis, and loss of other morphometric soft tissue structures in this tissue, may not be retrievable for comparison. This is the principal disadvantage of fingerprint, lip, rugae, and iris pattern analysis for identification.

Physical Anthropologic Examination of Bones and Teeth

Forensic anthropologists and forensic dentists often work together to resolve problems associated with identification. Both disciplines are concerned with analysis of calcified structures of the body—bones and teeth. Historically, this anatomic material has assisted forensic anthropologists and dentists in determining the ethnicity, age, and sex of a person (Table 19.1). These characteristics have become less distinct in some populations as individuals from different cultures and ethnic backgrounds have intermarried and blended these genetically determined features in their offspring.

In addition to the study of osseous material and despite variations in crown and root development within the dentition, the teeth can be studied clinically, radiographically, histologically, and biochemically to determine the age of a living individual or decedent.

Forensically, this information is essential in casework involving the need to establish legal age of majority (adulthood), medicolegal age at death, clarification of the age of undocumented immigrants, age estimation of unidentified remains, and separation of comingled remains in a multiple fatality incident among others.



From fetal development to adolescence, tooth maturation intervals are the principal method of dental age assessment. Lewis and Senn emphasize that dental age estimation of children becomes more accurate when teeth having less variance are used in these analyses and data derived from multiple teeth is considered. Studies also have been performed to assess differences in crown and root formation and eruption sequences among children of both genders and various ethnic populations. In 2010, AlQahtani et al. developed the London Atlas of Human Tooth Development and Eruption. This provides the forensic odontologist with "a comprehensive evidence-based atlas to estimate age using both tooth development and alveolar eruption for human individuals between 28 weeks in utero and 23 years" (Fig. 19.6). As one approaches adulthood, age estimation acquired by analysis of the dentition can be supplemented with radiographic data obtained from the calcification centers of the hand and

dentlearn.ir

TABLE 19.1 Skeletal Anthropologic Variations Associated With Ethnic and Sexual Characteristics of the Skull

	Ethnic Characteristics		
	European	**African**	**Asian/Native American**
Width	Narrow	Narrow	Broad
Height	High	Low	Intermediate
Profile	Straight	Prognathic	Intermediate
Orbit	Triangular/teardrop	Square	Circular
Nasal opening	Tapered	Wide	Rounded
Palate	Narrow	Wide	Intermediate

	Sexual Characteristics	
	Male	**Female**
Size	Large	Small
Glabellar (supraorbital) ridges	Pronounced	Not developed
Mastoid process	Large	Small
Occipital area	Pronounced muscle lines	Minimal muscle lines
Mandible	Larger, broader ramus	Smaller
Forehead	Steeper, slopes posteriorly	Rounded, more vertical

dentlearn.ir

wrist, ribs, clavicles, and other bones to determine the precise age of a person younger than 20 years of age.

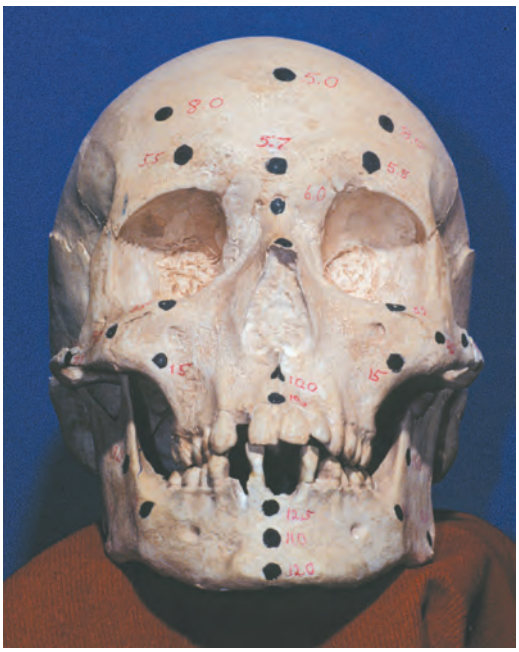
Biochemical laboratory procedures or assessment of dental post-formation changes are used to determine the age of adult individuals. Historically, dental post-formation changes of adult teeth included the study of their ground sections for variations in patterns of:

- Attrition
- Periodontal attachment
- Secondary dentin
- Cementum apposition
- Root resorption
- Transparency of root dentin

This approach, developed by Gustafson in 1947, has been modified to determine which of these factors are most significant—secondary dentin and transparency of root dentin.

Additionally, these contemporary methods of dental post-formation analysis have been supplemented by those relying on the following techniques:

- Evaluation of the rate of racemization of levels of metabolically stable aspartic acid enantiomers in enamel and dentin to determine an exact age.
- Occlusal tooth wear which can provide reliable estimates of age to within 3–5 years. Often, anthropologic analysis is helpful in arriving at a presumptive identification based on these criteria.



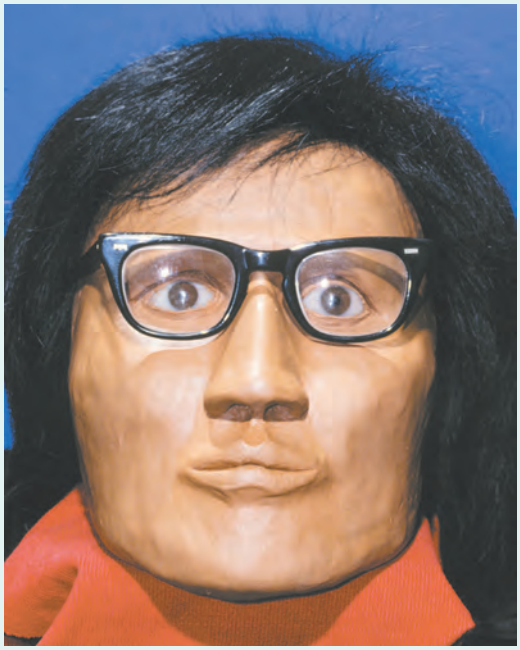
There are variations in the calcification and eruption patterns among various ethnic and cultural groups, and studies have been undertaken to delineate these differences further. After the third molars, long bones, and bones of the wrist and hand are completely developed, evaluation of biochemical components of the calcified structures and collagen is the most accurate method for determining chronologic age.

Methods that rely on an analysis of the rate of racemization of the stereoisomers of aspartic acid in enamel and dentin can be used to determine an accurate chronologic age. This is related to the fact that the change from the L-form of this amino acid to its mirror image D-form occurs over time. Thus, the ratio of the L- to D-forms of aspartic acid in the dentition is directly related to the age of the individual. Often, anthropologic and dental age analysis is helpful in arriving at a presumptive identification based on the criteria noted previously.

In 2022, after rigorous review, the Organization of Scientific Area Committees for Forensic Science (OSAC) Registry, administered by the National Institute of Standards and Technology (NIST), accepted the ADA Technical Report No. 1077 for Human Age Assessment by Dental Analysis.

Positive identification may be achievable when the skull and facial bones are used as a foundation to reconstruct the facial soft tissues (Figs. 19.7–19.9). Three-dimensional (3D) computer images, computed tomography (CT) images, and radiographs have even been used in the replication of the face of Europe's oldest mummified human, a male dubbed Ötzi, whose 5300-year-old remains were removed from glacial ice in the Ötztal Alps on the Austrian-Italian border.

With knowledge of the anatomic relationships between the skull and face, antemortem facial photographs or radiographs can be superimposed for comparison with the skull of an unknown. Video superimposition with two television cameras and an electronic mixing device has been used successfully to overlay a photograph of a human face on an image of a skull for identification. The development of



• **Fig. 19.7** Reconstruction of the facial soft tissue uses predetermined, standard anthropologic thickness measurements for specific points around the face. These measurements are based on variables that are related to ethnic and sexual characteristics. (Courtesy of Dr. Cleve Smith.)

• **Fig. 19.8** The soft tissue thickness points can be connected with sculpting clay or digitized on a computer screen. The ultimate result of these techniques is a re-creation of the contour of the soft tissue features that permits a visual identification. (Courtesy of Dr. Cleve Smith.)

• **Fig. 19.9** The width of the mouth is related to the interpupillary distance. The length and shape of the nose are determined by the relationship between the inferior and superior nasal spines. If known, then the addition of a specific hairstyle, eyeglasses, and eye color can further individualize a facial reconstruction. (Courtesy of Dr. Cleve Smith.)

computer software programs capable of superimposition has further facilitated the process.

The anterior dentition of the skull can be overlaid and compared with a smiling antemortem photograph. The shapes and positions of the individual teeth and their relationships to each other have been considered distinctive enough features on which to base identification, as have certain significant cranial and facial landmarks, including the orbits, nasal openings, malar eminence, and chin. Prosthetic joint replacements, intraosseous and dental implants, and radiographic signs of prior bone fracture are other anthropologic findings that can be used to facilitate identification.

Additionally, prosthetic devices, implanted defibrillators and pacemakers, and osseous implants, with the exception of dental implants, are designated with individual identification code numbers provided by their manufacturers. These codes can be visualized in the various devices and are useful in identifying individuals in cremation and dismemberment scenarios when the teeth and fingerprints are not available for evaluation.

Serologic and Genetic (DNA) Comparison

Every individual is unique by virtue of his or her chromosomal DNA—a polymer structured as a double helix and composed of four different nucleotides. The polymorphic sequencing of these nucleotides along the two strands of the DNA molecule accounts for the genetic diversity of all living things. This "ultimate identification material" was first used forensically to obtain a conviction in a criminal case in 1986, and DNA comparison has since become an accepted forensic method to resolve problems of identification.

Before 1986, comparison of antigenic markers found on red blood cells (RBCs) and in body fluids of secretors of these markers among the human population was traditionally used as a means of *exclusionary* (*exculpatory*) evidence. Because the ABH antigenic surface markers of RBCs are not discriminatory, this type of evidence was primarily used to exclude a suspect or victim when negative comparative results were achieved. Positive comparisons were justified only to place the suspect or victim in a population of individuals having similar serologic antigens.

Although DNA has become the principal biologic substance used to effect a positive identification, antigenic surface markers A, B, and H of the ABO blood group system, as well as various components of the rhesus (Rh) and Lewis systems, continue to be accepted for medicolegal comparison. The ability to secrete the ABH antigens in saliva and other body fluids is genetically determined, and more than 80% of individuals are secretors. With appropriate laboratory tests, even dried samples of fluid and blood can be analyzed for these markers.

DNA found in human cells is composed of chromosomal and mitochondrial DNA (mtDNA). Two copies of chromosomal DNA are incorporated into the nuclei of a person's cells by DNA provided from both parents. However, hundreds of copies of mtDNA are contained in the cytoplasm of these cells. This DNA is only maternally transferred and can be isolated from cells without nuclei, such as RBCs. Unlike nuclear DNA, mtDNA is single stranded and circular. Because there is no mixing of sequence types from generation to generation in maternally transferred mtDNA, it can be compared with that of distant maternal relatives to effect identification when other reference sources are unavailable.

Restriction fragment length polymorphism (RFLP) and polymerase chain reaction (PCR) analyses are the principal laboratory techniques used to compare and evaluate fragments of DNA material from a suspect or victim's biologic forensic specimens (e.g., semen, vaginal fluid, teeth, soft tissues, and saliva). Both are extremely accurate, precise, and reproducible; these methods are used when the conditions of the sample DNA presented dictate the need for their respective advantages.

RFLP methods result in splitting source DNA into thousands of fragments using "biologic scissors" known as *restriction enzymes.* Fragment size varies among individuals related to the variable number of tandem repeats (VNTR) of base pairs. These short segments of DNA contain a number of repeat units that differ among individuals. After gel separation of the fragments and transfer to a nylon mesh, specific DNA fragments are identified using oligonucleotides labeled with radioisotopes. Analysis of a series of different VNTR loci permits generation of an individual DNA profile.

A match of four or more VNTR loci is consistent with a positive match between DNA evidence gathered from suspect, victim, or crime scene evidence. The RFLP method requires large amounts of high molecular weight DNA, a major disadvantage. Small DNA samples (<100 ng) or degraded evidence in which the DNA has become denatured

dentlearn.ir

because of extreme heat or pH variation requires an analytic method other than RFLP.

The evaluation of minute quantities of DNA or DNA that has undergone degradation can be accomplished with the highly sensitive PCR test. Using this laboratory technique, smaller VNTR loci of a specific DNA sequence can be amplified into enough copies for sufficient analysis. Because of its high degree of sensitivity, PCR analysis has been used to evaluate small amounts of DNA from a suspect's clothing left at the scene of a crime, as well as from bone fragments from the Vietnam War. DNA amplification of microsatellite loci (referred to as *STRs*) and minisatellite loci (or *LTRs*) using PCR, is referred to as *AmpFLP analysis.*

The hard and soft tissues of the oral cavity and saliva are often good sources for DNA material. However, if the teeth or other hard structures of the mouth are to be used for the collection of DNA evidence, then the identification value of these structures should be considered (beyond their ability to yield a harvest DNA). A tooth or jaw fragment capriciously destroyed can result in the loss of valuable radiographic and anatomic sources for eventual dental identification. Besides the obvious source of DNA from human tissues, the forensic dentist often considers the evaluation of chewed gum, cigarette remains, licked envelopes, stamps, or similar inanimate objects as potential sources for DNA evidence using PCR analysis described previously.

Regardless of the surface from which DNA evidence may be harvested, the two-swab protocol developed by Dr. David Sweet and others at the Bureau of Legal Dentistry, University of British Columbia is the recovery method of choice:

- A sterile cotton swab is moistened with distilled water and rolled over the surface of the skin or object using moderate pressure and circular motion.
- This swab is air dried.
- A second *dry* cotton swab is rolled over the *same* surface of the skin or object using moderate pressure and circular motion *to absorb all moisture left by the first swab.*
- This swab is also air dried.
- Both swabs are placed in properly labeled storage containers and submitted to the laboratory for frozen storage at −20°C (−4°F).

Control samples may be collected from whole blood, autopsy tissue samples or oral buccal swabs from a living individual.

Passage of the DNA Identification Act of 1994 and the establishment of the FBI's National DNA Index System (NDIS) in 1998 have facilitated the exchange and comparison of DNA profiles among federal, state, and local crime laboratories in the United States. This is accomplished electronically through the FBI Laboratory's Combined DNA Index System (CODIS). Through the CODIS computer program's forensic and offender indexes, biologic evidence from crime scenes can be linked to DNA profiles of individuals convicted of sex offenses and other felonies.

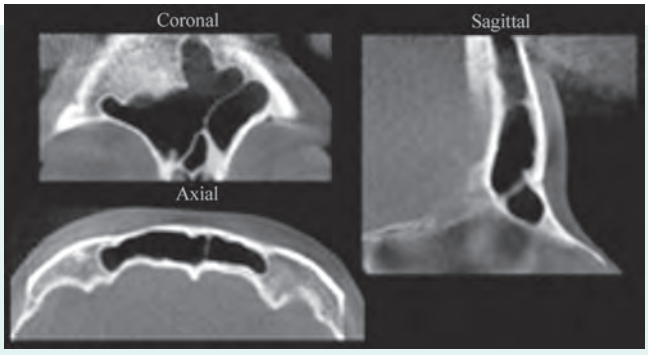
As of April 2021, the total number of DNA profiles contained in the FBI CODIS databases reached 20 million. Since its inception, approximately 550,000 successful comparisons ("hits") have been made among cases in which the CODIS system was activated. This represents a 98% success rate linking DNA from a crime scene with similar material from the convicted offender profiles. CODIS software has also been helpful in the identification of missing and unidentified individuals.

The US Department of Defense has initiated a policy of obtaining DNA samples on all military personnel. This DNA "fingerprint" has significantly reduced the possibility of another unknown soldier among future military casualties. Despite the positive effects of DNA evidence in resolving questions of identity, the technique is not without controversy. Challenges have been made by population geneticists, concerned about random matching and variations among ethnic subgroups.

Dental Evaluation

Basic Principles

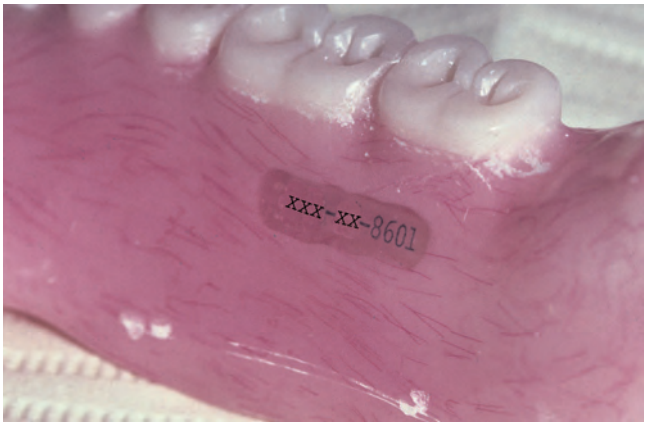
In an identification case, the principal advantage of dental evidence is that, like other hard tissue, it is often preserved indefinitely after death. Although the status of a person's teeth changes throughout life, the combination of decayed, missing, and filled teeth is measurable, reproducible, and comparable at any fixed point in time. Therefore, like the comparison of unique patterns in a fingerprint and other soft tissue morphometric structures, a scientific, objective analysis of antemortem and postmortem dental variables is achievable through an assessment of the presence and position of individual teeth. Thus, these respective anatomic, restorative, and pathologic dental components provide the database for the antemortem and postmortem comparison of dental structures (Fig. 19.10). For example, a unique dental restoration, such as seen in Fig. 19.11, might provide an important clue in making an identification. In addition, the legal community accepts the fact that dentists can recognize procedures that they have performed. Morphometric soft tissue patterns and the outline of the maxillary and frontal sinuses are also considered unique and can support the



• **Fig. 19.10** The combination of decayed, missing, and filled teeth, along with unique anatomic and pathologic findings, provides the database for comparison in a dental identification. Note the microdont in the maxillary left quadrant.

dentlearn.ir

• **Fig. 19.11** Unique dental restorations or prostheses may contribute important information allowing the identification of an individual.



• **Fig. 19.12** The outline shape of the frontal sinus is a unique morphometric factor that may be used in human identification when comparing cone-beam computed tomography (CBCT) and anterior-posterior radiographs of a known individual with those of an unknown person or decedent. (Courtesy of Dr. Robert Danforth.)

rationale for comparison of ante- and postmortem radiographs of the head (Fig. 19.12).

Problems associated with dental identification information are often related to acquiring and interpreting antemortem records. Most antemortem dental records are retrieved from private sector dental providers. However, dental records may be recovered from insurance carriers, dental schools, hospitals, clinics, state and federal prisons, military files, and the FBI National Crime Information Center (NCIC) databases.

To initiate a request for antemortem records, a putative (suspected) identification is required. Reports of missing and unidentified persons, obtained from law enforcement agencies, are the principal source for this material. Thousands of victims who cannot be identified by fingerprint methods remain unidentified because a putative identification has not been established.

The FBI-NCIC computer registry of missing and unidentified persons was established to help rectify this problem. This computer system maintains demographic, dental, and medical information on missing persons. It attempts to match these data with similar facts obtained from unidentified bodies. The latter information is submitted by various

• **Fig. 19.13** Denture identification is accomplished by inserting a typed name or code number (i.e., Social Security number or hospital patient number) in an area of the denture that will not interfere with the aesthetics of the prosthesis. This procedure is performed in the laboratory during the final acrylic pack. Information also can be engraved in the framework of an all-metal appliance.

investigative and legal agencies. Potentially, the otherwise unidentifiable victims of random violence, serial homicides, terrorist acts, and child abduction can now be identified without the need to determine a putative identification. A disadvantage of the NCIC computer identification system is that it does not have the capability to identify possible decedents based solely on dental information.

The National Dental Image Repository (NDIR) has been established to address this issue. Law enforcement agencies can voluntarily post supplemental dental images related to NCIC Missing, Unidentified, and Wanted Person records on the NDIR secure website. Thus, access, retrieval, and review of dental information by qualified forensic odontologists who are members of the NDIR Review Panel can facilitate dental comparisons. The NDIR website is located at Law Enforcement Online (LEO) at http://cgate.leo.gov. This repository permits law enforcement, criminal justice, and public safety authorities to maintain a national and international method of electronic communication, education, and sharing of dental information.

The Armed Forces, Department of Veterans Affairs, and many states require that identifying markings be placed on removable dental prostheses (Fig. 19.13). The American Dental Association and the National Association of Dental Laboratories (NADL) also support dental prosthetics identification (DPid). DPid also links with the US Food and Drug Administration's (FDA) Unique Device Identification (UDI) requirements. It is an attempt to provide a basis for identification among the substantial population of completely or partially edentulous individuals in the United States and internationally.

Identifying markings in dental prostheses are important because even if dental records of an edentulous person can be obtained, they may not reflect the current status of the ridges and alveolar bone. Commonly used information for identifying removable dental prostheses should include the following UDI documentation requirements:

dentlearn.ir

- A unique identification number
- Country of origin
- Dentist/Dental Laboratory contact information
- Patient identification
- Manufacturing date and subsequent changes
- Brand names of components.

This information is linked to a secure database via a 2D Code (Data Matrix) for comparison.

Even when a suspected identification is achieved, it may still be difficult to secure antemortem dental records. The family or acquaintances of the victim may not know where dental treatment was sought. Reviewing the putative victim's canceled bank checks or medical deductions on tax records may be helpful in locating antemortem dental records in such cases.

Although records obtained from institutional or governmental dental facilities routinely indicate all restored teeth, this is not true of charts forwarded from private dentists. In these instances, previously restored teeth often are not charted unless the current dentist intends to re-treat them. Therefore, in these records, the antemortem radiographs and progress notes become the principal sources for dental information.

Unfortunately, the nomenclature associated with dental charting systems is not standardized (Table 19.2). In 1984, the American Dental Association adopted the Universal Tooth Numbering System. All insurance companies, the Armed Forces, dental schools, and most dentists in the United States now use this system. It should be used in all forensic dental cases.

In the Universal Numbering System, a consecutive number from 1 to 32 is assigned to the adult dentition. It begins with the maxillary right third molar and ends with the mandibular right third molar. The deciduous dentition is identified by letters from A to T, beginning with the maxillary right deciduous second molar and ending with the mandibular right deciduous second molar. Thus, the quadrants are identified in a clockwise direction, beginning with the maxillary right.

Other tooth-numbering methods include the Zsigmondy/Palmer System and the Federation Dentaire Internationale (FDI) Two-Digit System. Each uses a different coding technique to identify dental quadrants and specific teeth.

The Zsigmondy/Palmer System stresses the anatomic likeness of the eight tooth types in each symbolically identified dental quadrant. Homologous permanent teeth are assigned the same number from 1 to 8. Deciduous teeth are assigned letters *A* through *E*.

The FDI Two-Digit System is endorsed by the World Health Organization (WHO) and is used in most developed countries, except the United States. The first digit represents the quadrant. Quadrants 1 to 4 are assigned for permanent teeth; 5 to 8 represent quadrants for the primary dentition. As in the Universal Numbering System, the quadrants are identified in a clockwise direction, beginning with the maxillary right. The second digit designates the permanent tooth type from 1 to 8, or deciduous tooth type from 1 to 5.

TABLE 19.2 Dental Numbering Systems

Permanent Teeth

Maxillary Right	Maxillary Left
Mandibular Right	Mandibular Left

Universal Numbering System

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
32	31	30	29	28	27	26	25	24	23	22	21	20	19	18	17

Zsigmondy/Palmer System

8	7	6	5	4	3	2	1 | 1		2	3	4	5	6	7	8
8	7	6	5	4	3	2	1 | 1		2	3	4	5	6	7	8

Federation Dentaire Internationale Two-Digit System

18	17	16	15	14	13	12	11	21	22	23	24	25	26	27	28
48	47	46	45	44	43	42	41	31	32	33	34	35	36	37	38

Deciduous Teeth

Universal Numbering System

A	B	C	D	E	F	G	H	I	J
T	S	R	Q	P	O	N	M	L	K

Alternate Universal Numbering System

4D	5D	6D	7D	8D	9D	10D	11D	12D	13D
29D	28D	27D	26D	25D	24D	23D	22D	21D	20D

Zsigmondy/Palmer System

E	D	C	B	A | A		B	C	D	E
E	D	C	B	A | A		B	C	D	E

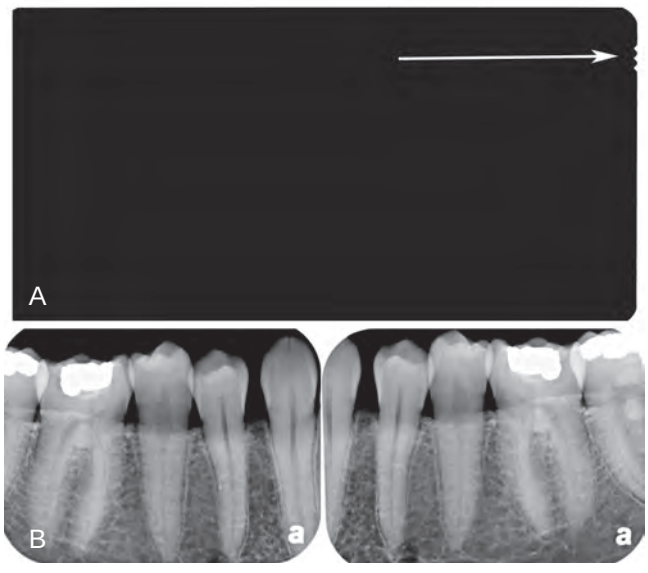
Federation Dentaire Internationale Two-Digit System

55	54	53	52	51	61	62	63	64	65
85	84	83	82	81	71	72	73	74	75

Thus, in the Universal Numbering System, tooth 12 is the maxillary left first bicuspid. In the FDI Two-Digit System, tooth 12 (one-two) is the maxillary right lateral incisor. In the Zsigmondy/Palmer System, all lateral incisors are designated with a No. 2 code. The position of a specific No. 2 tooth is diagrammatically indicated by a symbolic quadrant.

Unless the forensic dentist knows which system has been used to encode the teeth in the antemortem record, all teeth should be referred to by their actual names. This method will prevent errors because all dentists use the same anatomic nomenclature when referring to individual teeth.

Dental identification problems may be further compounded because dental radiographs can be mounted and viewed from right to left or vice versa. Intraoral radiographic



dentlearn.ir

duplicating film does not contain a raised dot to assist the dentist in orienting the film for mounting. The lack of this orienting device can lead to transposition of dental evidence and potential misidentification based on an incorrect comparison. Besides the lack of a raised dot, panoramic radiographic duplicating film can be detected because of its single-sided emulsion and series of notches on one edge to indicate that the image is not an original (Fig. 19.14, *A*).

Additionally, when using intraoral digital sensors, the operator must be careful not to inadvertently expose the device from the wrong side. This orientation error can remain undetected because the "**a**" placed on the sensor (which serves the same function as the raised dot on radiographic film) always appears in the same position after processing regardless of which side of the sensor has been exposed (see Fig. 19.14, *B*).

With the advent of aesthetic materials for posterior restorations and the reduction in the prevalence of caries, it may be difficult for the forensic dentist to determine whether restorations are present by simple visual assessment of the teeth. In addition, the postmortem dental evaluation is often performed in an autopsy room, temporary morgue, or funeral home. In these locations, proper lighting and access to dental instruments, supplies, and equipment that can facilitate analysis of the oral structures, are not readily available for detailed examination.

Often, there are additional demands for immediacy in providing a coroner, ME, or other legal agent with the results of a dental identification. These demands further compound the forensic dentist's technical and stress-related problems while performing the tasks related to this discipline. Because of the previous caveats, the forensic dentist should prepare an equipment kit (Box 19.1). The kit should be portable, containing instruments, supplies, and equipment specifically required for the performance of dental procedures in an autopsy room environment.

• **Fig. 19.14 A,** Panoramic duplicating film has a series of notches (*arrow*) on one edge to indicate that the image is not an original. **B,** When phosphor digital plates are inadvertently exposed from the wrong side, the error may not be detected because the "**a**" position marker always appears in the same location after processing regardless of which side of the sensor has been exposed. This problem can be prevented by placing a metal indicator on the side of the device that should not be exposed. (Courtesy of Dr. Richard A. Weems.)

Guidelines for Dental Identification

Although dental information can support the identification of a visually recognizable body, identification of dental remains is especially helpful when a decedent is skeletonized, decomposed, burned, or dismembered. Because each of these forensic situations presents different technical problems to the dentist, Body Identification Guidelines have been established by the American Board of Forensic Odontology (ABFO). The purpose of delineating these criteria is to assist dentists in comparing antemortem and postmortem dental information. Furthermore, the possibility of misidentification is reduced in both routine and mass-disaster cases.

Under the Body Identification Guidelines, provisions are made for the following:

- Examination of the postmortem dental remains in compliance with infection control and Occupational Safety and Health Administration (OSHA) requirements

• BOX 19.1 Suggested Instrument Kit for Forensic Identification

Dental explorers
Dental mirrors
Periodontal probes
Bite blocks
Tissue scissors
Osteotome
Rubber air/water syringe
Cotton swabs
Gauze
Flashlight or headlamp
Specimen containers
Scalpels and blades
Cheek retractors
ABFO No. 2 ruler
Bone mallet
Photographic mirrors
SLR film-based camera
Digital camera
Photographic film, digital memory card
Radiographic film and digital sensors
Rubber, latex, and nitrile gloves
Tissue forceps
Tissue clamp
Tongue clamp
Disclosing solution
Stryker saw
Writing instruments
Case labels
Appropriate charts
Masks and HEPA filter
Handheld portable radiation emitting device

ABFO, American Board of Forensic Odontology; *HEPA*, high-efficiency particulate air; *SLR*, single-lens reflex.

dentlearn.ir

- Examination of antemortem dental records
- Comparison of all dental and paradental information from the two databases
- Development of a written report listing conclusions and an opinion regarding the strength of the identification, for example positive, presumptive, insufficient, or exculpatory (Exculpatory evidence is favorable to the defendant in a criminal trial, clearing the defendant of guilt.)

Postmortem Examination

The postmortem dental evidence is gathered by photographic, radiographic, and charting techniques. All records should include the case number, date, demographic and anthropologic information, the name of the authority that is requesting the dental examination, the location of the examination, and the name of the examining dentist.

Photographs should be taken of full head and face views. Images of the occlusal planes of both dental arches and individual views of unusual pathologic or restorative findings are also obtained. A digital 35-mm single-lens reflex (DSLR) camera and appropriate electronic flash and lens systems for close-up photography should be used. Basic digital images should include color exposures which can also be converted to black and white images for analysis.

Jaw resection is no longer a commonly accepted method employed to facilitate access to the postmortem dentition. This change in practice has resulted from ethical and medicolegal challenges and concerns regarding its use. However, postmortem examination, dental impressions, and radiographs can be obtained by relieving the mandibular muscle attachments and those of the temporomandibular joint (TMJ). This procedure permits access to the oral structures by 180-degree reflection of the lower jaw. If requested by the coroner or ME, then the dental specimens from the autopsy may have to be retained and preserved in a 10% formalin solution.

The guidelines for body identification recognize that the dentist and dental auxiliary personnel involved in performing forensic dental procedures do so at the request and direction of a legal authority, such as a coroner or ME. Therefore, it is only with the permission of these individuals that techniques involving postmortem facial dissection or jaw resection are performed by the forensic dentist to achieve complete access to dental tissues.

These measures are used most often in decomposed, dismembered, or incinerated bodies to make postmortem dental charting and radiographic examination easier. Mandibular reflection or soft tissue dissection may be necessary in visually recognizable (viewable) bodies when the oral cavity is inaccessible because of rigor mortis. In this situation the procedure is performed from an inframandibular approach.

In those rare instances when the forensic dentist is authorized to remove the jaws this task is accomplished with a reciprocating (Stryker) saw or osteotome and mallet, causing a Le Fort I fracture of the maxilla. The dissection instruments are placed above the inferior nasal spine and malar processes to ensure that the apices of the maxillary teeth are not transected. Similarly, if the mandible is not removed by disarticulation, then cuts into the mandibular rami should be high enough to prevent damage to impacted third molars.

While obtaining postmortem radiographic evidence, the forensic dentist may encounter technical obstacles that need to be addressed. It often is difficult to place intraoral radiographic film or digital radiographic sensors securely against the mandible or maxilla of a deceased individual. A modified Rinn XCP self-supporting film holder, which does not require active participation from the examinee, has been developed for postmortem identification. Because all dental evidence may eventually be required to be relinquished in court, the use of double-pack intraoral radiographs permits the forensic dentist to retain a set of films. Digital radiographic exposure and storage of images precludes this problem.

When the jaws cannot be resected postmortem changes in rigor mortis cases and in bodies that are partially decomposed may prevent the positioning of intraoral periapical radiographic films or digital sensors. Occlusal films, 5X7 lateral plates, and panoramic radiographs are often used in these situations. Additionally, charting of dental evidence in fourth-degree burn cases, in which charring of soft tissues results in contraction of the muscles of mastication, may preclude the placement of these devices. With the coroner or ME's permission, the entire skull can be removed from the rest of the remains and placed in a panoramic radiographic machine.

Fifth-degree burn cases result in cremation (sometimes referred to as **cremains**). Dental evidence may be lost or compromised in these cases as temperatures range between 870 and 980°C (1600 and 1800°F). Most cremated skeletal and dental remains are structurally recognizable, and it is only the processing of these structures in commercial crematoria that creates the ash most associated with this process. The composition of bone and teeth is principally inorganic calcium hydroxyapatite. Thus, these structures can become very fragile, can crumble easily, and require extreme care when handled in severely burned remains.

Fragmentation of dental structures in dismemberment cases and total loss of soft tissues in skeletonized remains necessitate alterations in routine radiation exposure settings. Generally, when radiographs of this type of material are taken, 10-mA and 65-kVp exposure settings are used. Because there is little or no soft tissue, standard exposure times or impulse settings are halved to prevent overexposure of the radiograph.

The maxilla can be split along the midsagittal suture, and each half can be placed horizontally on an occlusal film. This projection can be used to simulate antemortem panoramic radiographs or bite-wing views. Similar exposures can be obtained from the mandible by mounting the jaw on the edge of a table or bracket tray and placing an occlusal film under the supporting half. Exposures of the opposite side of the arch are made by simply flipping the mandible and repeating the procedure.

Databases have been created from elemental analysis or chemical characterization of various dental restorative and endodontic materials using scanning electron microscopic/energy-dispersive X-ray spectroscopy (SEM/EDS) and X-ray fluorescence (XRF) techniques. Referral to these resources

dentlearn.ir

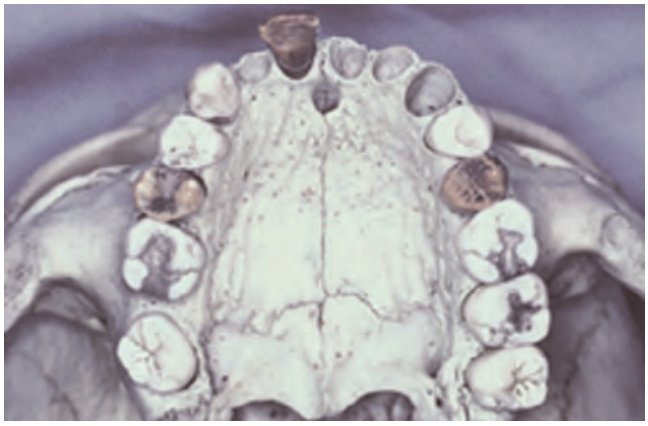
may assist the forensic odontologist in the postmortem analysis of dental restorations when severe destruction of the dentition or cremation precludes the efficacy of using more traditional analytical methods.

The charting (odontogram) of the postmortem dentition should provide for situations in which teeth are missing after death. If such a discrepancy remains unexplained, then it may preclude the positive identification of the body. Scavenging animals or poor investigation of a crime or disaster scene can cause postmortem loss of teeth. Environmental conditions at or around the time of death, such as tidal action in a saltwater drowning, can also contribute to perimortem loss of teeth. When teeth are lost in this manner, the crest of the alveolar bone remains intact. In addition, there is no reossification of the socket (Fig. 19.15). This pattern is inconsistent with what is observed after extraction of a tooth.

Postmortem tooth loss is associated with decomposition of the periodontal ligament. Thus, the tooth simply falls out when the body is moved by feral or wild animals or during crime scene recovery efforts.

Antemortem Record Examination

Antemortem records are usually obtained directly from the police, coroner, or ME. Before accepting this evidence, the forensic dentist should determine that the records indicate the name of the person to be identified and the name and address of the submitting dentist. In addition, most jurisdictions require an evidence transfer document to be signed. This form indicates that the continuity of evidence has been maintained by specifying where and when the evidence was obtained, who secured the evidence, and who was in control or currently in possession of this material.



Several antemortem records of the same person may be submitted from different dental practices for comparison with postmortem dental evidence. It is not uncommon for the general dental records of a decedent and those obtained from the oral and maxillofacial surgeon, endodontist, orthodontist, and other dental specialty practices to be forwarded for forensic analysis. Even if only one antemortem record is sent, the forensic dentist should rechart all information obtained from the radiographs, progress notes, and odontograms on a standardized form or computer-generated dental chart. This record should be identical to the one on which the postmortem information was documented. All of this material should be appropriately labeled as the antemortem record.

The use of computer software, such as the WinID3 program, in MFI situations accomplishes this same principle by entering all antemortem and postmortem dental information into the respective identification program. Besides making the comparison of records easier to manage, the creation of similar antemortem and postmortem analytic material is easier to present in court.

Comparison of Antemortem and Postmortem Records and Written Conclusions

After all dental information has been collected from the antemortem and postmortem databases it is compared for similarities and discrepancies. Comparison of dental evidence is unique among the techniques used to identify a decedent. A positive identification may still be established, even when some reconcilable discrepancies are observed.

Various codes and symbols have been used to chart the antemortem and postmortem status of the jaws. Currently in the United States, the WinID3 and Unified Victim Identification System/UVIS Dental Identification Module (UVIS/UDIM) dental identification software programs are most commonly used to compare dental records of missing individuals to those of unknown human remains and have been used similarly in MFI situations. The odontogram charting codes employed in WinID3 are presented in Table 19.3.

• **Fig. 19.15** Postmortem tooth loss results in an alveolar socket with unfractured margins and no reossification. In this example, teeth Nos. 7, 9, 10, and 11 represent postmortem tooth loss. Tooth No. 2 is a result of antemortem loss. Teeth Nos. 4, 8, and 13 were found near the body and reinserted into their respective sockets.

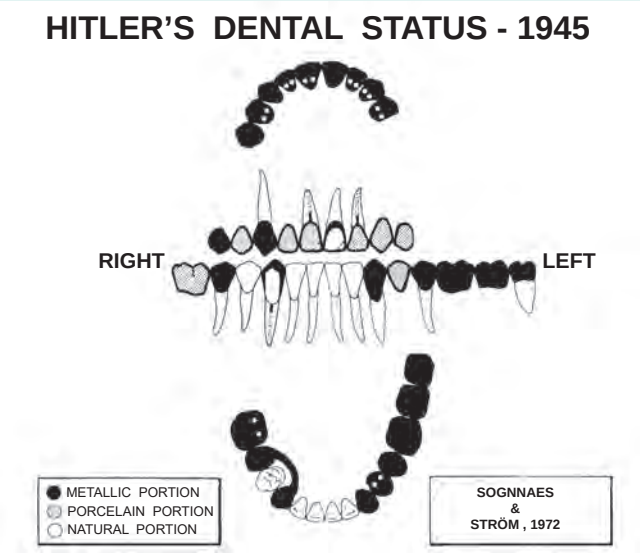
TABLE 19.3 WinID3 Charting Codes

Primary Codes	Secondary Codes
M—Mesial	A—Annotation
O—Occlusal	B—Deciduous
D—Distal	C—Crown
F—Facial	E—Resin
L—Lingual	G—Gold
I—Incisal	H—Porcelain
U—Unerupted	N—Nonprecious
V—Virgin	P—Pontic
X—Missing	R—Root canal
J—Missing crown	S—Silver amalgam
I—No data	T—Denture tooth
	Z—Temporary

dentlearn.ir

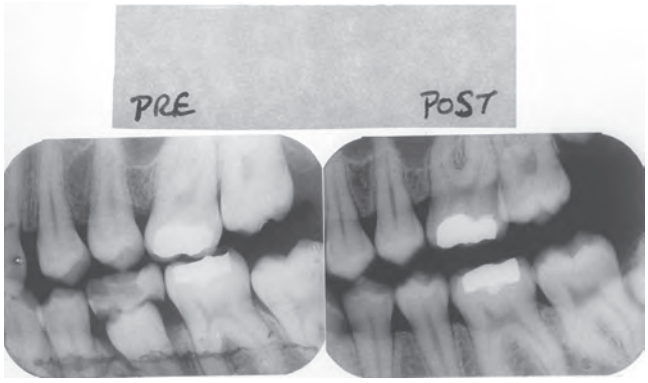
The UVIS/UDIM software and Plass Data DVI System International software have been employed by forensic odontologists in the office of the New York medical examiner and the International Organization (INTERPOL) National Central Bureau, respectively. Although these computer programs can facilitate the process of comparison among the numerous antemortem and postmortem dental records presented in MFI or individual unknown/missing identification cases, the ultimate decision regarding the concordance of information between the antemortem and postmortem records rests with the forensic odontologist not the computer program.

Furthermore, the forensic dentist must routinely rely on the belief that antemortem records are truly those of the person they are purported to represent. The latter problem is best exemplified by the controversy associated with the antemortem dental records used to identify the bodies of Adolph Hitler and Eva Braun. Until recently, there was uncertainty concerning the reliability of those records. This uncertainty was based on the possibility that the records had been falsified to encourage the misidentification of Hitler and his wife. However, among other comparable dental evidence, the presence of an unusual and easily recognizable solid metal fixed prosthesis replacing the mandibular right cuspid and second bicuspid teeth was observed in the antemortem dental records obtained from Hitler's dentist, Dr. Hugo Blaschke. This bridge, resembling a telephone receiver, was also found in the postmortem jaws recovered from the partially burned human remains (Hitler) in the garden of the Reich Chancellery ruins (Fig. 19.16).



The case demonstrated in Fig. 19.17 shows that all teeth, restorations, and anatomic structures are identical, except that deciduous tooth K is still present in the antemortem radiograph. Tooth No. 20 is erupted in the postmortem film. This difference could not support a positive identification if it were a component of fingerprint or DNA evidence. The facts that the deciduous tooth has exfoliated and the permanent tooth erupted before death are acceptable discrepancies in comparable dental evidence.

Comparison of dental evidence is often complicated by the quality of the evidence submitted. The physical status of the postmortem dental material can be compromised when teeth have fractured or are avulsed secondary to trauma. Often, only fragments of the jaws may be presented for comparison, and there may have been postmortem loss of teeth.



Dental restorations can be separated from the teeth or melted in a fire. Acrylic restorative material melts in temperatures less than 540°C (1000°F), gold and amalgam melt at 870°C (1600°F), and porcelain can withstand temperatures greater than 1100°C (2010°F). In addition, extreme temperature in a fire can cause the teeth to explode or appear shrunken. Although the principal role of the dentition of a fire victim is to provide data for identification, studies indicate that morphologic and microscopic tissue alterations of the teeth may assist forensic scientists, such as arson investigators, in determining temperature and duration of exposure to fire.

The problems associated with incomplete antemortem records are compounded when radiographs are of poor quality as a result of exposure and developing errors. Mischarted information in the antemortem record can also be considered a reconcilable discrepancy. This error often occurs when teeth have been extracted and adjoining teeth have moved into the position of the extraction site. Restorations may be inadvertently indicated on the wrong tooth when the clinician is charting or entering information into the progress record.

Regardless of the difficulties encountered when dental evidence is compared, the final conclusions must be based on an objective analysis of the data presented. The conclusions must be supportable and defensible when they are presented under oath in a court of law.

• **Fig. 19.16** Antemortem dental record of Adolph Hitler obtained from his dentist, Dr. Hugo Blaschke, by the Allies at the end of WWII. Note the "telephone bridge." (From Sognnaes RF, Ström F: The odontological identification of Adolf Hitler. Definitive documentation by X-rays, interrogations and autopsy findings, *Acta Odont Scand* 31:43–69, 1973.)

Dentistry's Role in Multiple (Mass) Fatality Incident Identification

The term *multiple (mass) fatality incident (MFI)* evokes images of a chaotic event, initiated by a destructive force, which results in numerous deaths necessitating identification. These mass disaster events resulting in MFIs can be classified in one of three ways:

1. Natural
2. Accidental
3. Criminal (e.g., serial homicide, mass suicide, and acts of terrorism)

Each type of MFI event results in the death of numerous victims. However, the problems faced by the forensic dental team responsible for identifying the decedents may vary, depending on the type of MFI encountered.

Natural Disasters

Natural MFIs include earthquakes, tornadoes, hurricanes, volcanic eruptions, fire storms, tsunamis, and floods. These may occur over relatively short periods or may be protracted over days or weeks. Victims may be scattered throughout broad areas, extending for miles. In addition, many victims in natural MFI situations may be unknowns who cannot be presumptively identified. Transients, homeless individuals, and tourists who are visiting an area involved in a natural MFI are often difficult to identify. Several countries or states can be affected, as in the 2004 Indian Ocean tsunami event and the 2021 western states forest fires in the United States.

In a natural disaster involving multiple fatalities, the principal problem for the dental identification team is that the environmental infrastructure is often compromised. For example, after the Category 5 Hurricane Katrina in 2005, medical and dental offices and hospital facilities containing antemortem records had been destroyed by tornadic activity and flooding. In addition, communication lines and roads were damaged, preventing the retrieval of most available antemortem records. Concurrently, many bodies from cemeteries in the affected areas were disinterred by the storm. All of these factors compounded, delayed, or precluded the prompt identification of many victims.

Accidents

Accidental MFI events are most often associated with transportation accidents, building fires, industrial and mining accidents, and military accidents. These situations usually occur over short time periods and are associated with defined populations (e.g., airplane, bus, or train passengers; mine, mill, or factory workers; residents in an affected structure).

Airlines maintain passenger logs of individuals who are registered on specific flights. However, it has been estimated that at any given time as many as 10% of air travelers may purchase their tickets using an alias for identification. This occurred among the passengers of Malaysia Airlines Flight MH370 when it was determined that two of the victims of this accident were traveling with stolen passports.

The mining company, mill, or industrial plant can document those who have reported for work. In these examples, the victims of accidents should logically come from the defined population of employees on that shift. Therefore, antemortem records are first solicited from the families and health care providers of these individuals. Another source of medical and dental records in these cases is the occupational health files of workers, which are maintained by the employer.

Problems can be associated with the identification of victims of industrial and military accidents because these populations may be of similar age, sex, and ethnicity. Commonly, individuals working in industrial or military settings wear similar clothing. Thus, military uniforms and protective industrial clothing decrease the potential use of personal recognition as an identification aid in these cases.

Criminal Disasters

Unlike natural and accidental MFIs, criminal situations resulting in multiple deaths may occur over extremely long time periods (years) and wide ranges of territory (e.g., different cities, states, or countries). This was the pattern of the rapes and murders committed by Ted Bundy, whose victims included young women residing in states from Washington to Florida from 1974 to 1978. The remains of the victims of serial killers can be hidden, as in the Green River homicides in the Pacific Northwest and the murders of young men committed by John Wayne Gacy in Chicago. Dismemberment and mutilation of victims is exemplified by the Jeffrey Dahmer case. Dental structures in these situations may not always be available for postmortem review.

Law enforcement agencies are often unaware of the victims of serial killers from other jurisdictions. Each agency may be investigating an individual homicide without recognizing a pattern of broader criminal involvement. Until the development of the FBI-NCIC computer registry, coordinated efforts at identification were hampered.

The rise in national and international terrorism in the 21st century has changed the paradigm associated with the traditional participation of the dental profession in an MFI setting. Until recently, forensic odontologists and other dental professionals were simply tasked as experts in the identification of the decedents. Currently, there are ongoing efforts within organized dentistry to develop effective responses to acts of bioterrorism. These efforts are exemplified by the profession's encouragement of legislation authorizing dental professionals, in federally declared emergencies, to perform various procedures that are routinely not within the practice of the profession. Under these provisions, dentists registered and trained in emerging medical diseases, bioterrorism, and emergency medical care would be indemnified for actions taken in the performance of these humanitarian services.

Acts of terrorism may include exposure to biologic agents, chemical toxins, and the discharge of nuclear devices. Thus, the dentist involved in MFI recovery and identification after an act of terrorism may additionally be required to assist medical workers in providing care for the injured. In these scenarios, dentists must consider their personal safety and that of their families. Civil defense and emergency preparedness organizational plans are beginning to include dentists among those charged with triaging the injured. Additional

dentlearn.ir

roles for the dental professional in future acts of bioterrorism and nuclear or chemical attack include providing first aid care and immunizations to injured and exposed survivors.

Responsibilities

In the United States, the National Response Framework (NRF) provides a comprehensive, risk-based, emergency management plan to respond to any hazardous event. The NRF establishes guidelines to manage domestic response to radiological, technical, natural, or terrorist incidents by developing 15 emergency support functions and delineating the agencies charged with performing specific tasks in a response (Table 19.4).

As part of the presidential directive that created the US Department of Homeland Security after the September 11, 2001 terrorist attacks, the National Incident Management System (NIMS) was also developed. The overall objective of this system is coordination of governmental agencies, nongovernmental organizations, and the private sector in the resolution of nationally significant incidents.

Regardless of the type of MFI, the local coroner or ME is ultimately responsible for performing the autopsies and identifying the victims. In accidents that involve modes of public transportation, the National Transportation Safety Board (NTSB) is empowered to investigate and determine the cause of the crash. Other agencies with jurisdiction at a disaster scene may represent local police, public safety, and funeral home personnel. In addition, there may be representatives of the Federal Emergency Management Agency (FEMA), members of the FBI fingerprint team, representatives of the United States Department of Health and Human Services (DHHS) National Disaster Medical System (NDMS) division personnel mobilized with a federal Disaster Mortuary Operational Response Team (DMORT) or Disaster Medical Assistance Team (DMAT), the clergy, and community volunteer organizations.

Although DMORT and DMAT units include dental personnel, these teams may not be mobilized in all MFIs. In these situations, forensic dentists and support staff responsible for identification or care of the injured should also be organized into teams. Several state dental associations (including California, Washington, Michigan, New York, South Carolina, Nevada, and Iowa) have developed, supplied, and trained such groups in preparation for emergencies requiring their expertise. Training sessions include mock MFI exercises. These drills can prepare the dental team members for dealing with the technical problems of cases involving multiple fatalities.

In addition, training sessions can be used to counsel the dental team and to inform members of the posttraumatic stress often associated with this type of forensic work. This delayed stress is a result of the sensory and psychological insults encountered by the dentist, hygienist, or dental assistant who is dealing with human death on a large scale.

During an MFI the NDMS, under its emergency support functions, is authorized and has responsibility to assist local authorities by establishing temporary morgue facilities; identifying victims using scientific techniques; and processing, preparing, and disposing of victims' remains to families, funeral homes, or proper legal representatives. This mission has been accomplished through the development of ten regional DMORTs administered by the DHHS. Each DMORT is composed of funeral directors, MEs, coroners, pathologists, forensic anthropologists, medical records technicians and transcribers, fingerprint specialists, forensic dentists, dental hygienists, dental assistants, radiology technicians, mental health specialists, computer professionals, administrative support staff, and security and investigative personnel.

These individuals are private citizens, each with a specific field of expertise, who are mobilized during a disaster. The licensure and certification of the DMORT members is recognized by all states because they are considered temporary federal employees during the emergency response.

Working with the authorization of the local coroner or ME, a local dental disaster team or dental component of a federally deployed DMORT is responsible for antemortem record assembly and interpretation, postmortem physical and dental radiographic examination, and final comparison of dental information. These are the same principles used to establish an individual identification. Yet, when numerous victims need to be identified in a short time, problems of identification are compounded exponentially.

No remains have been found for one-third of the 3000 victims who died in the World Trade Center terrorist attack in 2001. Fewer than 300 victims were found intact, although

dentlearn.ir

tens of thousands of fragmentary human remains and personal effects have been recovered and processed through the Staten Island landfill that has been used as a temporary sorting facility. Many of these remains have yet to be linked to a victim.

Dividing the forensic dental team into subsections responsible for each of the three identification domains (antemortem, postmortem, and record comparison) permits a division of labor among the team members. This division reduces errors in identification, in that specific tasks in the identification process are assigned to separate subsections. A chain of command should be established, and the team leader of each shift should be directly responsible to the local coroner or ME. This person is the only member of the team authorized to release the results of the dental identification process to appropriate investigative agencies.

Technologic Aids in Multiple Fatality Incident Analysis

Advances in photographic, radiographic, and computer technology have provided the forensic dental team with additional resources to enable recovery, documentation, storage, and comparison of forensic dental evidence in MFIs, as well as in other situations requiring forensic dental expertise (e.g., bite mark analysis and documentation of human abuse). Among these advances are developments in the following:

- **Digital photography.** The basic digital camera used for forensic evidence documentation should include a through-the-lens (TTL), light-metering, SLR, 35-mm digital camera body with interchangeable lenses or an adjustable lens capable of normal range (30–50 mm) to macro range (90–100 mm) focal length. A removable flash memory card with adequate storage capacity is also required. The Scientific Working Group on Imaging Technology (SWGIT) imaging guidelines provide the forensic odontologist with information regarding the limitations and parameters imposed by the judicial system regarding the manipulation and presentation of digital photographic evidence.
- **Digital radiography (DR) equipment.** Electronically generated and stored radiographic imaging can be accomplished by the following:
  - Scanning normally processed radiographic film into a computer
  - Using a phosphor substrate shaped and used like radiographic film to expose and scan radiographic information into the computer by a special proprietary device
  - Using a sensor sized and shaped like a radiographic film that is made of a scintillation screen and a charge-coupled device (CCD) or complementary metal oxide semiconductor (CMOS)
- **Direct digital radiography (DDR).** When energized by radiation, this device creates a direct image on the pixels of its CCD or CMOS. This radiographic image is then sent to a computer through wire or wireless technology. Thus, because of its ability to save time, DDR technology is recommended for clinical and forensic casework. Additionally, DDR procedures reduce exposure times by requiring 90% less radiation than that required to expose a standard type D film radiograph and 50% less radiation than that required in exposure of type E film radiographs. The parameters by which the quality of a radiograph is evaluated include resolution and contrast sensitivity. Image resolution describes the detail an image holds. In film-based radiographs, this is expressed as a function of how close lines can be to each other and still be visibly distinguished. Digital imaging measures resolution as pixel counts. The contrast sensitivity is a measure of the smallest percentage change in an object's base thickness (density) that can be detected in a radiograph. The high resolution of the image produced by the DDR sensor is one of its most advantageous properties.
- **Cone-beam computed tomography (CBCT).** CBCT provides a 3D imaging modality to collect a complete maxillo-mandibular-facial anatomic volume of data. Computer software can be used to analyze the obtained image, and the diagnostic interpretation provided can be used for treatment planning, assessment of pathologic conditions, and evaluation of dental implants. Application of CBCT in forensic dental situations can overcome intraoral access problems with some specimens (e.g., fourth-degree burn cases).
- **Portable hand-held X-ray generation devices** (e.g., Kavo Nomad™ Pro 2 Intraoral X-Ray System, Genoray Handheld Portable Dental X-Ray Unit, Rextar X Portable X-Ray Generator, and the MinXray HF 120/60HPPWV PowerPlus™ Portable X-Ray Unit, among others). With these devices, the forensic dentist is able to expose film or digital radiographs quickly and effortlessly with a battery-powered unit that can be carried to the body on the gurney in the morgue. Additional applications for the use of these devices in special care dental settings include exposure of radiographs on pediatric or sedated patients, those having endodontic therapy, or individuals receiving dental treatment in a hospital operating room. These devices have been used in the identification of MFI victims in numerous disasters worldwide. However, they are still not licensed for use by Radiation Safety Boards in every state in the United States.
- **X-ray fluorescence (XRF) methodology.** As discussed previously, analysis of dental materials in cremation and other difficult forensic identification cases may be facilitated by analysis of specimens with this technology.
- **Computer software technology.** The advent of computer software has assisted MFI dental identification teams in filing, storing, sorting, and matching bits of antemortem and postmortem information. Computer assistance has proved beneficial in disasters involving hundreds of victims. Commonly used programs include the following:
  - The FBI-NCIC program, based on the California Dental Identification System, developed by Dr. Norman Sperber and Dr. Robert Siegel (San Diego, CA)
  - CAPMI-4 (Computer-Assisted Postmortem identification—version 4.0), developed by Dr. Lewis

dentlearn.ir

Lorton of the US Army Institute of Dental Research (It was first used in 1985 in support of the Arrow Air-US military charter aviation runway accident in Gander, Newfoundland.)
- WinID3 dental comparison software, developed by Dr. James McGivney (St Louis, MO) (Bridged with the Dexis DR program, WinID3 facilitated comparison of antemortem and postmortem dental records in Hurricane Katrina recovery efforts and various transportation and industrial MFI events.)
- UDIM (UVIS Dental Identification Module), the dental recording/search component of the UVIS system, developed by Dr. Kenneth Aschheim (New York, NY)

Each of these computer software systems is user friendly, can be run on readily available and accessible hardware, is automated and capable of networking, and relies on objective data entry and storage of antemortem and postmortem dental records, digital radiographs, and digital images. The use of these computer software programs in MFI situations reduces the time and effort that had to be expended in past events. Before their use, an examiner in the dental identification team walked along tables with a postmortem record comparing the dental data and radiographs at each station containing an antemortem record.

Despite the fact that these technologic advances have facilitated forensic casework, the caveat for the forensic dentist remains that identification is the result of human thought processes and not the highly technical supportive procedures that provide the material being evaluated. To arrive at correct comparative conclusions based on the evidence, individual dental team members must evaluate the computer-generated matches for definitive identification.

◆ BITE PATTERN EVIDENCE

Basic Principles

A bite mark is a patterned injury or surface disturbance produced by teeth on the skin of an individual or inanimate object. Historically, analysis of this type of evidence presumes that the dentition of the biter (animal or human) is unique (being the only one of its kind) and can be compared scientifically and related to the resultant patterned mark on the surface of a victim or inanimate object. Initial studies indicated the uniqueness of the human dentition. However, because of the similar size and shape of the dental structures among humans, there evolved a debate among forensic odontologists and those in the legal profession related to the ability of these "unique" features to be transferred into skin, which is acknowledged as a poor impression material.

Because it is reasonable to consider the teeth as cutting or mashing tools, the basis for accepting bite pattern evidence can be supported on the same scientific principles used to evaluate tool marks. However, it is now believed that although individual human dentitions may have distinctive features, the patterned marks left by the teeth may not be unique for each person as once thought. Variations in tooth size, wear, fractures, and position in the dental arch, diastemata, and restored surfaces contribute to the principle of distinctiveness within an individual dentition, but not uniqueness among human dentitions.

Thus, issues related to the validity, reliability, and admissibility of bite mark evidence continue to rest with the judicial system and its various rules pertaining to the introduction of scientific evidence in court. The Innocence Project, founded in 1992, has brought significant legal appeals regarding bite mark evidence, which has resulted in this evidence being overturned in several jurisdictions. Because bite mark pattern evidence is often questionable, as of 2020, 26 incarcerated individuals have been released when DNA revealed that bite mark analysis resulted in a wrongful conviction.

Based on these legal decisions and a 2009 report from the National Academy of Sciences critical of this use of bite mark evidence, it has become the most controversial component of the forensic dental discipline. This has resulted in the current philosophy regarding the significance of bite mark evidence resting in its *exculpatory* rather than *inclusionary* power when comparing the dentition of a putative suspect to a bite mark on an inanimate object or bite mark patterned injury (BMPI) in most cases.

Victims of mammalian animal bites account for most bite injuries reported annually. Bite-related injuries represent approximately 1% of all hospital emergency visits that require medical attention. Of these, >1.6 million dog bites were recorded by the National Emergency Department Sample (NEDS) between 2010 and 2014. This represented 26% of all bite-related admissions to emergency rooms in the United States. The second and third most likely mammalian biters are cats and humans, respectively. Each represents from 5% to 20% of cases reporting to urban emergency rooms.

As the habitats of wild animals in North America continue to recede, humans are more likely to come in contact with these dangerous carnivores. This is reflected in the increase in attacks on humans by mountain lions and brown, black, and grizzly bears, resulting in biting injuries or death from biting and clawing. In 2020, the International Shark Attack File (ISAF) of the Florida Museum of Natural History reported 57 unprovoked shark bites on humans and 39 provoked bites worldwide.

Animal bites may be observed postmortem when a body has not been buried or discovered quickly. Commonly, insect bites are made by ants and roaches, which leave patterned injuries that can be mistakenly interpreted as antemortem human BMPIs or trauma (Fig. 19.18). Postmortem bites from rats and scavenging feral and wild dogs and cats are often avulsive and of narrower or smaller diameter than human bites.

Injuries caused by human bites are routinely related to either aggressive or sexual behavior. Ironically, it is not uncommon for the perpetrator of an aggressive act to be bitten by the victim (as a means of self-defense). In children, biting is a form of expression that occurs when verbal communication fails. Biting injuries in children can result from

dentlearn.ir

• **Fig. 19.18** Insect bites on the skin that mimic the pattern injury associated with bite mark trauma. In a decedent, this pattern may additionally be mistakenly interpreted as antemortem trauma. (Courtesy of Dr. David K. Ord.)

playground altercations or sports competition and are especially common among 13- to 30-month-old children who attend day care centers. The resultant injuries in this population are usually mild, requiring only washing, cold compresses, and comforting the victim.

Self-inflicted bites are observed in **Lesch-Nyhan syndrome.** This syndrome is an X-linked, recessively transmitted disease manifesting insensitivity to pain and self-mutilation (among other signs) by chewing away the lips. This disease is rare, and self-inflicted bites are more commonly seen in adults and children who are victims of physical abuse or sexual assault. These individuals may bite their own forearms or hands in anguish or to prevent themselves from crying out while they are being traumatized.

Injuries resulting from animal or human bites may become septic or may progress to systemic infections. Secondary bacterial infections are more commonly associated with human bites than with animal bites, although 80% of domestic cat bites become infected because bacteria are injected into the deep puncture wounds inflicted by their needlelike, carnassial teeth. Infectious complications include tetanus, tuberculosis, syphilis, actinomycosis, cat-scratch disease (caused by *Bartonella henselae*), and those infectious complications related to streptococcal and staphylococcal organisms. Anaerobic organisms associated with bite injuries may eventually result in complications, such as osteomyelitis, septic arthritis, tenosynovitis, meningitis, and infections of the lymphatic system.

Viral complications, including hepatitis B virus, herpes simplex, and cytomegalovirus, have resulted from transmission through human bites. The human immunodeficiency virus (HIV) can also potentially be transmitted through the exchange of blood and saliva in a bite injury. The risk of seroconversion from this mode of HIV transmission, however, is believed to be extremely low. An immunocompromised individual who is already infected with the HIV virus is at increased risk of secondary infection when bitten by a cat.

Rabies is the most serious infectious complication that results from mammalian animal bites. Rabid dogs account for approximately 90% of cases worldwide, whereas in the United States bats have become the major cause of rabies related human fatalities. It is often necessary to identify the specific offending animal for rabies control or potential litigation. This identification is not routinely done by matching the animal's teeth to the pattern injury. When humans bite, however, the marks left in injured tissue or inanimate objects are often analyzed and compared with the alleged perpetrator's dentition.

Historical and Legal Issues

References to biting during acts of passion or aggression can be found in the *Bible, Kama Sutra,* and Old English law. In colonial America, the Reverend George Burroughs was charged with the crime of biting one of the women accused of witchcraft during the Salem, Massachusetts witch hunt incidents in 1692. He was hanged for this offense. Bite mark evidence was provided in expert dental testimony in the 1870 Ohio trial of Ansil L. Robinson, who was accused of murdering his mistress. Although the defendant was eventually acquitted, the expert dental presentation by Dr. Jonathan Taft regarding the pattern injury on the victim's arm became a benchmark for future experts in the discipline.

The concept of accepting evidence related to the analysis of patterns created by the dentition was first accepted by the appellate level courts of the United States justice system in 1954. At that time, *Doyle vs State of Texas* became the first modern case in which a criminal conviction was based on evidence relating a suspect's dentition to pattern marks in an inanimate object (a piece of cheese). Because of the *Doyle* case, more than 260 decisions involving bite mark evidence have been entered into the case law records of the appellate courts of the United States.

The legal community has recognized tool mark and fingerprint pattern analysis as scientifically acceptable forensic disciplines for some time. The evidence presented by experts in these areas has been accepted in 20% of state courts under the *Frye* standard *(Frye vs United States),* and the remaining 80% of state courts and all federal courts under the Federal Rules of Evidence 702–705. These are special rules dealing with the admissibility of scientific evidence in the American judicial system. Thus, they are also applicable to bite mark information.

The *Frye* test had been the standard for scientific admissibility or acceptance in most state and federal courts since 1923. The three components of scientific evidence admissibility that are considered under the *Frye* test include the following:

1. The scientific principle must be recognizable.
2. The scientific principle must be sufficiently established.
3. The scientific principle must have gained general acceptance within the scientific discipline to which it belongs.

Among the three requirements, only the concept of "general acceptance" must be met to satisfy the *Frye* test of admissibility.

Evidentiary use of genomic DNA profiling has undermined the general acceptance of bite mark evidence although according to Forensic Science Reform, there is "inordinate

dentlearn.ir

resistance (by the legal community) to create fair pathways towards exoneration because of its systemic structure of '*Stare Decisis*' and its resistance to correct mistakes in both its own system and the forensic science communities." *Stare Decisis* is the legal doctrine which bases current court decisions regarding an issue on prior rulings concerning the same issue. Therefore, courts in the United States have been hesitant to rule against the "general acceptance" of bite mark evidence as scientific in recent legal decisions.

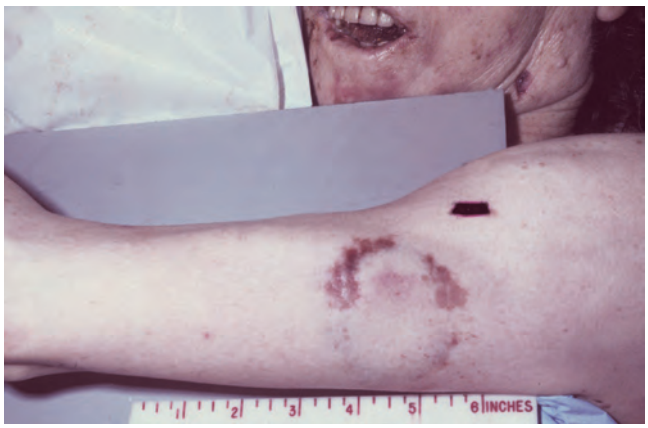
In 2013, Texas legislators passed the Texas Junk Science Law (SB 344). This legislation provides prisoners the right to challenge their conviction due to any uncertainty related to forensic science evidence used to obtain the conviction (e.g., fingerprint, bite mark, blood splatter, shoe print, tire track patterns, etc.).

In 1993, the US Supreme Court ruled on the admissibility of scientific evidence in *Daubert vs Merrell Dow Pharmaceuticals.* It was the Court's decision in this case that the general acceptance aspect of the *Frye* test should no longer be the sole, determining factor used in considering admissibility of scientific evidence. Essentially, the Court replaced this principle with one that stresses scientific validity. This decision removes the responsibility of determining sound scientific evidence from the scientific community in which it has gained general acceptance.

Instead, the *Daubert* ruling gives great latitude to the trial judge in considering the admissibility of scientific evidence. Trial judges often have limited knowledge of scientific methodology; however, under *Daubert* they are required to determine if the weight and admissibility of expert testimony is not only scientifically valid but also relevant and germane to the issues in individual cases. Thus, the results of the Supreme Court's decision in *Daubert* are to make the judge a "gatekeeper" to ensure that the expert witness is providing scientifically valid evidence.

The "general acceptance" concept is no longer the sole determinant of admissibility in *Daubert.* It becomes one of several factors that must be met for scientific evidence to be admissible. These factors include the following:

- Techniques used must be testable and tested.
  - Peer review and publication of results are not required but may persuade the judge in admitting evidence.
  - Standards should be established for evaluation of the scientific methods and error rates associated with the techniques used.
  - Consideration is given to acceptance of scientific principles that have gained general acceptance within the scientific discipline to which they belong.



Bite mark evidence is currently admissible under the *Frye* standard and Federal Rules of Evidence as determined by the *Daubert* decision. Although some legal experts believe the Federal Rules of Evidence provide better guidelines for admissibility decisions, challenges to the scientific basis of bite mark evidence may be averted under either set of standards. Currently, this evidence is used more routinely in an *exculpatory* manner to exclude rather than include a suspect as the perpetrator.

Characteristics of Bite Marks

To evaluate a patterned mark, its characteristics must be recognizable and distinguishable. Reasonably, the mark should be consistent with the face of the instrument from which it was generated. Specific teeth can create representative patterns that are recognizable. These are described as individual characteristics of the entire bite mark. Human incisors make rectangular marks. Depending on the amount of attrition observed on the incisal edges of cuspids, these surfaces may be associated with point or triangular patterns. Unlike mandibular bicuspid teeth, which have a diminutive lingual cusp, maxillary bicuspids often mark in a pattern that resembles a "figure eight."

Class characteristics of a human bite mark are related to the shapes that are created when groups of teeth from both dental arches are impressed into a bitten surface. Semicircular, ovoid, or elliptical patterns are usually observed, but variations may be associated with tapered, square, and U-shaped arches. Typically, bite marks are composed of two arc-shaped areas corresponding to the maxillary and mandibular arches and their respective teeth. When only one arch contacts a surface, a crescent pattern may be formed. The greatest dimensions of an adult human bite mark do not usually exceed 4 cm (Fig. 19.19).

Individual and class characteristics of bite patterns are generated by groups of specific teeth. The dynamics of occlusion and muscle function must also be accounted for when variations in individual and class characteristics of a bite mark are considered. Such variations can be caused by malocclusion, individual tooth mobility associated with periodontal disease, and movement of facial muscles during biting. Class II malocclusion can cause the palatal surfaces of the maxillary anterior teeth, rather than their incisal edges, to contact the material being bitten. Shield-like imprints of the palatal surfaces are generated in the bite mark rather than the rectangular patterns routinely associated with these teeth.

• **Fig. 19.19** A bite mark pattern inflicted prior to death demonstrating the individual and class characteristics associated with impressions made by the human dentition. An ecchymotic area in the center of the ovoid pattern is observed, which is not always related to the sucking action of a sexual bite. Therefore, this finding should not be overinterpreted to imply sexual intent on the part of the biter. The impressions made by the teeth of the mandibular arch are more delicate.

dentlearn.ir

Aberrant muscle forces associated with tongue thrusting can alter the way the teeth contact a bitten surface. Temporomandibular joint dysfunction can also contribute to variations in bite patterns. It can be associated with midline shifts or inability to achieve maximum opening while biting. Periodontal disease may result in individual tooth mobility, which could affect the bite mark pattern.

When bitten, many inanimate objects tend to act like dental-impression material, retaining the marks of the teeth. Such cases have involved bite marks in foods, chewing gum, paper toweling, and a roll of masking tape. Unlike inanimate material, the skin is a dynamic tissue that can change after it is injured. Swelling, caused by the acute inflammatory response of the tissue, can distort and affect the interpretation of the pattern. Bleeding into the area of a bite mark can mask the pattern.

The age of an injury is the time elapsed from its infliction to the analysis of the damaged tissue. Reliable determination of the age of antemortem skin injuries requires histopathologic and histochemical analysis to relate the injury to the time of the alleged incident (Table 19.5). Color changes in the bitten tissue, associated with the degradation of hemoglobin from lysed RBCs, can be used only to broadly estimate the time of occurrence and qualify the age of a bruise as recent or old. Environmental factors, including seasonal temperature, location of the body, and presence or absence of clothing, may additionally act as important variables requiring consideration when attempting to determine the age of injury patterns.

Contusions and areas of ecchymosis are not unusual in bite marks made in living tissue. The absence of bleeding into the injury may imply that it was inflicted after death. Additional postmortem soft tissue changes that can affect the quality of a bite pattern injury and its eventual weight as evidence include artifacts created by lividity (caused by the settling of blood pigments in dependent body areas), decomposition, and embalming.

Bite marks from sexual attacks are commonly found on the neck, breasts, arms, buttocks, genitalia, and thighs. Axillary bites and bite patterns on the back, shoulder, penis, and scrotum are often associated with homosexual activity. Abused children may be bitten in areas of the face, particularly the cheek, ear, and nose. Assailants also can be bitten. The analysis of these bite pattern injuries may be just as incriminating as those found on the victim of a violent act.

A review of 778 bite mark injuries concerning the anatomic locations most often bitten, victim and biter demographics, the type of crimes in which biting occurred, and legal disposition of cases revealed the following information:

- Females were bitten more often than males.
- Perpetrators were male more often than female.
- The most common sites bitten were the arms. Bites in these locations occurred more commonly among males.
- Females were bitten on the breast more often than males. This location accounted for the second most commonly bitten area of the body.
- The type of crime and the age of the victim were related to patterns in location, distribution, and number of bites.

Guidelines for Bite Mark Analysis

In 1984, the American Board of Forensic Odontology (ABFO) established Guidelines for Bite Mark Analysis. Additional workshops of the Board have provided further insight into the techniques available to recover, store, analyze and evaluate bite mark evidence based on the Guidelines. The development of the Guidelines also created a scientific approach to the description of the bite mark, collection of evidence from suspect and victim, and subsequent analysis of the evidence.

The Guidelines do not mandate specific analytic methods for comparison. Through their careful use, however, the

TABLE 19.5 Histopathologic and Clinical Changes Used to Monitor the Time Elapsed (Aging) in Skin Injuries Associated With Bite Marks

Time	Predominant Cellular Infiltrate and Deposits	Healing	Variable Clinical Color
Hours			
4–8	Polymorphonuclear leukocytes with a peripheral front		Red-blue-purple
12	Polymorphonuclear leukocytes		
16–24	Macrophages peak		Blue-black
24–36	Polymorphonuclear leukocytes peak	Peripheral fibroblasts

10–14		Granulation tissue	Tan-yellow

dentlearn.ir

quality of the investigation and conclusions based on bite mark evidence follow customary procedures. Thus, with these guidelines, it should be possible to determine the weight of bite mark evidence required to establish the validity of bite mark comparison. According to the current Guidelines, *bite mark, suggestive of a bite mark,* and *not a bite mark* are the terms used to indicate the confidence level of the odontologist that a patterned mark represents a bite mark.

Description of the Bite Mark

Demographic information (i.e., age, ethnicity, sex, and name of the victim; examination date; referring agency; case number) is obtained in cases involving both living and deceased victims. The names of the forensic dental examiner and referring agency contact person should also be included.

The location of the bite is then described. Attention is directed to the anatomic location, surface contour, and tissue characteristics of the bitten area. Underlying structures, such as bone or fat, may influence the analytic quality of the pattern injury. Relative skin mobility is also evaluated.

The shape, color, size, and type of injury are recorded. Metric measurements of the horizontal and vertical dimensions of the bite mark are determined. Irregularities and variations from the standard semicircular, ovoid, and crescent shapes associated with human bite marks are noted. Injury types include abrasion, laceration, ecchymotic and petechial hemorrhage, incision, and avulsion. Artifactual injuries, such as proximate stab and bullet wounds, should be recorded because these may distort the pattern by separating anatomic cleavage lines of the skin **(Langer lines)**.

Evidence Collection

Examination of the Victim and the Suspect

Both the victim and the suspect are examined, and evidence from each is gathered for comparative study and evaluation. Collection of evidence must be performed in a manner that protects the rights of the person who is providing the evidence and that permits the eventual acceptance of the evidence in court. Therefore, to ensure objective analysis, it is recommended that dental impressions, photographs, and demographic information obtained from the putative suspected biter be collected by a dentist other than the odontologist making the comparison.

A standard health history and informed consent are obtained before any evidence recovery procedure regarding the suspect is performed. An intraoral and extraoral examination of the suspect is completed, which includes dental charting, soft tissue and tongue evaluation, and probing of the periodontium. Therefore, knowledge of the medical history of the suspect relative to systemic problems associated with cardiovascular disease, allergy, seizure disorder, diabetes, and respiratory disease or requirements for antibiotic prophylaxis has medicolegal importance in forensic casework, as well as in traditional patient evaluation.

A search warrant, court order, or legal consent may be required before evidence is collected from a suspect. A specific list of the dental-related evidence desired should be recorded in the legal document. This list usually includes facial and oral photographs, impressions of the teeth, occlusal registrations and bite exemplars, and saliva samples. These documents protect the rights of the suspect against unreasonable search and seizure and provide for due process, as guaranteed by the Fourth and Fourteenth Amendments, respectively, to the US Constitution.

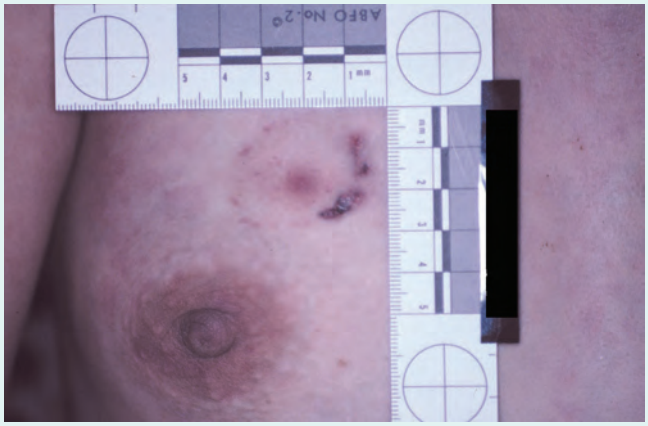
Bite marks are considered similar to such physical evidence as fingerprints, hair, blood, and semen samples, as well as to sobriety tests. Therefore, this material is not protected under provisions of the Fifth Amendment, which deals with self-incrimination.

Evidence collection from the victim entails non-invasive and invasive techniques. The former includes photography, saliva trace evidence collection, fabrication of study casts of the bite mark, and stereolithography (SLA) to create 3D models of the BMPI. The latter may involve tissue incision, excision, and preservation of a BMPI in a decedent. Preservation of this tissue permits analysis of the injury by transillumination and observation of the area from the side opposite the light source.

Photography

Because evidence associated with bite marks, human abuse, and sexual and physical assault is transitory, there is an immediacy associated with the collection of physical evidence in these cases. Initial photographs of the pattern mark should be taken before any investigative procedures that may alter the pristine bite mark evidence (e.g., touching, removing, impressing, swabbing, and cleansing).

Ideally, standard visible light photographic techniques include the use of a 35-mm DSLR camera with a flat-field macro lens and dedicated electronic flash. Numerous images using different camera and lighting positions, exposure settings, and color and black-and-white exposures should be obtained. Additional legal considerations and protocols related to the documentation of image enhancement, restoration, compression, and analysis have been established for digital bite mark images.



Orientation positions and close-up views with a reference scale are required. A reference scale permits the bite mark images to be measured and prepared as life-size (i.e., 1:1) representations of the pattern injury. Ultimately, these images can then be compared with casts and other exemplars obtained from the suspect. The scale should be stabilized and positioned next to, and in the same plane as, the bite mark to eliminate potential distortion artifacts in the resultant images. It should never be hand-held. The scale should be omitted from at least one image to document that no marks or other injuries have been intentionally hidden by it.

The ABFO No. 2 photomacrographic reference scale (Lightning Powder Company, Inc.; Salem, OR) was developed by the ABFO for use in bite mark photography (Fig. 19.20). This standardized, L-shaped, rigid, accurate scale has become the gold standard in bite mark photographic analysis. Variations of it have eventually come to be used in all varieties of forensic casework requiring accurate measurement of evidence at crime scenes or in the laboratory (e.g., analysis of shoe print, tire track, and blood splatter patterns).

dentlearn.ir

This nonflexible instrument contains two metric scales, an 18% color gray scale, three circular symbols, and rectifying grids. Each of these components is used to account for photographic distortions, which can negate the value of the photographic evidence. Techniques using Adobe Photoshop and Mideo Systems CASEWORKSeis computer software have been used to rectify distortions observed in the ABFO No. 2 reference scale and ultimately to eliminate these from a bite mark image being analyzed.

With living victims, serial pictures of the BMPI are taken over several days. This series provides documentation of the color changes associated with healing and age of the wound. In addition, special advanced photographic techniques, using nonvisible energy sources at the extremes of the electromagnetic spectrum and fluorescent alternative light sources, can be used to identify latent images of the teeth that may remain after the bite mark has clinically disappeared. These techniques require special films and illumination sources, bracketing of aperture (f-stop) openings, variations in shutter speeds, and/or lens filters to work within the desired wavelengths and include the following (Table 19.6):

• **Fig. 19.20** The American Board of Forensic Odontology (ABFO) No. 2 Reference Scale.

- **Reflective ultraviolet (UV) photography.** This technique enhances the bite mark image by selectively identifying photoactive **chromophores,** such as melanin and hemoglobin pigment in the superficial layers of the injured tissue. Variations in the amount of these natural light–absorbing organic pigments in the traumatized tissue are observable in images exposed with this energy source. This is based on the fluorescence created when the skin is exposed to UV light in the 200–400-nm wavelength range. Although there may be focusing problems associated with UV photography and exposures *must* be made with a tripod-mounted camera, the fact that this technique may permit recovery of latent evidence, even months after all clinical signs of a bite mark injury have disappeared, makes the effort worthwhile.
- **Infrared (IR) photography.** Tungsten lamps and quartz-halogen lamps are good sources of IR radiation when attempting to expose IR images from unfiltered light sources. To expose images specifically within the IR wavelengths of 750–1000 nm, a filter must be placed in front of the lens to absorb visible light. The Kodak 87 gel filter accomplishes this task by limiting all transmittance of

TABLE 19.6 Comparison of Photographic Electromagnetic Energy Spectrum Sources and Their Forensic Imaging Capabilities

	Visible Light	Ultraviolet Light	Infrared Light	Alternate Light Imaging Fluorescence
Light wavelength	400–700 nm	200–400 nm	700–1000 nm	450 nm
Filter	None	Kodak Wratten Filter No. 18A gel (visibly opaque glass filter)	Kodak Gel 87	Kodak Gel 15
Target Pigment or Material

dentlearn.ir

light except at the designated wavelengths. Additionally, IR photography requires that the camera lens be refocused (focus shift) after initial focusing under visible light and before exposure of the image. Like alternate light source photography, the focal plane for IR photography lies below the skin surface. The deeper focal depth permits visualization of faded tattoos and wound damage within a blood stain. This technique is not the best for identifying individual characteristics in bite mark injuries.

- **Alternate light source (alternate light imaging [ALI]) photography.** This technique is also referred to as *fluorescent photography*. It is advantageous in assisting investigators to locate and document evidence involving the presence of ink residues, fingerprint patterns, and the chromophores previously indicated. ALI enhances visualization of pigments derived from chromophores that may be found within evidence involving latent serologic fluids and subdermal bruises or pattern injuries of victims of violent or sexual crimes. ALI techniques illuminate deeper tissue targets by using a predominantly monochromatic band of light between the wavelengths of 430 and 460 nm. To accomplish the visualization of the weak fluorescent glow from the desired pigments, ALI photography must be performed by eliminating all other sources of light from striking the imaging surface (film or digital sensor). This requires that ALI techniques be performed in total darkness with yellow filters, such as the Kodak gelatin No. 15. Because longer exposure times are also required, images exposed using ALI *must* be made with a tripod-mounted camera.

As previously stated, photographs of the suspect should involve the same attention to technical quality control. Extraoral, intraoral, and occlusal photographs are taken. Additional images of wax or acrylic test bites and measurements of maximum interincisal opening are also recorded.

Saliva Evidence

Although the forensic dentist is concerned principally with the analysis of the physical evidence associated with a bite mark, biologic evidence in the form of serologic and DNA material is also of probative importance. To ensure that the DNA sample has not been contaminated, collection of saliva trace evidence from the surface of the bite injury of the victim is performed before other evidence-gathering manipulation of the injury. There is an increase in the yield of recovered DNA for analysis when this procedure is carried out according to the two-swab protocol described previously.

Using this technique, a saliva sample is collected by first rubbing the bitten area with a cotton swab that has been moistened in sterile, distilled water. The swab should contain no preservatives. The bite mark is subsequently rolled with a second, dry, cotton swab. Both samples can be considered a single exhibit because they have been collected from the center of the pattern injury. They are placed in an evidence box and permitted to air-dry before submission to the laboratory. No control swabs are required from adjacent areas of the victim's skin.

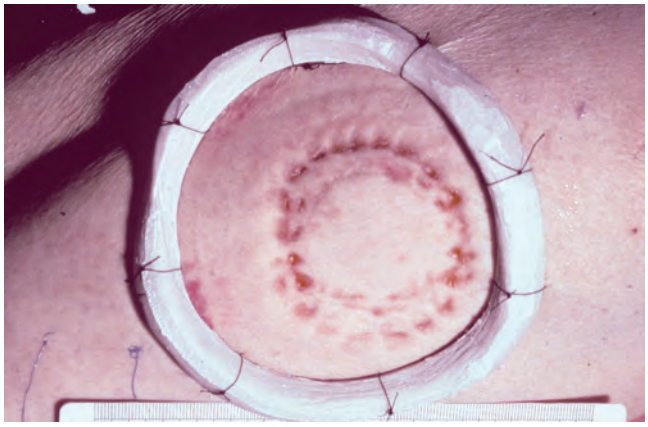
DNA from the victim of a BMPI should be obtained from whole blood samples or buccal swabs. Additionally, autopsy tissue samples can be obtained from decedent victims. All samples can be used for DNA comparison with bodily fluid or tissue samples obtained from the suspect.

Because a victim may be bitten through the clothing, areas of garments that approximate a BMPI should also be retained and evaluated for saliva. Many victims of sexual abuse wash the area of a bite mark before reporting for treatment. This is unfortunate because biologic evidence associated with DNA recovery can be lost. In this regard, emergency room personnel should be trained to recognize potential BMPIs and be instructed not to wash or disinfect these areas until saliva evidence can be obtained.

Impressions and Study Casts

When a bite injury exhibits indentations that can be related to the dentition of an alleged biter, accurate, 3D, life-size exemplars (casts) can be obtained from molds of the area. Dental impression materials are used to create the molds that are then reinforced to prevent dimensional changes and distortions.

The Guidelines for Bite Mark Analysis deliberately do not dictate which impression materials should be used to create exemplars of a bite mark. Low- and medium-viscosity vinyl polysiloxane (VPS) impression materials are dimensionally stable, meet American Dental Association specifications, and are all acceptable. Hydrocolloid, polysulfide, polyether, and alginate materials are not recommended because of problems associated with long-term stability.



Orthopedic cast materials, heavy-body VPS materials, and non-exothermic resins have been used to create the rigid, stable trays for bite mark impressions. All impression trays and study casts should be appropriately labeled with demographic information for the specific case. Additionally, anatomic direction markers should be added to the impression tray before its removal from the skin surface. This will ensure that the impression is correctly oriented relative to the actual pattern injury.

Original impression trays and study casts are retained for eventual presentation in court. Working casts and models should be duplicated from the original impression or master casts. It is recommended that master casts be poured in type IV stone, according to the manufacturer's specifications, and that these casts remain pristine.

Tissue Samples

Tissue samples of a bite mark can be retained from decedents. With the permission of the ME or coroner, the epidermis, dermis, and underlying muscle and adipose tissue can be removed for transillumination analysis. Before excision, an acrylic ring or stent must be secured within 1 inch of the borders of the injured tissue sample. The ring or stent prevents shrinkage and distortion of the specimen when it is placed into a 4% formalin solution for fixation. The acrylic material is bound to the skin surface with cyanoacrylate and sutures (Fig. 19.21). These tissue samples can be transilluminated by backlighting. This process permits observation of the pattern

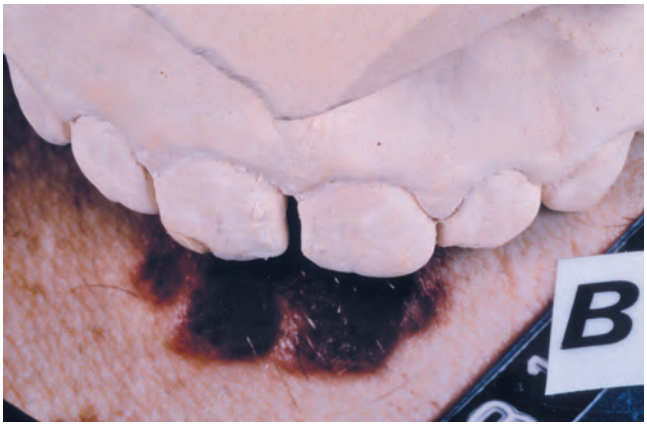
dentlearn.ir

• **Fig. 19.21** An experimental bite pattern injury on a cadaver. This bite mark has had an acrylic stent glued and sutured around its circumference before dissection and fixation in 4% formalin. (Courtesy of Dr. E. Steven Smith.)

injury in the bruised skin by a manner that is not possible when the tissue is *in situ.*

Evidence Analysis and Comparison

The responsibility of comparing the photographs of the bite pattern injury with the dentition of the suspect rests with the forensic dentist. As an expert in the analysis of these patterns, this person objectively evaluates the evidence. The forensic dentist first determines whether the pattern is truly a result of biting or whether it is an artifact. Patterns of blood splatter around a wound, other tool marks, or insect artifacts unrelated to the teeth may be mistaken for bite marks in photographs provided for evaluation by crime scene investigators, police, and emergency room or autopsy personnel.

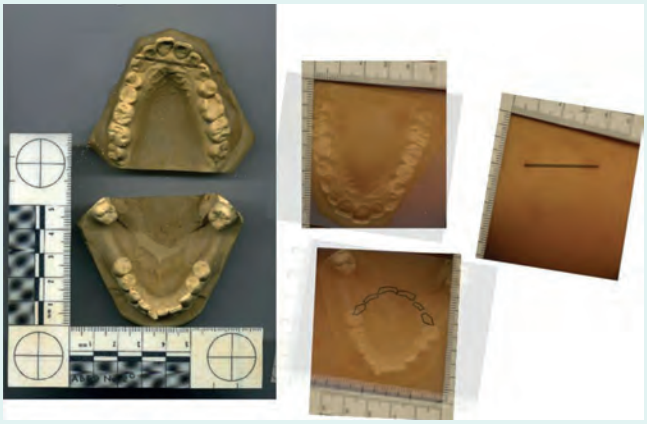


Once it is established that the pattern is related to the teeth, it can be compared to the dentition of the suspect for *inclusionary* or *exclusionary* purposes. An expert opinion is then made according to the results of the relationship of the bite pattern and suspect's teeth. According to the ABFO Guidelines for Investigative and Final Bite Mark Reports, *the biter, the probable biter, not excluded as the biter, excluded as the biter,* and *inconclusive* are the terms used to indicate the confidence level of the odontologist that the dentition of the putative suspect is concordant with a bite patterned mark observed on an inanimate object or victim.

To accomplish these goals, the dentist uses numerous methods that have been accepted in the courts. Images of the bite mark and the teeth can be digitized in a computer. This information can then be enhanced and subsequently overlaid for matching purposes.

Historically, a clear overlay of the chewing surfaces of the teeth was made by simply tracing these surfaces on a sheet of transparent acetate. Placing the incisal edges of the study casts on the glass of an office photocopier and duplicating on special paper achieved the same end. A similar effect was obtained by placing an opaque powder, such as barium sulfate, into wax or acrylic test bites and by obtaining radiographs of these exemplars. All of these overlays were then superimposed over the bite mark for comparison.

• **Fig. 19.22** An overlay of the maxillary cast of a suspect's dentition on a photograph of a bite pattern injury. Note the diastema between the central incisor teeth. The distal incisal surfaces of the lateral incisor teeth are not in the plane of occlusion.



• **Fig. 19.23** A repositioned overlay of the maxillary cast of a suspect's dentition on a photograph of a bite pattern injury (same case as depicted in Fig. 19.22). The drag marks, diastema space, and mesial contact points of the lateral incisor teeth become apparent in the pattern. (From Nuckles DB, Herschaft EE, Whatmough LN: Forensic odontology in solving crimes: dental techniques and bite-mark evidence, *Gen Dent* 42:210–214, 1994. Published with permission by the Academy of General Dentistry. © 1994 by the Academy of General Dentistry. All rights reserved.)

Studies indicate that there are limitations to the accuracy of these potentially subjective, biased overlay techniques and it has been suggested that hand-traced overlay methods be discontinued. Additionally, a stone cast exemplar of the dentition of a suspect has been placed over a 1:1 image of a BMPI for comparison (Figs. 19.22 and 19.23). This method of comparison may have limitations as well considering that current computer based technology, intended to assist the odontologist more objectively in bite mark casework, also may possess foundational constraints.

Presently, images of the bite mark and the incisal edges of the teeth of the suspect are routinely digitized and computer-generated hollow volume overlays are fabricated, enhanced, and subsequently compared using Adobe Photoshop or other graphics editing programs (Fig. 19.24).

dentlearn.ir

• **Fig. 19.24** On the left side, dental casts of an alleged suspect are being scanned and scaled to 1:1 before digitizing their image. The right half of the illustration shows three photographs of bite marks on the victim. Transparent overlays of the teeth of the alleged suspect have been digitally superimposed over 1:1 digital images of the victim's bite mark using a software program developed by Mideo Systems, Inc. (Huntington Beach, CA). (Courtesy of Dr. David K. Ord.)

In court, bite mark evidence must be able to withstand legal challenges based on its scientific validity and the credibility of the expert witness who presents the evidence. This is true regardless of the techniques used to retrieve, compare, and determine a conclusion based on the evidence. When the Guidelines for Bite Mark Analysis are used, such challenges can be minimized.

◆ HUMAN ABUSE

Epidemiology and Classification

Dental professionals are likely to encounter more victims of physical, neglective, sexual, and psychological abuse as the scope of the problems associated with violent human behavior become more recognized and openly discussed. Currently in the United States, statistics reveal more than 3.5 million cases of child abuse were investigated in 2018. Of these, almost 700,000 were confirmed to be victims of abuse or neglect. This figure represents approximately 1% of all children in the United States. In addition, 1809 cases of child abuse in 2019 resulted in death.

A 2017 report indicated that, worldwide, approximately 1 in 6 people (16%) 60 years of age and older had their human rights violated through the following forms of abuse:

- Physical
- Sexual
- Psychological and emotional
- Financial and material
- Abandonment
- Neglect
- Serious loss of dignity and respect.

In the United States, more than 10 million adult victims experience intimate partner violence (IPV) annually. This represents one incident of IPV occurring every three seconds.

Child abuse is the non-accidental, physical, mental, emotional, or sexual trauma; exploitation; or neglect endured by a child younger than 18 years of age while under the care of a responsible person, such as a parent, sibling, babysitter, teacher, or other person acting *in loco parentis.* The latter term refers to "the legal responsibility of a person or organization to take on some of the functions and responsibilities of a parent."

Elder abuse and abuse of the disabled are similar in all regards to child abuse, except that they deal with geriatric victims or individuals who are physically and/or mentally impaired or disabled. These populations often require special care or have been institutionalized. Staff members in facilities where these patients reside may perpetrate this form of human abuse on occupants.

Victims of IPV are unique and differ from those of child, elder, or disabled abuse because they often have autonomy to choose their circumstances. It is estimated that 1 in 4 women and 1 in 10 men have experienced sexual, physical violence, and/or stalking by an intimate partner. However, unlike the abused child, or geriatric or disabled resident in a nursing home, an abused intimate partner can make choices to leave the traumatic, violent environment. However, many do not and remain committed to the relationship!

The National Child Abuse and Neglect Data System (NCANDS) is a federally sponsored program directed by the Department of Health and Human Services to collect and analyze annual data on child abuse and neglect. Recognizing the global problem, in 2020 the World Health Organization (WHO) released a *Global Status Report on Preventing Violence Against Children*. This document addresses violence against children in the home, school, workplace, community, and other settings. The project is a comprehensive, global study conducted by the WHO on all forms of violence against children (Box 19.2).

More than 200 million girls between infancy and age 15, and women have undergone some form of female genital mutilation (FGM), which has no health benefits. Cutting and partial or total removal of external female genitalia or other injury to the female genital organs occurs principally in African, Middle Eastern, and Asian countries.

It is estimated that 218 million children between the ages of 5 and 17 years old are employed. Among these, 160 million are child labor or child slavery victims required to perform hazardous work. This represents an increase of 8.4 million child labor victims since 2016. Boys are more likely to be involved and, worldwide, agricultural production accounts for the largest number of children employed. Over 40 million individuals have been forced into prostitution and pornography, and 10 million children were victims of human trafficking.

Victims and their abusers come from all ethnic, religious, socioeconomic, and educational backgrounds. Reports concerning the distribution of cases among the different types of abuse vary widely. Up to 70% of child abuse cases may be the result of physical trauma. Some studies relate 15%–25% of the cases to sexual abuse and 50% to neglect. Neglective abuse is subclassified by the caretaker's neglect of the child's

dentlearn.ir

• BOX 19.2 World Health Organization 2020: Global Status Report on Preventing Violence Against Children

- Internationally, one billion children (1 out of 2) are affected by some form of violence annually.
- Worldwide, more than 40,000 children aged <1 to 17 years old died as a result of abuse.
- Almost 3 in 4 children aged 2–4 years *regularly* are subjected to physical or psychological violence by a parent of caregiver.
- One-hundred and twenty million girls and young women <20 years old experienced forced sexual intercourse or other forms of sexual violence.
- Men are routinely less likely to report sexual abuse; however, those who have experienced this trauma as children are at greater risk of post-traumatic stress disorder (PTSD) and depression, alcoholism and drug abuse, and suicidal inclinations.
- Twenty-five percent of children <5 years old have a mother victimized by IPV.
- Thirty-three percent of 11–15-year-old students have been bullied and 13% of these children are less likely to graduate.
- Adult men who have experienced multiple abuse experiences as children are 14 times more prone to commit acts of physical and/or sexual IPV.
- Adult women who have experienced multiple abuse experiences as children are 16 times more prone to be victims of physical and/or sexual IPV.

medical, dental, and safety needs; physical well-being; or education.

Intentional drugging or poisoning and failure to thrive are additional types of maltreatment classified as abusive. Munchausen syndrome by proxy is a form of child abuse in which the caregiver intentionally overstates, contrives, and/or creates a physical, emotional, or behavioral problem in the child. The victim is made to appear sick or is harmed in some other way to deceive health care professionals and others in order to gain attention and sympathy for the caregiver.

It should be recalled that there are numerous metabolic, cutaneous, and congenital diseases that may mimic the signs and symptoms associated with child abuse. These include hemophilia, various vitamin deficiencies, Ehlers-Danlos syndrome, incontinentia pigmenti, Fanconi syndrome, and osteogenesis imperfecta among others.

Many abusive individuals were themselves abused as children. Criminal charges are often lodged against an abusing caretaker. It is recognized, however, that counseling and psychological and emotional support can also help to stabilize a violent, dysfunctional family unit.

Signs and Symptoms

Regardless of the overall statistical variations in subclassification of the problem of abuse, the dentist is most likely to encounter physical and sexual abuse, as well as health care and safety neglect among pediatric, older adult, and disabled dental patients. Of the children and older adults who are physically abused, 50% manifest orofacial and scalp injuries

• Fig. 19.25 An avulsed tooth, a fractured tooth, and a torn labial frenum associated with oral facial injuries in physical child abuse.

• Fig. 19.26 Bilateral periorbital ecchymoses (raccoon mask) and fractured nasal bone in a 77-year-old white female victim of physical elder abuse. (Courtesy of Dr. John D. McDowell.)

(Figs. 19.25 and 19.26). These unexplained injuries are inappropriately reported by the caretaker or are inconsistent with the history provided. Abusive trauma to the face, mouth and skull includes the following:

- Laceration of the labial or lingual frenum, which results from a blow to the lip or forceful feeding
- Repeated fracture or the avulsion of teeth
- Zygomatic arch and nasal fractures
- Bilateral contusions of the lip commissures from the placement of a gag
- Bilateral periorbital ecchymoses (raccoon mask)
- Mastoid ecchymosis (Battle sign) indicating fracture of the middle cranial fossa and related traumatic brain injury (Fig. 19.27)
- Traumatic alopecia secondary to grabbing the head hair of the victim while throwing them.

Pattern injuries can be associated with the semicircular or crescent shape of bite marks. Other instruments that contact the skin may leave parallel linear patterns; these include injuries made by a hanger, strap, belt, or ruler. Multiple parallel lines are associated with finger marks after an open-handed slap. Multiple circular, punched out, or ulcerated areas are

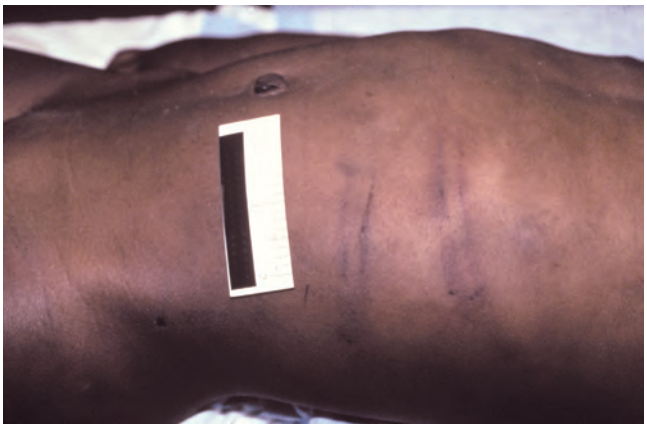
dentlearn.ir

caused by intentional burning with a cigarette or cigar. Loop patterns are created by electrical cord, rope, and wire (Figs. 19.28 and 19.29).

Other characteristics of child and elder abuse injuries are related to their multiplicity and repetitive nature. They often appear in various stages of resolution. Some injuries are acute; others are healing or even scarred. Therefore, the dentist should examine the skin of the pediatric, geriatric, or disabled dental patient. Suspicion of abuse is increased when the child or older patient appears overdressed for seasonal conditions; overdressing may be an attempt to mask or hide the physical signs of abuse.

• **Fig. 19.27** Battle sign—mastoid ecchymosis.

• **Fig. 19.28** Multiple circular ulcerated injuries are associated with intentional burns from a cigarette. When a child is accidentally burned by a cigarette, only one elliptic ulcer is observed.



By adulthood, 10% of men and 25% of women are the victims of sexual abuse. Oral infections associated with sexually transmitted diseases (STDs) are obviously signs of sexual abuse when they are observed in a minor. Erythematous or petechial lesions of the palate or ulceration of the sublingual area should be noted because these findings can result from the physical trauma associated with performing fellatio or cunnilingus (see page 297).

Among siblings, nursing or "baby bottle caries" is a sign of neglective abuse and indicates the caretaker's inattention to the dental needs of the children. When infants and toddlers are placed to bed with a nursing bottle filled with cariogenic solutions (e.g., milk, soft drinks, and sweet juices), the maxillary incisors are bathed in the sugary solution and can manifest severe caries. The mandibular teeth, protected from the cariogenic material by the position of the tongue and nipple during sucking, are spared the destructive effects, and the child takes on the appearance of a pseudoprognathism or pseudo-Class III malocclusion (Fig. 19.30).

The dentist may become aware of other abusive behavior directed to a child or older patient by a responsible caretaker. Abusive behavior can involve refusal or delay in seeking treatment for serious medical or dental problems, abandonment, refusal to cooperate with planned treatment, and failure to return to the same physician or dentist for treatment.

Role of Dentistry in Recognizing and Reporting Human Abuse

Awareness of the signs and symptoms of abuse among individuals of all ages should be a goal for every dentist. As a component of the dental relicensure process, the state of New

• **Fig. 19.29** Parallel linear ("railroad track") patterns are associated with blows to the skin with such straight-edged objects as a belt, a hanger, an electrical cord, and a ruler.

dentlearn.ir

York requires documentation of continuing education credits in the area of child abuse recognition and the dental professional's responsibility to report such cases.

By statute, all states require that dental personnel, other health care professionals, teachers, and day care and nursing home employees report suspected cases of child and elder abuse. Unfortunately, the reporting of IPV is limited in most jurisdictions to cases involving the use of a weapon while committing a violent act. Unlike the requirement for dental professionals to report child and elder abuse, the dentist has no legal requirement to report IPV because these victims are autonomous. However, the American Dental Association's Principles of Ethics and Code of Professional Conduct indicate a responsibility on behalf of dental professionals to intercede in cases involving family violence.

The agency to which the report is made varies among the different jurisdictions. Commonly, the police, social service, child welfare, senior services agencies, or family services departments are the governmental offices designated to accept reports. When a report is made in good faith, the dentist is immune from any counter prosecution or civil liability that might stem from a false report. Failure to report is considered a misdemeanor in most states. In addition, the dentist may be subject to license revocation or malpractice litigation by failing to make a report.

When a dentist determines that a report of child or elder abuse should be made, documentation of the physical evidence to support the charge is mandatory. All evidence is collected according to the principles described for identification and bite mark cases. Descriptions of the injuries and their locations, supporting photographs and radiographs, and information stating the basis for suspicion of abuse are included in the report. When abuse is considered, the dentist should examine the patient and assess the problem separately from the abusive caregiver. Parental consent is not required to obtain appropriate physical evidence from victims younger than the age of majority.

Therefore, all parents and accompanying siblings should be directed to remain in the office waiting area while a minor patient is being treated. This policy should be maintained whether abuse is suspected or not so that the dentist, acting *in loco parentis*, can examine each patient for signs and symptoms of abuse and obtain the child's report concerning the findings without influence or pressure from the caregiver.

◆ DENTISTS AS EXPERT WITNESSES

Observational, or lay, witnesses testify only to the facts known to them. They are referred to as *witnesses of fact.* Such witnesses are permitted to make inferences about physical facts based on ordinary experience. The witness of fact is not entitled to present hearsay evidence related by another person.

The judicial system recognizes that people with a scientific background or specialized field of study that is admissible under the *Frye* rule or Federal Rules of Evidence can provide the courts with analyses or explanations relative to that discipline. The facts and opinions offered by such a witness are beyond the scope of information that could be expected to be provided by a lay person or witness of fact. A witness who is qualified to testify under this standard is acknowledged as an "expert."

Members of the dental profession are experts. They are qualified to testify by the judge, who bases his or her opinion on educational background, dental and forensic expertise, publications, and other professional qualifications. Dentists who have additional training in one of the dental specialties may be called on to present specific information from that discipline.

Dental experts assist attorneys and, ultimately, the triers of fact (judges and juries) in understanding the scope and complexities of dental science and practice in relation to questions of law. The dentist should not become an advocate for either side in a case but should strive to be an educator and friend of the court.

In addition to their expertise in criminal trials involving bite marks, human abuse, and/or identification of homicide victims, dentists may be required to testify as experts in civil litigation cases that involve the following situations:

- **Malpractice based on negligence.** This category includes battery (e.g., extraction of the wrong tooth); misdiagnosis; and failure to diagnose, refer, or inform. All of these actions fall outside the standard of care for the profession.
- **Personal injury.** TMJ damage or dental trauma suffered in vehicular, home, sports, recreational, and work-related accidents fall under this category.
- **Dental fraud.** Charging for materials or procedures that were not used or performed are examples of fraud.
- **Identification of multiple fatality incident victims.** These may include casualties of natural disasters and accidents that are adjudicated civilly or criminal acts in which an offender is brought before the criminal judicial system.

Dentists are often unfamiliar with, and may be intimidated by, the adversarial nature of courtroom procedure and protocol. When presenting evidence, the dental expert should remember that his or her role in the legal process is to help the trier of fact understand the dental issues in the case. To this end, and as a scientist, the dental expert witness should present the evidence confidently, accurately, and objectively, relating information in nontechnical terms.

When cross-examined by the opposing attorney, the dental expert witness should remain composed and confident. As an expert, the dentist has the right to refer to records and exemplars prepared for the case. The dentist is entitled to read and review any books or articles proffered by the opposing attorney with the intent of discrediting the testimony.

Pretrial preparation is required if the dental expert and the attorney who has retained his or her services are to develop the evidence to be presented in court. Both must be aware of the strengths and weaknesses of the material and decide how best to provide the jury with this information. Adequate time must be allotted to prepare exhibits for court. It is also advantageous to attempt to determine the position that will be taken by dental experts called by the opposing side.

SUMMARY

Each practitioner has a responsibility to understand the forensic implications associated with the practice of his or her profession. This understanding should include more than ethics and jurisprudence, which were traditionally the only aspects of knowledge of the law acquired by dental professionals. Appreciation of forensic dental problems involving body identification, dental age estimation methods, recognition and reporting of human abuse, and bite mark analysis permits clinicians to maintain legally acceptable records and assist legal authorities in the identification of victims of individual or multiple fatality incidents and criminal acts.

The pursuit of justice in cases of rape, homicide, and human abuse often relies on dental testimony to interpret bite marks or BMPIs. The development of UV and IR wavelength photographic techniques and equipment has given forensic dentists the opportunity to provide objective scientific evidence in these types of cases. Evidence gathered using these resources can be analyzed and assessed with computer software, laboratory, and clinical procedures that also enhance the ability of the forensic odontologist to interpret results.

The reliance of the legal community on the dental profession to continue to provide expertise in civil and criminal proceedings ensures that forensic dentistry will remain a viable component of the forensic sciences and the practice of dentistry.

Appendix

Differential Diagnosis of Oral and Maxillofacial Diseases

The most important aspect of patient care is the accurate diagnosis of the patient's disease. Unfortunately, the clinical presentation of many disease processes can be strikingly similar, despite their vast differences in etiology and pathogenesis. Because treatment and, ultimately, prognosis are based on the diagnosis, the diagnostic process is critical in optimal patient management. This appendix provides some guidelines for expediting and facilitating the diagnostic process from a clinical perspective.

The first step in gathering information is the acquisition of a thorough history of the disease process. This step typically includes items such as the onset, severity, location, duration, character, and course of the signs and symptoms being experienced by the patient. Additional information regarding medical, social, and family history may be necessary. With this information, the clinician can often start the process of formulating a list of possible diagnoses, even before performing an examination.

The information obtained during the clinical examination is also important because many lesions have characteristic appearances. By evaluating these characteristics in conjunction with the patient's history, often the clinician can narrow the list of diagnostic possibilities. This list, known as a *differential diagnosis*, essentially includes possible pathologic entities, usually ranked in order from most likely to least likely.

DEFINITIONS

To better describe the appearances of lesions and communicate these features to colleagues, the clinician should be familiar with the following terms:

Macule. Focal area of color change that is not elevated or depressed in relation to its surroundings.

Papule. Solid, raised lesion that is less than 5 mm in diameter.

Nodule. Solid, raised lesion that is greater than 5 mm in diameter.

Sessile. Describing a tumor or growth whose base is the widest part of the lesion.

Pedunculated. Describing a tumor or growth whose base is narrower than the widest part of the lesion.

Papillary. Describing a tumor or growth exhibiting numerous surface projections.

Verrucous. Describing a tumor or growth exhibiting a rough, warty surface.

Vesicle. Superficial blister, 5 mm or less in diameter, usually filled with clear fluid.

Bulla. Large blister, greater than 5 mm in diameter.

Pustule. Blister filled with purulent exudate.

Ulcer. Lesion characterized by loss of the surface epithelium and frequently some of the underlying connective tissue. It often appears depressed or excavated.

Erosion. Superficial lesion, often arising secondary to rupture of a vesicle or bulla, that is characterized by partial or total loss of the surface epithelium.

Fissure. Narrow, slitlike ulceration or groove.

Plaque. Lesion that is slightly elevated and is flat on its surface.

Petechia. Round, pinpoint area of hemorrhage.

Ecchymosis. Nonelevated area of hemorrhage, larger than a petechia.

Telangiectasia. Vascular lesion caused by dilatation of a small, superficial blood vessel.

Cyst. Pathologic epithelium-lined cavity, often filled with liquid or semi-solid contents.

Unilocular. Describing a radiolucent lesion having a single compartment.

Multilocular. Describing a radiolucent lesion having several or many compartments.

By using these terms, the clinician can describe the characteristics of lesions efficiently and uniformly. Applying these clinical descriptors to the lesions also can help categorize them with respect to the differential diagnosis. By adding additional characteristics such as prevalence, patient race or nationality, patient age at diagnosis, patient sex, and sites of predilection, the clinician can hone the differential diagnosis list considerably.

HOW TO USE THIS APPENDIX

This appendix is designed to help the clinician formulate a differential diagnosis by organizing and categorizing disease entities according to their most prominent or identifiable

dentlearn.ir

clinical features. Under each "clinical feature" heading is a list of lesions with that clinical feature as a prominent component. Diseases are listed according to estimated frequency relative to similar diseases or lesions.

The most common lesions are marked with triple asterisks (***), less common lesions are marked with double asterisks (**), and rare lesions are marked with a single asterisk (*). Such estimated frequency indicators should not be compared between lists; they are intended only for the single differential diagnosis list in which they occur.

Clinical features that most readily distinguish the lesions are listed with each disease process to help focus the clinician's search for the most accurate diagnosis. Finally, the corresponding page number in the book is provided for each disease entity so that the reader can refer to the text for a more detailed discussion.

INDEX TO THE APPENDIX: DIFFERENTIAL DIAGNOSIS LISTS

Part 1: Mucosal and Soft Tissue Pathology: Color Changes

A. White Lesions: Can Be Scraped Off 916
B. White Lesions: Cannot Be Scraped Off 916
C. White and Red Lesions 917
D. Red Lesions 917
E. Petechial, Ecchymotic, and Telangiectatic Lesions 918
F. Blue and/or Purple Lesions 918
G. Brown, Gray, and/or Black Lesions 918
H. Yellow Lesions 919

Part 2: Mucosal and Soft Tissue Pathology: Surface Alterations

A. Vesiculoerosive and Ulcerative Lesions: Acute (Short Duration and Sudden Onset) 920
B. Vesiculoerosive and Ulcerative Lesions: Chronic (Long Duration) 920
C. Papillary Growths: Focal or Diffuse 921

Part 3: Mucosal and Soft Tissue Pathology: Masses or Enlargements

A. Soft Tissue Masses (Lumps and Bumps): Lower Lip 922
B. Soft Tissue Masses (Lumps and Bumps): Upper Lip 922
C. Soft Tissue Masses (Lumps and Bumps): Buccal Mucosa 922
D. Soft Tissue Masses (Lumps and Bumps): Gingiva/Alveolar Mucosa 922
E. Soft Tissue Masses (Lumps and Bumps): Floor of Mouth 923
F. Soft Tissue Masses (Lumps and Bumps): Tongue 923
G. Soft Tissue Masses (Lumps and Bumps): Hard or Soft Palate 923
H. Soft Tissue Masses (Lumps and Bumps): Multiple Lesions 924
I. Soft Tissue Masses (Lumps and Bumps): Midline Neck Lesions 924
J. Soft Tissue Masses (Lumps and Bumps): Lateral Neck Lesions 924
K. Generalized Gingival Enlargement 925

Part 4: Radiographic Pathology

A. Unilocular Radiolucencies: Pericoronal Location 926
B. Unilocular Radiolucencies: Periapical Location 926
C. Unilocular Radiolucencies: Other Locations 926
D. Multilocular Radiolucencies 927
E. Radiolucencies: Poorly Defined or Ragged Borders 927
F. Radiolucencies: Multifocal or Generalized 928
G. Radiopacities: Well-Demarcated Borders 928
H. Radiopacities: Poorly Demarcated Borders 929
I. Radiopacities: Multifocal or Generalized 929
J. Mixed Radiolucent/Radiopaque Lesions: Well-Demarcated Borders 929
K. Mixed Radiolucent/Radiopaque Lesions: Poorly Demarcated Borders 930
L. Mixed Radiolucent/Radiopaque Lesions: Multifocal or Generalized 930
M. Unique Radiographic Appearances: "Ground Glass" (Frosted Glass) Radiopacities 930
N. Unique Radiographic Appearances: "Cotton Wool" Radiopacities 930
O. Unique Radiographic Appearances: "Sunburst" Radiopacities 930
P. Unique Radiographic Appearances: "Onion-Skin" Radiopacities 930
Q. Soft Tissue Radiopacities 931

Part 5: Pathology of Teeth

A. Hyperdontia (Extra Teeth) 932
B. Hypodontia (Missing Teeth) 932
C. Macrodontia (Larger Than Normal Teeth) 932
D. Microdontia (Smaller Than Normal Teeth) 932
E. Malformed Crown 932
F. Enamel Loss After Tooth Formation 933
G. Extrinsic Staining of Teeth 933
H. Intrinsic Discoloration ("Staining") of Teeth 933
I. Abnormally Shaped Roots 933
J. Enlarged Pulp Chamber or Canal 934
K. Pulpal Calcification 934
L. Thickened Periodontal Ligament 934
M. Generalized Loss of Lamina Dura 934
N. Premature Exfoliation of Teeth 935

dentlearn.ir

Part 1: Mucosal and Soft Tissue Pathology: Color Changes

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
A. White Lesions: Can Be Scraped Off			
***	White-coated tongue	May be scraped off slightly, with difficulty	12
***	Pseudomembranous candidiasis	"Milk curd" or "cottage cheese" appearance; may leave red base when rubbed off	201
***	Morsicatio	Surface may appear to be peeling off	272
***	Toothpaste or mouthwash reaction	Filmy whiteness; leaves normal appearing mucosa when rubbed off	342
**	Thermal burn	Example: pizza burn	276
**	Sloughing traumatic lesion	Example: cotton roll "burn"	280
**	Chemical burn	Example: aspirin burn secondary to direct application for toothache	278
*	Secondary syphilis	Mucous patch; may be only partially scraped off	179
*	Diphtheria	Gray-white pseudomembrane of oropharynx	177
B. White Lesions: Cannot Be Scraped Off			
***	Linea alba	Buccal mucosa along occlusal plane	272
***	Leukoedema	Primarily in blacks; milky white alteration of buccal mucosa bilaterally; disappears when stretched	7
***	Leukoplakia	May show benign hyperkeratosis, epithelial dysplasia, or invasive carcinoma	381
***	Tobacco pouch keratosis	Usually in mandibular vestibule; associated with use of snuff or chewing tobacco	391
***	White-coated tongue	Diffuse involvement of dorsal tongue	12
**	Lichen planus	Wickham's striae; typically bilateral on buccal mucosa	787
**	Morsicatio	Most common on anterior buccal mucosa, labial mucosa, and lateral border of tongue; exhibits ragged surface	272
**	Actinic cheilosis	Pale, gray-white, scaly alteration of lower lip; usually in older men with history of chronic sun exposure; precancerous	395
*	Nicotine stomatitis	Usually associated with pipe smoking; occurs on hard palate	397
*	Hairy leukoplakia	Usually lateral border of tongue; rough surface with vertical fissures; usually associated with HIV infection	253
*	Hyperplastic candidiasis	Most commonly affects anterior buccal mucosa	206
*	Lupus erythematosus	Most common on buccal mucosa; may mimic lichen planus or leukoplakia; associated skin lesions usually present	798
*	Skin graft	History of previous surgery	—
*	Submucous fibrosis	More common in South Asia; associated with betel quid chewing	393
*	White sponge nevus	Hereditary; onset in childhood; generalized lesions, especially buccal mucosa	748
*	Hereditary benign intraepithelial dyskeratosis	Hereditary; onset in childhood; generalized lesions, especially buccal mucosa; ocular involvement possible	749
*	Pachyonychia congenita	Hereditary; onset in childhood; most common on dorsal tongue and areas of trauma; nail, palmar, and plantar changes also present	750

dentlearn.ir

Part 1: Mucosal and Soft Tissue Pathology: Color Changes—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
*	Dyskeratosis congenita	Hereditary; onset in childhood; dystrophic nail changes	752
*	Uremic stomatitis	Renal failure	852
C. White and Red Lesions			
***	Erythema migrans	Geographic tongue; continually changing pattern; rarely involves other oral mucosal sites	784
***	Candidiasis	White component may be rubbed off	201
**	Lichen planus	Atrophic or erosive forms; Wickham's striae; typically bilateral on buccal mucosa	787
**	Burns	Examples: pizza burn, aspirin burn, other chemical burns; white component may be rubbed off	276
**	Actinic cheilosis	Pale, gray-white and red alteration to lower lip; usually in older men with history of chronic sun exposure	395
**	Erythroleukoplakia	Usually shows epithelial dysplasia or carcinoma	390
**	Cinnamon reaction	Related to cinnamon-flavored gum; typically on buccal mucosa and lateral tongue	344
*	Nicotine stomatitis	Usually associated with pipe smoking; occurs on hard palate	397
*	Lupus erythematosus	Most common on buccal mucosa; may mimic lichen planus or leukoplakia; associated skin lesions usually present	798
*	Scarlet fever	Secondary to β-hemolytic streptococcal infection; strawberry/raspberry tongue	175
*	Verruciform xanthoma	Most common on gingiva and hard palate; surface may be papillary	365
D. Red Lesions			
***	Pharyngitis	Examples: strep throat, viral pharyngitis	174
***	Traumatic erythema	Caused by local irritation	—
***	Denture stomatitis	Denture-bearing palatal mucosa	205
***	Erythematous candidiasis	Example: central papillary atrophy (median rhomboid glossitis)	202
***	Erythema migrans	Geographic tongue (cases with absence of white borders); continually changing pattern; rarely involves other mucosal sites	784
***	Angular cheilitis	Erythema and cracking at labial commissures	204
**	Thermal burns	Example: caused by hot liquids	276
**	Erythroplakia	Usually shows epithelial dysplasia or carcinoma	390
**	Lichenoid and granulomatous stomatitis	Most common on the upper labial mucosa	336
*	Anemia	Atrophic, red tongue; can be due to pernicious anemia, iron-deficiency anemia, hypovitaminosis B	582
*	Hemangioma	Develops in younger patients; may blanch; may show bluish hue	547
*	Lupus erythematosus	Usually with associated skin lesions	798
*	Scarlet fever	Secondary to β-hemolytic streptococcal infection; strawberry/raspberry tongue	175
*	Plasma cell gingivitis	Allergic reaction usually related to flavoring agents	152
*	Radiation mucositis	Patient currently undergoing radiotherapy	281

(Continued)

dentlearn.ir

Part 1: Mucosal and Soft Tissue Pathology: Color Changes—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
E. Petechial, Ecchymotic, and Telangiectatic Lesions			
***	Nonspecific trauma	History of injury to lesional site	296
**	Upper respiratory infections	Soft palate petechiae	296
*	Infectious mononucleosis	Soft palate petechiae; tonsillitis and/or pharyngitis may be present	241
*	Idiopathic thrombocytopenic purpura	Areas of trauma; gingival bleeding possibly present	590
*	Trauma from fellatio	Posterior palatal petechiae or ecchymosis	297
*	Hemophilia	Hereditary; childhood onset; gingival bleeding may be present	579
*	Leukemia	Caused by secondary thrombocytopenia; gingival bleeding may be present	593
*	Hereditary hemorrhagic telangiectasia	Multiple, pinhead-sized telangiectasias; possible history of nosebleeds or gastrointestinal bleeding	759
*	CREST syndrome	Multiple, pinhead-sized telangiectasias; **C**alcinosis cutis, **R**aynaud's phenomenon, **E**sophageal motility defect, **S**clerodactyly, **T**elangiectasias	805
F. Blue and/or Purple Lesions			
***	Varicosities	Especially after 45 years of age; most common on ventral tongue and lips	13
***	Submucosal hemorrhage	Also see Appendix List, Part 1, E. (previous topic) Petechial, Ecchymotic, and Telangiectatic Lesions	296
***	Amalgam tattoo	Most common on gingiva; blue-gray; radiopaque amalgam particles sometimes discovered on radiographs	298
***	Mucocele	Especially on lower labial mucosa; typically pale blue; cyclic swelling and rupturing often exhibited	460
**	Eruption cyst	Overlying an erupting tooth	688
**	Salivary duct cyst	Usually pale blue	463
**	Hemangioma	Usually red-purple; may blanch under pressure; onset in younger patients	547
**	Ranula	Pale blue, fluctuant swelling of lateral floor of mouth	462
*	Kaposi sarcoma	Especially in AIDS patients; usually purple; most common on palate and maxillary gingiva	564
*	Nasopalatine duct cyst	Midline of anterior palate	27
*	Salivary gland tumors	Especially mucoepidermoid carcinoma and pleomorphic adenoma; usually pale blue; most common on posterior lateral palate	Chapter 11
*	Gingival cyst of the adult	Most common in mandibular bicuspid-cuspid region	698
*	Blue nevus	Most common on hard palate	377
*	Melanoma	Most common on hard palate and maxillary gingiva; may show mixture of deep blue, brown, black, and other colors	434
G. Brown, Gray, and/or Black Lesions			
***	Racial pigmentation	Most common on attached gingiva in darker complexioned patients	—
***	Amalgam tattoo	Most common on gingiva; usually slate-gray to black; opaque amalgam particles may be found on radiographs	298

dentlearn.ir

Part 1: Mucosal and Soft Tissue Pathology: Color Changes—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
***	Black/brown hairy tongue	Discoloration and elongation of filiform papillae	12
***	Melanotic macule	Brown; most common on lower lip	372
**	Smoker's melanosis	Most common on anterior facial gingiva	306
**	Non-amalgam tattoos	Example: graphite from pencil	298
*	Melanocytic nevus	Most common on hard palate; can be flat or raised	374
*	Melanoma	Most common on hard palate and maxillary gingiva; may show mixture of deep blue, brown, black, and other colors	434
*	Oral melanoacanthoma	Rapidly enlarging pigmented lesion; usually occurs in blacks	373
*	Drug ingestion	Examples: chloroquine, chlorpromazine, minocycline; especially on hard palate	307
*	Peutz-Jeghers syndrome	Freckle-like lesions of vermilion and perioral skin; intestinal polyps; hereditary	758
*	Addison disease	Chronic adrenal insufficiency; associated with bronzing of skin	843
*	Neurofibromatosis type I	*Café au lait* pigmentation; cutaneous neurofibromas	537
*	McCune-Albright syndrome	*Café au lait* pigmentation; polyostotic fibrous dysplasia; endocrine disorders	643
*	Heavy metal poisoning	Typically along marginal gingiva (e.g., lead, bismuth, silver)	304
*	Melanotic neuroectodermal tumor of infancy	Anterior maxilla; destroys underlying bone	541
H. Yellow Lesions			
***	Fordyce granules	Sebaceous glands; usually multiple submucosal papules on buccal mucosa or upper lip vermilion	6
**	Superficial abscess	Example: parulis from nonvital tooth	129
**	Accessory lymphoid aggregate	Most common in oropharynx and floor of mouth; may exhibit orange hue	578
**	Lymphoepithelial cyst	Most common on lingual and palatine tonsils, and floor of mouth; may be yellow-white	36
**	Lipoma	Most common on buccal mucosa; soft to palpation	530
*	Jaundice	Generalized discoloration, especially involving soft palate and floor of mouth; sclera usually affected also	823
*	Verruciform xanthoma	Most common on gingiva and hard palate; surface may be rough or papillary	365
*	Pyostomatitis vegetans	"Snail-track" pustules; associated with inflammatory bowel disease	851

dentlearn.ir

Part 2: Mucosal and Soft Tissue Pathology: Surface Alterations

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
A. Vesiculoerosive and Ulcerative Lesions: Acute (Short Duration and Sudden Onset)			
***	Traumatic ulcer	Mild-to-moderate pain; history of local trauma	273
***	Aphthous stomatitis	Extremely painful; may be single or multiple; nonkeratinized movable mucosa; often recurs	321
***	Recurrent herpes labialis	Vermilion and labial skin; begins as multiple vesicles; often recurs	231
**	Primary herpetic gingivostomatitis	Fever and malaise; children and young adults; multiple vesicles; gingiva consistently affected	230
**	Necrotizing (ulcerative) gingivitis (NUG)	Painful destruction of gingival papillae; fetid odor; mostly in teenagers and young adults	151
**	Mucosal burns	Chemical or thermal	276
**	Recurrent intraoral herpes simplex	Gingiva or hard palate (except in immunocompromised); focal cluster of vesicles and shallow ulcers	232
**	Allergic reactions	Example: Caused by topical medications or dental materials; erythema and vesicles	342
**	Erythema multiforme / Stevens-Johnson syndrome	Predominantly in children and young adults; multiple blisters and ulcers; often crusting, hemorrhagic lip lesions; may have associated "target" skin lesions or involvement of ocular and genital mucosa	781
**	Herpangina	Especially in children; multiple small ulcers on soft palate and tonsillar pillars	244
*	Varicella (chickenpox)	Associated with skin eruption; few oral vesicles and ulcers; usually in children	235
*	Herpes zoster	Unilateral involvement along nerve distribution; usually middle-aged and older adults; painful vesicles and ulcers	238
*	Hand-foot-and-mouth disease	Especially in children; multiple vesicles and ulcers; associated vesicles on hands and feet	244
*	Necrotizing sialometaplasia	Usually posterior lateral hard palate; prior swelling may be present; deep crater-like ulcer; may be only minimal pain	477
*	Anesthetic necrosis	Usually at site of palatal injection	294
*	Primary syphilis	Chancre at site of inoculation; usually painless with clean ulcer bed	179
*	Behçet syndrome	Aphthous-like ulcers; genital ulcers and ocular inflammation	326
B. Vesiculoerosive and Ulcerative Lesions: Chronic (Long Duration)			
***	Erosive lichen planus	Associated with white striae; usually in middle-aged and older adults; most common on buccal mucosa and gingiva ("desquamative gingivitis")	787
**	Traumatic granuloma	Solitary, non-healing ulcer	273
**	Squamous cell carcinoma	Usually in middle-aged and older adults; usually indurated and may have rolled border; may be painless	401
**	Mucous membrane pemphigoid	Most common in middle-aged and older women; most commonly presents as a "desquamative gingivitis"; may involve ocular and genital mucosa	775
*	Lupus erythematosus	May have associated red and white change; usually with skin involvement	798
*	Pemphigus vulgaris	Usually in middle-aged and older patients; multiple oral blisters and ulcers usually precede skin lesions	769
*	Deep fungal infections	Examples: histoplasmosis, blastomycosis; may be painless	Chapter 6
*	Tuberculosis	Associated mass may be present; may be painless	185

dentlearn.ir

Part 2: Mucosal and Soft Tissue Pathology: Surface Alterations—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
*	Sarcoidosis	May be associated with erythematous macules or plaques; may be painless	328
*	Epidermolysis bullosa	Hereditary (except epidermolysis bullosa acquisita); onset in infancy and childhood; multiple skin and oral blisters or ulcers in areas of trauma; may result in extensive scarring	766
*	Pyostomatitis vegetans	Yellowish "snail-track" pustules; associated with inflammatory bowel disease	851
*	Granulomatosis with polyangiitis (Wegener granulomatosis)	Usually palatal ulceration and destruction; associated lung and kidney involvement may be present; may show "strawberry gingivitis"	333
*	Extranodal NK/T-cell lymphoma, nasal-type (midline lethal granuloma)	Palatal lymphoma with ulceration and destruction of underlying bone; may be painless	607
*	Noma	Gangrenous necrosis secondary to necrotizing ulcerative gingivitis; usually in malnourished children or immunocompromised individuals	191
*	Tertiary syphilis	Gumma; associated mass may be present; may be painless; may perforate palate	180
C. Papillary Growths: Focal or Diffuse			
***	Hairy tongue	Usually brown or black discoloration; hyperkeratotic elongation of filiform papillae on posterior dorsal tongue	12
***	Papilloma	Can be white or pink; most common on soft palate and tongue; usually pedunculated	355
***	Inflammatory papillary hyperplasia	Usually involves midportion of hard palate beneath denture	519
**	Leukoplakia (some variants)	Examples: proliferative verrucous leukoplakia, granular or nodular leukoplakia	381
**	Squamous cell carcinoma	Examples with papillary surface changes	401
**	Giant cell fibroma	Usually in children and young adults; most common on gingiva	514
*	Spongiotic gingival hyperplasia	Usually in children; some examples appear papillary	150
*	Verruca vulgaris	Common wart; especially in younger patients; most common on labial mucosa	357
*	Hairy leukoplakia	Usually lateral border of tongue; rough surface with vertical fissures; usually associated with HIV infection	253
*	Verruciform xanthoma	Most common on gingiva and hard palate	365
*	Verrucous carcinoma	Especially in older patients with long history of snuff or chewing tobacco use; especially in mandibular vestibule and buccal mucosa; may be white or red	421
*	Condyloma acuminatum	Venereal wart; broad-based lesions with blunted projections; frequently multiple	358
*	Multifocal epithelial hyperplasia	Usually multiple, flat-topped papular lesions; usually in children; most common in Native Americans and Inuit; color may vary from normal to white	360
*	Darier's disease	Most commonly appears as pebbly appearance of hard palate; associated crusty, greasy skin lesions; hereditary	756
*	Acanthosis nigricans (malignant type)	Most commonly appears as generalized pebbly alteration of upper lip; pigmented, pebbly skin changes in flexural areas; associated gastrointestinal malignancy	806

dentlearn.ir

Part 3: Mucosal and Soft Tissue Pathology: Masses Or Enlargements

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
A. Soft Tissue Masses (Lumps and Bumps): Lower Lip			
***	Mucocele	Typically pale blue; often exhibits cyclic swelling and rupturing; labial mucosa only	460
***	Fibroma	Usually normal in color	514
**	Pyogenic granuloma	Red, ulcerated, bleeds easily; usually on vermilion border	525
**	Squamous cell carcinoma	Tumor with rough, granular, irregular surface; usually on vermilion border	401
*	Other mesenchymal tumors	Examples: hemangioma, neurofibroma, lipoma	Chapter 12
*	Salivary duct cyst	May be bluish; labial mucosa only	463
*	Salivary gland tumor	Usually mucoepidermoid carcinoma	Chapter 11
*	Keratoacanthoma	Volcano-shaped mass with central keratin plug; rapid development; vermilion border only	398
B. Soft Tissue Masses (Lumps and Bumps): Upper Lip			
**	Fibroma	Usually normal in color	514
**	Minor gland sialolith	Small, hard submucosal mass: may be tender	465
**	Salivary gland tumor	Usually canalicular adenoma (older than age 40) or pleomorphic adenoma (younger than age 40)	Chapter 11
*	Salivary duct cyst	May be bluish	463
*	Other mesenchymal tumors	Examples: hemangioma, neurofibroma, schwannoma	Chapter 12
*	Nasolabial cyst	Fluctuant swelling of lateral labial vestibule	26
C. Soft Tissue Masses (Lumps and Bumps): Buccal Mucosa			
***	Fibroma	Usually normal in color; along occlusal plane	514
**	Lipoma	May be yellow; soft to palpation	530
**	Mucocele	Typically pale blue; often exhibits cyclic swelling and rupturing	460
*	Hyperplastic lymph node	Usually buccinator node; movable submucosal mass	578
*	Other mesenchymal tumors	Examples: hemangioma, neurofibroma	Chapter 12
*	Squamous cell carcinoma	Tumor with rough, granular, irregular surface	401
*	Salivary gland tumor	Pleomorphic adenoma and mucoepidermoid carcinoma most common	Chapter 11
D. Soft Tissue Masses (Lumps and Bumps): Gingiva/Alveolar Mucosa			
***	Parulis	Fistula from nonvital tooth	130
***	Epulis fissuratum	Ill-fitting denture	517
***	Pyogenic granuloma	Usually red, ulcerated, easily bleeding; increased frequency in pregnant women	525
***	Peripheral ossifying fibroma	May be red or normal in color; may be ulcerated	529
***	Fibroma	Usually normal in color	514
***	Peripheral giant cell granuloma	Reddish purple; frequently ulcerated	527
**	Spongiotic gingival hyperplasia	Usually in children; most common on maxillary anterior facial gingiva	150
**	Squamous cell carcinoma	Tumor with rough, granular, irregular surface	401
*	Metastatic tumors	May be painful and destroy bone	569

dentlearn.ir

Part 3: Mucosal and Soft Tissue Pathology: Masses Or Enlargements—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
*	Gingival cyst of the adult	Most common in mandibular bicuspid-cuspid region; may be blue	698
*	Traumatic neuroma	Edentulous mandible in mental foramen area; often painful to palpation	532
*	Kaposi sarcoma	Especially in AIDS patients; usually purple	254
*	Peripheral odontogenic tumors	Example: peripheral ameloblastoma	715
*	Congenital epulis	Usually in females; especially anterior maxilla	546
*	Melanotic neuroectodermal tumor of infancy	Anterior maxilla; destroys underlying bone; may be pigmented	541
*	Other mesenchymal tumors	Examples: hemangioma, neurofibroma	Chapter 12
E. Soft Tissue Masses (Lumps and Bumps): Floor of Mouth			
***	Ranula/mucocele	Typically a pale blue, fluctuant swelling	462
**	Sialolith	Usually hard mass in submandibular duct; may be associated with tender swelling of affected gland; radiopaque mass	465
**	Lymphoepithelial cyst	Small, yellow-white submucosal lesion	36
**	Squamous cell carcinoma	Tumor with rough, granular, irregular surface	401
*	Epidermoid or dermoid cyst	Midline yellow-white submucosal lesion	32
*	Salivary gland tumors	Especially mucoepidermoid carcinoma	Chapter 11
*	Mesenchymal tumors	Examples: lipoma, neurofibroma, hemangioma	Chapter 12
F. Soft Tissue Masses (Lumps and Bumps): Tongue			
***	Fibroma	Usually normal in color; most common on margins of tongue	514
**	Squamous cell carcinoma	Tumor with rough, granular, irregular surface; usually lateral or ventral border	401
**	Mucocele	Usually anterior ventral surface; usually bluish or clear color	460
**	Pyogenic granuloma	Usually red, ulcerated, easily bleeding	525
*	Granular cell tumor	Dome-shaped; usually on dorsum of tongue	544
*	Other mesenchymal tumors	Examples: lymphangioma, hemangioma, neurofibroma, osseous choristoma	Chapter 12
*	Salivary gland tumors	Especially mucoepidermoid carcinoma and adenoid cystic carcinoma	Chapter 11
*	Lingual thyroid	Usually posterior midline of dorsal surface; usually in women	10
G. Soft Tissue Masses (Lumps and Bumps): Hard or Soft Palate			
***	Palatal abscess	Associated with nonvital tooth	129
***	Leaf-like denture fibroma	Pedunculated hyperplastic growth beneath ill-fitting denture	517
**	Salivary gland tumors	Especially pleomorphic adenoma, mucoepidermoid carcinoma, adenoid cystic carcinoma, polymorphous low-grade adenocarcinoma; may have bluish hue	Chapter 11
**	Nasopalatine duct cyst	Fluctuant swelling of anterior midline palate	27
*	Lymphoma	Often boggy and edematous; may have bluish hue; may be bilateral	600
*	Kaposi sarcoma	Usually purple; may be multiple; usually associated with AIDS	254
*	Other mesenchymal tumors	Examples: fibroma, hemangioma, neurofibroma	Chapter 12
*	Squamous cell carcinoma	Tumor with rough, granular, irregular surface; occasionally arises from maxillary sinus	401

(Continued)

dentlearn.ir

Part 3: Mucosal and Soft Tissue Pathology: Masses Or Enlargements—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
*	Mucocele/salivary duct cyst	Usually has bluish hue	460
*	Melanocytic nevus/melanoma	Usually pigmented	374, 434
*	Necrotizing sialometaplasia	Early stage lesion; often associated with pain or paresthesia	477
*	Adenomatoid hyperplasia of minor salivary glands	Asymptomatic, painless mass	477
H. Soft Tissue Masses (Lumps and Bumps): Multiple Lesions			
**	Multiple fibromas	Some patients may develop more than one fibroma on the oral mucosa	514
*	Kaposi sarcoma	Usually purple lesions of palate and maxillary gingiva; usually associated with AIDS	254
*	Neurofibromatosis type I	Oral and skin neurofibromas; *café au lait* skin pigmentation	537
*	Multifocal epithelial hyperplasia	Usually flat-topped papular lesions; usually in children; most common in Native Americans and Inuit; color may vary from normal to white	360
*	Amyloidosis	Pale, firm deposits, especially in tongue; periocular cutaneous lesions frequently present; most often associated with multiple myeloma	824
*	Granulomatous diseases	Examples: sarcoidosis, Crohn disease, leprosy	328
*	Multiple endocrine neoplasia type 2B	Mucosal neuromas of lips and tongue; adrenal pheochromocytomas; medullary thyroid carcinoma; marfanoid body build	540
*	Tuberous sclerosis	Small fibroma-like growths on gingiva; angiofibromas of face; epilepsy; intellectual disability	762
*	Multiple hamartoma syndrome	Cowden syndrome; small fibroma-like growths on gingiva; multiple hamartomas of various tissues; breast cancer in affected women	765
I. Soft Tissue Masses (Lumps and Bumps): Midline Neck Lesions			
**	Thyroid gland enlargement	Examples: goiter, thyroid tumor	—
*	Thyroglossal duct cyst	May move up and down with tongue motion	33
*	Dermoid cyst	Soft and fluctuant	32
*	Plunging ranula	Soft and compressible	462
J. Soft Tissue Masses (Lumps and Bumps): Lateral Neck Lesions			
***	Reactive lymphadenopathy	Secondary to oral and maxillofacial infection; often tender to palpation	578
**	Epidermoid cyst	Soft and movable	31
**	Lipoma	Soft mass	530
**	Metastatic carcinoma	Deposits from oral and pharyngeal carcinomas; usually indurated and painless; may be fixed	410
**	Lymphoma	May be unilateral or bilateral; usually painless; Hodgkin and non-Hodgkin types	598
*	Infectious mononucleosis	Fatigue; sore throat; tender lymph nodes	241
*	Salivary gland tumors	Arising from submandibular gland or tail of parotid gland	Chapter 11
*	Submandibular sialadenitis	Example: secondary to sialolithiasis	467
*	Branchial cleft cyst	Soft and fluctuant; most common in young adults	35
*	Granulomatous diseases	Examples: tuberculosis, sarcoidosis	185, 328

dentlearn.ir

Part 3: Mucosal and Soft Tissue Pathology: Masses Or Enlargements—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
*	Cat-scratch disease	History of exposure to cat	194
*	Cystic hygroma	Infants; soft and fluctuant	553
*	Plunging ranula	Soft and compressible	462
*	Other mesenchymal tumors	Examples: neurofibroma, carotid body tumor	Chapter 12
K. Generalized Gingival Enlargement			
***	Hyperplastic gingivitis	Examples: associated with puberty, pregnancy, diabetes	147
**	Drug-related gingival hyperplasia	Examples: phenytoin, calcium-channel blockers, cyclosporine; may be fibrotic	156
*	Gingival fibromatosis	May be hereditary; onset in childhood	158
*	Leukemic infiltrate	Usually boggy and hemorrhagic	593
*	Granulomatosis with polyangiitis (Wegener granulomatosis)	"Strawberry" gingivitis; may have palatal ulceration and destruction; lung and kidney involvement	333
*	Scurvy	Vitamin C deficiency	828

dentlearn.ir

Part 4: Radiographic Pathology

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
A. Unilocular Radiolucencies: Pericoronal Location			
***	Hyperplastic dental follicle	<5 mm in thickness	687
***	Dentigerous cyst	>5 mm in thickness	685
**	Eruption cyst	Bluish swelling overlying erupting tooth	688
**	Odontogenic keratocyst	—	689
*	Orthokeratinized odontogenic cyst	—	693
*	Ameloblastoma	Especially unicystic type	707
*	Ameloblastic fibroma	Usually in younger patients	724
*	Adenomatoid odontogenic tumor	Usually in anterior region of jaws; most often with maxillary canine; usually in teenagers	718
*	Calcifying odontogenic cyst	Gorlin cyst	701
*	Carcinoma arising in dentigerous cyst	Mostly in older adults	705
*	Intraosseous mucoepidermoid carcinoma	Mostly in posterior mandible	496
*	Other odontogenic lesions	Examples: calcifying epithelial odontogenic tumor, odontogenic myxoma, central odontogenic fibroma	Chapter 15
B. Unilocular Radiolucencies: Periapical Location			
***	Periapical granuloma	Nonvital tooth	123
***	Periapical cyst	Nonvital tooth	126
**	Periapical cemento-osseous dysplasia (early)	Especially in black females; usually apical to mandibular anteriors; teeth are vital	646
*	Periapical scar	Usually endodontically treated tooth with destruction of cortical plate	125
*	Radicular dentin dysplasia (Dentin dysplasia type I)	Multiple periapical granulomas or cysts; shortened, malformed roots	108
C. Unilocular Radiolucencies: Other Locations			
***	Developing tooth bud	Within alveolar bone	—
**	Lateral radicular cyst	Nonvital tooth; lateral canal	126
**	Nasopalatine duct cyst	Between and apical to maxillary central incisors; palatal swelling may occur	27
**	Lateral periodontal cyst	Especially in mandibular bicuspid-cuspid region	699
**	Residual (periapical) cyst	Edentulous area	126
**	Odontogenic keratocyst	—	689
**	Central giant cell granuloma	Especially in anterior mandible	631
**	Stafne bone defect	Angle of mandible below mandibular canal	23
*	Cemento-osseous dysplasia	Early stage; usually in young adult and middle-aged black women; usually in mandible	645
*	Central ossifying fibroma	Early-stage lesion	652
*	Ameloblastoma	Especially unicystic type	707

dentlearn.ir

Part 4: Radiographic Pathology—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
*	Buccal bifurcation cyst	Buccal aspect of erupting mandibular first or second molar	704
*	Other odontogenic cysts and tumors	Examples: ameloblastic fibroma, central odontogenic fibroma, calcifying odontogenic cyst	Chapter 15
*	Langerhans cell histiocytosis	"Histiocytosis X"; usually in children or young adults	596
*	Melanotic neuroectodermal tumor of infancy	Anterior maxilla; may be pigmented	541
*	Median palatal cyst	Clinical midline swelling of hard palate	30
*	Schwannoma/ neurofibroma	Usually associated with mandibular nerve	534
D. Multilocular Radiolucencies			
***	Odontogenic keratocyst	—	689
***	Ameloblastoma	Especially in posterior mandible; often associated with impacted tooth	707
**	Central giant cell granuloma	Especially in anterior mandible	631
*	Ameloblastic fibroma	Especially in young patients	724
*	Odontogenic myxoma	"Cobweb" trabeculation	735
*	Central odontogenic fibroma	—	731
*	Calcifying epithelial odontogenic tumor	Often associated with impacted tooth	720
*	Orthokeratinized odontogenic cyst	Often associated with impacted tooth	693
*	Lateral periodontal cyst (botryoid type)	Especially in mandibular bicuspid-cuspid region	699
*	Calcifying odontogenic cyst	Especially in cases with minimal or no calcifications; often associated with impacted tooth	701
*	Central hemangioma/ arteriovenous malformation	Especially in younger patients; may have honeycombed radiographic appearance; may pulsate	549
*	Aneurysmal bone cyst	Especially in younger patients	638
*	Cherubism	Hereditary; onset in childhood; multiple quadrants involved	634
*	Hyperparathyroidism (brown tumor)	Usually elevated serum calcium levels	840
*	Intraosseous mucoepidermoid carcinoma	Usually in posterior mandible	496
*	Fibrous dysplasia	Very rarely on panoramic films of mandibular lesions	641
E. Radiolucencies: Poorly Defined or Ragged Borders			
***	Periapical granuloma or cyst	Nonvital tooth	123
***	Focal osteoporotic marrow defect	Especially edentulous areas in posterior mandible; more common in females	625
**	Osteomyelitis	Usually painful or tender	134

(Continued)

dentlearn.ir

Part 4: Radiographic Pathology—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
**	Medication-related osteonecrosis of the jaw (MRONJ)	Exposed necrotic bone; most often associated with bisphosphonate drugs	286
*	Simple bone cyst	Mandibular lesion that scallops up between roots of teeth; usually in younger patients	636
*	Metastatic tumors	Painful; paresthesia; usually in older adults	673
*	Osteoradionecrosis	History of radiation therapy; painful	283
*	Multiple myeloma	May be painful; in older adults	609
*	Primary intraosseous carcinomas	Odontogenic or salivary origin	716
*	Osteosarcoma	Often painful; usually in young adults	665
*	Chondrosarcoma	—	669
*	Ewing sarcoma	Usually in children	671
*	Other primary bone malignancies	Examples: fibrosarcoma, lymphoma	—
*	Desmoplastic fibroma of bone	Especially in younger patients	663
*	Massive osteolysis	Phantom (vanishing) bone disease	627
F. Radiolucencies: Multifocal or Generalized			
***	Cemento-osseous dysplasia	Early stage lesions; usually in black females; usually in mandible	645
**	Nevoid basal cell carcinoma syndrome	Odontogenic keratocysts	694
**	Multiple myeloma	Painful; in older adults; "punched-out" lesions	609
*	Cherubism	Usually multilocular; onset in childhood; hereditary	634
*	Hyperparathyroidism	Multiple brown tumors	840
*	Langerhans cell histiocytosis	"Histiocytosis X"; in children and young adults; teeth "floating in air"	596
G. Radiopacities: Well-Demarcated Borders			
***	Torus or exostosis	Associated with bony surface mass	19
***	Retained root tip	Remnants of periodontal ligament usually seen	—
***	Idiopathic osteosclerosis	Most commonly associated with roots of posterior teeth; no apparent inflammatory etiology	626
***	Pseudocyst of the maxillary sinus	Homogeneous, dome-shaped relative opacity rising above bony floor of maxillary sinus	310
**	Condensing osteitis	Usually at apex of nonvital tooth	141
**	Odontoma, compound	Toothlike structures with thin, radiolucent rim at junction with surrounding bone; may prevent eruption of teeth; more common in anterior segments of jaws	729
**	Odontoma, complex	Amorphous mass with thin, radiolucent rim at junction with surrounding bone; may prevent eruption of teeth; more common in posterior segments of jaws	729
**	Cemento-osseous dysplasia	Late-stage lesions; especially in middle-aged and older black women; usually in mandible	645

dentlearn.ir

Part 4: Radiographic Pathology—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
**	Soft tissue radiopacity superimposed on bone	Examples: sialoliths, calcified nodes, phleboliths, bullet fragments, shotgun pellets, amalgam tattoos (See also Appendix List, Part 4, Q, page XXX)	—
*	Intraosseous foreign body	—	—
*	Osteoma	Associated with bony surface mass	655
*	Enamel pearl	Furcation area of molar tooth	90
*	Osteoblastoma/osteoid osteoma/ cementoblastoma	Late-stage lesions	658
H. Radiopacities: Poorly Demarcated Borders			
**	Cemento-osseous dysplasia	Late stage lesions; especially in middle-aged and older black women; usually in mandible	645
**	Medication-related osteonecrosis of the jaw (MRONJ)	Sclerosis of alveolar crestal bone; exposed necrotic bone; most often associated with bisphosphonate drugs	286
**	Condensing osteitis	Usually at apex of nonvital tooth	141
**	Sclerosing osteomyelitis	May be painful	137
*	Fibrous dysplasia	"Ground glass" appearance; onset usually in younger patients	641
*	Paget disease of bone	"Cotton wool" appearance; late-stage lesions; in older patients	628
*	Proliferative periostitis	"Onion-skin" cortical change; in younger patients; often associated with nonvital tooth	141
*	Osteosarcoma	May have "sunburst" cortical change; frequently painful; usually in young adults	665
*	Chondrosarcoma	—	669
I. Radiopacities: Multifocal or Generalized			
**	Florid cemento-osseous dysplasia	Late-stage lesions; especially in middle-aged and older black women; usually in mandible	647
**	Medication-related osteonecrosis of the jaw (MRONJ)	Multifocal sites of involvement; sclerosis of alveolar crestal bone; exposed necrotic bone; most often associated with bisphosphonate drugs	286
*	Idiopathic osteosclerosis	Occasionally may be multifocal	626
*	Paget disease of bone	"Cotton wool" appearance; late-stage lesions; in older patients; more common in maxilla	628
*	Gardner syndrome	Multiple osteomas; epidermoid cysts; gastrointestinal polyps with high tendency toward malignant transformation; hereditary	656
*	Polyostotic fibrous dysplasia	"Ground glass" appearance; onset usually in younger patients; may be associated with *café au lait* skin pigmentation and endocrine abnormalities (McCune-Albright syndrome)	641
*	Osteopetrosis	Hereditary; recessive form may be associated with secondary osteomyelitis, visual and hearing impairment	620
J. Mixed Radiolucent/Radiopaque Lesions: Well-Demarcated Borders			
***	Developing tooth	—	—
***	Cemento-osseous dysplasia	Intermediate-stage lesions; especially in middle-aged black women; usually in mandible	645
**	Odontoma	Compound or complex type; in younger patients; may prevent eruption of teeth	729

(Continued)

dentlearn.ir

Part 4: Radiographic Pathology—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
*	Central ossifying fibroma	—	652
*	Ameloblastic fibro-odontoma	Usually in children	725
*	Adenomatoid odontogenic tumor	Usually in anterior region of jaws; most often with maxillary canine; usually in teenagers	718
*	Calcifying epithelial odontogenic tumor	Pindborg tumor; often associated with impacted tooth; may show "driven snow" opacities	720
*	Calcifying odontogenic cyst	Gorlin cyst; may be associated with odontoma	701
*	Osteoblastoma/osteoid osteoma	Intermediate-stage lesion; usually in younger patients; often painful	658
*	Cementoblastoma	Intermediate-stage lesion; attached to tooth root	659
K. Mixed Radiolucent/Radiopaque Lesions: Poorly Demarcated borders			
**	Medication-related osteonecrosis of the jaw (MRONJ)	Exposed necrotic bone; most often associated with bisphosphonate drugs	286
**	Osteomyelitis	With sequestrum formation or with sclerosing type; often painful	134
*	Metastatic carcinoma	Especially prostate and breast carcinomas; may be painful	673
*	Osteosarcoma/chondrosarcoma	May be painful	665
L. Mixed Radiolucent/Radiopaque Lesions: Multifocal or Generalized			
**	Florid cemento-osseous dysplasia	Intermediate-stage lesions; especially in middle-aged black women; usually in mandible	647
**	Medication-related osteonecrosis of the jaw (MRONJ)	Exposed necrotic bone; most often associated with bisphosphonate drugs	286
*	Paget disease of bone	In older patients; more common in maxilla	628
M. Unique Radiographic Appearances: "Ground Glass" (Frosted Glass) Radiopacities			
*	Fibrous dysplasia	Onset usually in younger patients	641
*	Hyperparathyroidism	May cause loss of lamina dura	840
N. Unique Radiographic Appearances: "Cotton Wool" Radiopacities			
**	Cemento-osseous dysplasia	Especially in middle-aged black women; usually in mandible	645
*	Paget disease of bone	In older patients; more common in maxilla	628
*	Gardner syndrome	Multiple osteomas; epidermoid cysts; gastrointestinal polyps with high tendency toward malignant transformation; hereditary	656
*	Gigantiform cementoma	Hereditary; facial enlargement may be present	650
O. Unique Radiographic Appearances: "Sunburst" Radiopacities			
*	Osteosarcoma	Often painful; usually in young adults	665
*	Intraosseous hemangioma	Especially in younger patients	549
P. Unique Radiographic Appearances: "Onion-Skin" Radiopacities			
*	Proliferative periostitis	In younger patients; often associated with nonvital tooth; best seen with occlusal radiograph	141
*	Ewing sarcoma	In young children	671
*	Langerhans cell histiocytosis	"Histiocytosis X"; usually in children or young adults	596

dentlearn.ir

Part 4: Radiographic Pathology—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
Q. Soft Tissue Radiopacities			
***	Amalgam tattoo	Markedly radiopaque; associated with surface discoloration	298
**	Other foreign bodies	Examples: bullet fragments, shotgun pellets	—
**	Sialolith	Glandular pain may be present while patient is eating	465
**	Tonsilloliths	Superimposed on mandibular ramus	176
*	Phlebolith	May occur in varicosities or hemangiomas	14
*	Calcified lymph nodes	Example: tuberculosis	185
*	Osseous and cartilaginous choristomas	Most common on tongue	559
*	Calcinosis cutis	May be seen with systemic sclerosis (especially CREST syndrome)	805
*	Myositis ossificans	Reactive calcification in muscle	—

dentlearn.ir

Part 5: Pathology of Teeth

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
A. Hyperdontia (Extra Teeth)			
***	Idiopathic supernumerary teeth	Mesiodens, paramolar, distomolar	75
**	Cleft lip and palate	Extra lateral incisor or canine	1
*	Gardner syndrome	Osteomas and gastrointestinal polyps	656
*	Cleidocranial dysplasia	Hypoplastic or missing clavicles; failure of tooth eruption	623
B. Hypodontia (Missing Teeth)			
***	Idiopathic hypodontia	Missing third molars, lateral incisors	75
**	Cleft lip and palate	Missing lateral incisor or canine	1
*	Hereditary hypohidrotic ectodermal dysplasia	Cone-shaped teeth	747
*	Incontinentia pigmenti	Cone-shaped teeth	755
*	Radiotherapy during childhood	Stunted tooth development	56
C. Macrodontia (Larger Than Normal Teeth)			
**	Fusion	Joining of two tooth germs	82
**	Gemination	Incomplete splitting of a tooth germ	82
*	Idiopathic macrodontia	—	81
*	Facial hemihyperplasia	Affected side only; nondental tissues also enlarged	37
*	Gigantism	Abnormally tall stature	834
D. Microdontia (Smaller Than Normal Teeth)			
***	Supernumerary teeth	Mesiodens; fourth molars	75
***	Peg-shaped lateral incisors	Cone-shaped teeth	81
**	Dens invaginatus	Cone-shaped teeth; tendency for pulpal death and periapical pathosis	88
*	Idiopathic microdontia	Usually generalized	81
*	Hereditary hypohidrotic ectodermal dysplasia	Cone-shaped teeth; sparse, blond hair; diminished sweating	747
*	Radiotherapy during childhood	Stunted tooth development	56
*	Congenital syphilis	Hutchinson's incisors	181
*	Hypopituitarism	Associated dwarfism	833
E. Malformed Crown			
***	Mesiodens and other supernumeraries	Cone-shaped teeth or microdont	75
**	Environmental enamel hypoplasia	Example: high fever during tooth development	51
**	Peg-shaped lateral incisors	Cone-shaped teeth	81
**	Dens invaginatus	Cone-shaped teeth; tendency toward pulpal death and periapical pathosis	88
**	Turner tooth	Infection or trauma to associated primary tooth	53
**	Fusion or gemination	"Double" tooth	82
*	Talon cusp	Extra cusp on lingual of anterior tooth	85
*	Dens evaginatus	Extra cusp on occlusal of premolar tooth	86
*	Amelogenesis imperfecta	Hereditary defect in enamel formation	98

dentlearn.ir

Part 5: Pathology of Teeth—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
*	Dentinogenesis imperfecta	Fracturing away of enamel due to hereditary defect in dentin formation; gray-yellow opalescent teeth; calcified pulp chambers	104
*	Regional odontodysplasia	Poor tooth formation in a focal area; "ghost teeth"	110
*	Congenital syphilis	Hutchinson's incisors; mulberry molars	181
*	Vitamin D–resistant rickets	Hereditary condition; high pulp horns	848
*	Renal osteodystrophy	Abnormal calcium and phosphate metabolism	841
*	Hypoparathyroidism	Possible associated endocrine-candidiasis syndrome	838
*	Pseudohypoparathyroidism	—	839
*	Epidermolysis bullosa	Hereditary blistering skin disease	766
*	Radiotherapy during childhood	Stunted tooth development	56
*	Globodontia	Associated with otodental syndrome	96
*	Lobodontia	Cusp anatomy resembles teeth of carnivores	97
F. Enamel Loss After Tooth Formation			
***	Caries	—	—
***	Trauma	Fractured tooth	—
***	Attrition	Physiologic loss of tooth structure	58
***	Abrasion	Pathologic loss of tooth structure	58
**	Erosion	Chemical loss of tooth structure	58
*	Dentinogenesis imperfecta	Hereditary defect in dentin formation; poor junction between enamel and dentin	104
*	Amelogenesis imperfecta	Hereditary defect in enamel formation; especially hypocalcified types	98
G. Extrinsic Staining of Teeth			
***	Tobacco	Black or brown	67
***	Coffee, tea, and cola drinks	Brown or black	67
**	Chromogenic bacteria	Brown, black, green, or orange	67
**	Chlorhexidine	Yellow-brown	67
H. Intrinsic Discoloration ("Staining") of Teeth			
***	Aging	Yellow-brown; less translucency	—
***	Death of pulp	Gray-black; less translucency	118
**	Fluorosis	White; yellow-brown; brown; mottled	57
**	Tetracycline	Yellow-brown; yellow fluorescence	70
**	Internal resorption	"Pink tooth of Mummery"	62
*	Calcific metamorphosis	Yellow	120
*	Dentinogenesis imperfecta	Blue-gray; translucent	104
*	Amelogenesis imperfecta	Yellow-brown	98
*	Congenital erythropoietic porphyria	Yellow; brown-red; red fluorescence	68
*	Erythroblastosis fetalis	Yellow; green	69
I. Abnormally Shaped Roots			
***	External root resorption	Secondary to infection, cyst, tumor	62
***	Dilaceration	Abnormal curvature	94

(Continued)

dentlearn.ir

Part 5: Pathology of Teeth—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
**	Hypercementosis	Excessive cementum production	93
**	Supernumerary roots	—	96
**	Concrescence	Joining of teeth by cementum	82
**	Taurodontism	Enlarged pulp chambers; shortened roots	92
**	Enamel pearl	Ectopic enamel in furcation	90
*	Benign cementoblastoma	Tumor attached to root	659
*	Radiotherapy during childhood	Stunted root development	56
*	Dentinogenesis imperfecta	Shortened roots; obliterated pulps	104
*	Radicular dentin dysplasia (Dentin dysplasia type I)	Shortened, pointed roots ("rootless teeth"); obliterated pulps; periapical pathosis	108
J. Enlarged Pulp Chamber or Canal			
**	Internal resorption	Secondary to caries or trauma	62
**	Taurodontism	Enlarged pulp chambers; shortened roots	92
*	Severe form of dentinogenesis imperfecta	"Shell teeth"	104
*	Regional odontodysplasia	"Ghost teeth"	110
*	Vitamin D–resistant rickets	High pulp horns	848
*	Hypophosphatasia	—	847
*	Mild form of dentinogenesis imperfecta ("Dentin dysplasia type II")	"Thistle-tube" pulps with pulp stone formation in permanent dentition	104
K. Pulpal Calcification			
***	Pulp stones	Asymptomatic radiographic finding	121
***	Secondary dentin	Response to caries	119
**	Calcific metamorphosis	Pulpal obliteration secondary to aging or trauma	120
*	Dentinogenesis imperfecta (moderate form)	Pulpal obliteration by excess dentin	104
*	Radicular dentin dysplasia (Dentin dysplasia type I)	Pulpal obliteration by excess dentin; "chevron"-shaped pulp chambers	108
*	Mild form of dentinogenesis imperfecta ("Dentin dysplasia type II")	Pulpal obliteration of primary teeth; pulp stones in permanent teeth	104
L. Thickened Periodontal Ligament			
***	Periapical abscess	Focal thickening at apex of nonvital tooth; painful, especially on percussion of involved tooth	129
***	Current orthodontic therapy	—	—
**	Increased occlusal function	—	—
*	Systemic sclerosis (scleroderma)	Generalized widening	801
*	Sarcoma or carcinoma infiltration	Especially osteosarcoma; localized to teeth in area of tumor	667, 673
M. Generalized Loss of Lamina Dura			
*	Hyperparathyroidism	Calcium removed from bones; bone may have "ground glass" appearance	840
*	Osteomalacia	Vitamin D deficiency in adults	829
*	Paget disease of bone	"Cotton wool" change hides lamina dura	628

dentlearn.ir

Part 5: Pathology of Teeth—cont'd

Frequency of Occurrence	Lesion or Condition	Comments or Special Characteristics	Page
*	Fibrous dysplasia	"Ground glass" change hides lamina dura	641
N. Premature Exfoliation of Teeth			
***	Trauma	Avulsed tooth	—
**	Aggressive periodontitis	Premature alveolar bone loss	160
**	Immunocompromised states	AIDS, leukemia, chemotherapy	257
**	Diabetes mellitus	Increased susceptibility to infection and severity of periodontitis	844
*	Osteomyelitis	Bone destruction loosening teeth	134
*	Cyclic or chronic neutropenia	Increased susceptibility to infection; premature alveolar bone loss	589
*	Langerhans cell histiocytosis	"Histiocytosis X"; eosinophilic granuloma; premature alveolar bone loss	596
*	Radicular dentin dysplasia (Dentin dysplasia type I)	"Rootless teeth"	108
*	Regional odontodysplasia	"Ghost teeth"	110
*	Papillon-Lefèvre syndrome	Palmar and plantar hyperkeratosis; premature periodontitis	167
*	Down syndrome	Premature periodontitis	—
*	Hypophosphatasia	Lack of cementum production in primary teeth	847
*	Scurvy	Vitamin C deficiency	828

ACE (angiotensin-converting enzyme) inhibitors, angioedema due to 348, 350
Acinic cell carcinoma 497–498, 497–498f
Acinic cell tumor 497
Ackerman's tumor 421–423, 422–423f
Acquired immunodeficiency syndrome (AIDS) See Human immunodeficiency virus (HIV)
Acquired melanocytic nevus(i)
  clinical features of 375–376, 375–376f
  histopathologic features of 376, 376–377f
  treatment and prognosis for 376–377
Acral keratosis in multiple hamartoma syndrome 765
Acral lentiginous melanoma 436
Acral melanoma 436
Acrobrachycephaly 41, 42f
Acrocephalosyndactyly 41–43, 42f
Acrodynia 305
Acrodysostosis 839–840
Acromegaly 834–835
  clinical and radiographic features of 834, 834–835f
  laboratory findings and diagnosis of 835
  treatment and prognosis for 835
  vs. gigantism 834
Acro-osteolysis in systemic sclerosis 802, 802f
Acrosclerosis 805–806, 805–806f
Actinic cheilitis See Actinic cheilosis
  clinical features of 395, 395f
  histopathologic features of 395, 396f
  treatment and prognosis of 396, 396f
Actinic cheilosis 395–396
  and actinic keratosis 396
  clinical features of 395, 395f
  histopathologic features of 395, 396f
  treatment and prognosis of 396, 396f
Actinic keratosis 396–397, 396–397f
  in xeroderma pigmentosum 753
Actinic lentigo(igines) 369–370, 370f
  vs. seborrheic keratosis 366
Actinomycosis 192–194
  clinical features of 193, 193f
  diagnosis of 194
  histopathologic features of 193–194, 194f
  pathogenesis of 192
  treatment and prognosis for 194
Acute chest syndrome 583
Acute lymphonodular pharyngitis 244
Acute necrotizing ulcerative gingivitis (ANUG) 151
Acute retroviral syndrome 252
Adamantiades, Benedict 326–328
Adamantiades syndrome See Behçet syndrome
Addison disease 843–844, 844f
  due to histoplasmosis 212
  due to paracoccidioidomycosis 216
Adenoid cystic carcinoma 501–503
  clinical and radiographic features of 501–502, 501–502f
  histopathologic features of 502–503
    cribriform pattern as 502, 503f
    perineural invasion as 503, 503f
    solid variant as 502–503
    tubular pattern as 502
  treatment and prognosis for 503
Adenoid form of seborrheic keratosis 367–368
Adenolymphoma 488–489
Adenoma(s)
  basal cell 491–492, 492f
  canalicular 490–491, 490f
  monomorphic 490
  oxyphilic 487–488, 487f
  pleomorphic See Pleomorphic adenoma
  sebaceum, in tuberous sclerosis 763, 763f
Adenomatoid hyperplasia of minor salivary glands 477
Adenomatoid odontogenic tumor 718–720
  calcifying odontogenic cyst with 701
  clinical and radiographic features of 718–719, 718–719f

epidemiology of 718
histopathologic features of 720, 720f
relative distribution of 721, 721f
treatment and prognosis for 720
Adenosquamous carcinoma 424–425
Age spot 369–370, 370f
Ageusia 870
Aggressive ossifying fibroma 653–655
Aglossia 8
Agranulocytosis 589
congenital 589
AIDS See Human immunodeficiency virus
AIDS-dementia complex 252
AIDS-related complex (ARC) 252
Albers-Schönberg disease See Osteopetrosis
Albright hereditary osteodystrophy 839–840
Alcohol, and squamous cell carcinoma 403
ALI (alternate light imaging) photography 905
Allergic contact stomatitis 342–343, 343f
Allergic disease(s)
allergic contact stomatitis as 342–343, 343f
angioedema as 348–350, 348–349f
contact stomatitis from artificial cinnamon flavoring as 344–346
lichenoid and granulomatous stomatitis as 336–337
lichenoid contact reaction from dental restorative materials as 346–347, 347f
mucosal reactions to systemic drug administration as 337–342
perioral dermatitis as 343–344, 344f
Allergic gingivostomatitis 152–154, 153f
Alternate light imaging (ALI) photography 905
Alternative light source photography 905
Aluminum chloride, allergic contact stomatitis to 343f
Alveolar cyst of newborn 697–698, 698f
Alveolar masses, differential diagnosis of 922–925t
Alveolar osteitis 143–144
Alveolar ridge keratosis 383, 383f
Alveolar soft-part sarcoma 568–569, 569f
Alveolitis, fibrinolytic 143–144
Amalgam discoloration 69, 70f
Amalgam, lichenoid reaction to 346–347, 347f, 791
Amalgam tattoo 298–300
clinical and radiographic features of 299, 299–300f
from endodontic-related implantation 298, 298f
from floss-related implantation 298, 298f
histopathologic features of 300, 300f
treatment and prognosis for 300
Amelanotic melanoma 436
Ameloblastic carcinoma 716–717, 716–717f
Ameloblastic carcinosarcoma 728
Ameloblastic dentinosarcomas 728
Ameloblastic fibroma 724–725, 724–725f
Ameloblastic fibro-odontoma 725–727, 726–727f
Ameloblastic fibro-odontosarcomas 728
Ameloblastic fibrosarcoma 727–728, 728f
Ameloblastic odontoma 728–729
Ameloblastic sarcoma 727–728, 728f
Ameloblastoma 707–716
acanthomatous 710, 712f
calcifying odontogenic cyst with 701
conventional solid or multicystic
acanthomatous pattern in 710, 712f
basal cell pattern in 712, 712f
desmoplastic 711–712, 712f
granular cell pattern in 711, 712f
treatment and prognosis for 712–713, 713f
conventional solid or multicystic intraosseous 708–713
clinical features of 708–709, 708–710f
desmoplastic 709, 711f
epidemiology of 708
follicular pattern in 709–712, 711f
histopathologic features of 709
plexiform pattern in 709–710, 711f
radiographic features of 708–709, 708–710f
relative distribution of 708, 708f
vs. lateral periodontal cyst 708, 711f
desmoplastic 709, 711–712, 711–712f
granular cell 711, 712f
malignant 716–717, 716–717f
mural 714, 715f
pathogenesis of 707
peripheral (extraosseous) 715–716, 715f
pigmented 541–543, 542f
transformation of dentigerous cyst to 688
treatment and prognosis for 715
unicystic 713–715
clinical and radiographic features of 713–714, 713–714f
histopathologic features of 714, 714f
intraluminal (plexiform) 714, 714f
luminal 714, 714f
Amelogenesis imperfecta 98–104
classification of 98t
clinical and radiographic features of 100–103
defined 51, 98
genetic basis for 99t, 100–103
histopathologic features of 103
hypocalcification 101–102, 103f
hypocalcified 98
hypomaturation 98, 101–102
pigmented 102
snow-capped 102, 102f
X-linked 102, 102f
hypomineralization 101–102
hypomineralized 98
hypoplastic 98, 100–101
generalized pattern of 100, 100f
generalized thin variants of 100, 101f
localized pattern of 100
with taurodontism (hypomaturation/hypoplastic) 102–103, 103f
tooth discoloration due to 67
AMELX gene 99t, 100
AmpFLP analysis 889
Amphotericin B for candidiasis 209, 211t
Amputation neuroma 532, 532–533f
Amyloid 824
Amyloidosis 824–827
clinical features of 824–826, 825f
defined 824
diagnosis of 826
hemodialysis-associated 825
heredofamilial 825–826
histopathologic features of 826, 826f
macroglossia in 9
myeloma-associated 825, 825f
organ-limited 824
pathogenesis of 824
primary 825
secondary 825
systemic 825
treatment and prognosis for 826–827
ANCA (antineutrophil cytoplasm antibodies) in Wegener granulomatosis 336
Anemia 582–583
aplastic 586–587, 587f
associated with chronic disorders 583b
clinical features of 582–583
defined 582
with disturbed iron metabolism 583b
etiology of 582, 583b
Fanconi 587
hemolytic 583b
jaundice in autoimmune 823

iron-deficiency 830
megaloblastic 583b
myelophthisic 593
pernicious 831–833, 832f
sickle cell 583–585, 584f
jaundice in 823
treatment and prognosis for 583
Anesthesia dolorosa 866
Anesthetic necrosis 294, 294f
Aneurysmal bone cyst 638–640, 639f
Angiitis, granulomatous 240
Angina
bullosa hemorrhagica, vs. mucous membrane pemphigoid 778, 779f
Ludwig
clinical features of 133, 133f
pathogenesis of 132
treatment and prognosis for 134
Angiocentric immunoproliferative lesion 607–609, 608f
Angiocentric T-cell lymphoma 607–609, 608f
Angioedema 348–350, 348–349f
Angiofibroma(s)
facial, in tuberous sclerosis 763, 763f
nasopharyngeal 552–553, 553f
Angiogenesis 416
Angiolipoma 531
Angiomas, leptomeningeal 551
Angiomatosis
bacillary 195
encephalotrigeminal (Sturge-Weber) 551–552, 551–552f
meningeal 551
Angiomyolipoma in tuberous sclerosis 764
Angiomyoma 556, 556f
Angioneurotic edema 348–350, 348–349f
Angiosarcoma 563–564, 563f
Angiotensin-converting enzyme (ACE) inhibitors, angioedema due to 348, 350
Angular cheilitis 202t, 204–205, 204f
exfoliative vs. 294
in Plummer-Vinson syndrome 830, 831f
Animal bites 899
Ankyloglossia 10, 10f
Ankylosis 873
of tooth 73–74, 74f
Anodontia 75, 77
in ectodermal dysplasia 747
Anosmia 870
Antemortem records
comparison of postmortem and 894–895, 894t, 895f
examination of 894
request for 890
Anthropologic examination of bones and teeth 885–888, 886t, 886f
Anthropometry 884
Antiangiogenic agents, osteonecrosis of jaw due to 286, 286b
Antibiotic sore mouth 202–203, 203f
Antigenic markers 888
Antimalarial medications, oral mucosal discoloration due to 308–309, 308f
Antineoplastic therapy
enamel hypoplasia due to 56, 56f
noninfectious oral complications of 280–286
clinical features of 281–284
dermatitis as 282, 282f
developmental abnormalities as 284
hemorrhage as 281
mucositis as 281, 281–282f, 284–285
osteoradionecrosis as 283–284, 283–284f
taste disorders as 283, 285
treatment and prognosis for 284–286
trismus as 284
xerostomia as 282–283, 283f, 285
Antineutrophil cytoplasm antibodies (ANCA) in Wegener granulomatosis 336
Antiresorptive osteonecrosis of the jaw (ARONJ) 286, 286b, 288f
Antiretroviral therapy 264
Antoni A pattern 534, 536f
Antoni B pattern 534, 536f
Antral pseudocysts 310–312, 311–312f
Antrolith 197
ANUG (acute necrotizing ulcerative gingivitis) 151
APECED (autoimmune polyendocrinopathy-candidiasis ectodermal dystrophy) syndrome 206–207, 208f
and hypoparathyroidism 839
Apert syndrome 41–43, 42f
Aphthosis
complex 324–325
simple 324–325
Aphthous stomatitis, recurrent See Recurrent aphthous stomatitis
Aphthous ulcerations, recurrent See Recurrent aphthous stomatitis
Apical periodontal cyst See Periapical cyst
Apical periodontitis, chronic See Periapical granuloma
Aplastic anemia 586–587, 587f
Aquamid (polyacrylamide), oral lesions associated with 302
ARC (AIDS-related complex) 252
Arc burn 276
Argyria 305, 306f
Argyrosis, localized 298
ARONJ (antiresorptive osteonecrosis of the jaw) 286, 286b, 303f
Arsenic intoxication 305
Artecoll (polymethylmethacrylate), oral lesions associated with 302, 303f
ArteFill (polymethylmethacrylate), oral lesions associated with 302, 303f
Arteriovenous malformations 549
Arteritis, giant cell (temporal, granulomatous) 867–868
Arthralgia due to temporomandibular disorders 875
Arthritis
degenerative 871–872
psoriatic 797
reactive 786–787
rheumatoid 872–874
Arthropathy due to temporomandibular disorders 875
Artificial cinnamon flavoring, contact stomatitis from 344–346
clinical features of 344, 345f
diagnosis of 345–346
histopathologic features of 345, 345f
treatment and prognosis for 346
Ascher syndrome 5, 6f
Ascorbic acid deficiency 827
Ash-leaf spots in tuberous sclerosis 763
Aspergilloma 221, 221f
Aspergillosis 221–222
clinical features of 219–220, 221f
diagnosis of 222
disseminated 221–222
histopathologic features of 222, 222f
pathogenesis of 221
treatment and prognosis for 222
Aspirin, chemical injury due to 278, 278f
Asteroid bodies 329, 330f
Astrocytoma, subependymal giant cell, in tuberous sclerosis 763
Attrition, tooth wear due to 58–59, 59f, 61
Atypical eosinophilic ulcerations 275, 275f
Atypical Spitz tumor 378
Auriculotemporal syndrome 862–863, 863f
Autoantibodies, molecular sites of attack of 768–769, 769f
Autoimmune hemolytic anemia, jaundice in 823

Autoimmune polyendocrinopathy candidiasis-ectodermal dystrophy (APECED) syndrome
and hypoparathyroidism 839
Autoimmune polyendocrinopathy syndrome, type 1 206–207, 208f
Autoimmune polyglandular syndrome, type 1 and hypoparathyroidism 839
Autopsy 883

B

"Baby bottle caries" 909, 909f
Bacillary angiomatosis 195
Bacillary peliosis hepatis 195
Bacille Calmette-Guérin (BCG) vaccine 185
Bacteria and squamous cell carcinoma 404
Bacterial infection(s) 172–200
actinomycosis as 192–194, 193–194f
cat-scratch disease as 194–196, 195f
diphtheria as 177–179
erysipelas as 173–174, 174f
gonorrhea as 184–185
impetigo as 172–173
leprosy as 188–191

syphilis as 179–184
tonsillar plugs and tonsillolithiasis as 176–177, 177f
tuberculosis as 185–188
Bacterial stains, tooth discoloration due to 67–68
Balanitis circinata in reactive arthritis 786
Ballooning degeneration in herpes simplex virus 233–234, 233f
Banal nevus 375
Bannayan-Riley-Ruvalcaba syndrome, multiple hamartoma syndrome and 765
Barbell 301, 301f
Bartonella henselae 194
Basal cell adenocarcinoma 492
Basal cell adenoma 491–492, 492f
Basal cell carcinoma 430–432, 431–432f
in nevoid basal cell carcinoma syndrome 694, 695f
vs. peripheral ameloblastoma 715–716
in xeroderma pigmentosum 753
Basal cell cytoplasmic antibody 341
Basaloid squamous carcinoma 425, 425f
Basaloid squamous cell carcinoma 425, 425f
Basic multicellular unit (BMU) 287–288, 288f
Basosquamous carcinoma 432
Bathing trunk nevus 379
Batson plexus in metastasis 569
BCG (bacille Calmette-Guérin) vaccine 185
BCR-ABL fusion gene 593
Beckwith-Wiedemann syndrome 9
Behçet disease See Behçet syndrome
Behçet, Hulusi 326
Behçet syndrome 326–328
clinical features of 326–327, 327f
diagnosis of 327, 328t
histopathologic features of 328
pathogenesis of 326
treatment and prognosis for 328
Bell palsy 861–862, 862f
Bence Jones protein 609
Benign juvenile melanoma 378–379
Benign lymphoepithelial lesion 475, 475f
Benign migratory glossitis in diabetes mellitus 846
Benign mixed tumor See Pleomorphic adenoma
Beriberi 828
Bertillon, Alphonse 884
β-hemolytic streptococci
erysipelas due to 173
scarlet fever due to 175
Betel chewer's mucosa 394
vs. morsicatio mucosae oris 272–273
Betel quid
oral submucous fibrosis due to 393–395, 394f
and squamous cell carcinoma 403
Betel quid lichenoid lesions 394
Bifid condyle 19, 19f
Bifid tongue 300–301, 301f
Bifid uvula 2, 3f
Bilateral ossifying fibromas 650
Biofilm 161
Birbeck granules 597, 598f
Bismuth intoxication 305
Bisphosphonate-related osteonecrosis of the jaw (BRONJ) 286, 286b, 288f
clinical and radiographic features of 288–289, 288–289f
histopathologic features of 289, 290f
treatment and prognosis for 289–292
Bite(s)
infectious complications of 900
self-inflicted 900
Bite mark(s)
characteristics of 901–902, 901f, 902t
defined 899
description of 903
Bite mark evidence
for animal bites 899
for insect bites 899
Bite mark patterned injury (BMPI) 899
saliva evidence from 905
serial pictures of 904–905
Bite pattern evidence 899–907
basic principles of 899–900, 900f
characteristics of bite marks in 901–902, 901f, 902t
description of bite mark in 903
evidence analysis and comparison in 906–907, 906–907f
evidence collection in 903–906
examination of victim and suspect in 903
guidelines for bite mark analysis in 902–907
historical and legal issues with 900–901
impressions and study casts in 905
photography in 903–905, 904t, 904f
saliva evidence in 905
tissue samples in 905–906, 906f
Black hairy tongue 12–13
clinical features of 12–13, 12f
histopathologic features of 13, 13f
treatment and prognosis for 13
Black lesions, differential diagnosis of 916–919t
Blastomycosis 214–216
acute 214
chronic 214
clinical and radiographic features of 214–215, 214–215f
cutaneous lesions of 214, 214f
diagnosis of 215
epidemiology of 214
histopathologic features of 215, 215f
oral lesions of 215, 215f
pathogenesis of 214
South American 216–217, 216f
treatment and prognosis for 217
Blast transformation 595
Bloch-Sulzberger syndrome 755–756, 755–756f
Blue lesions, differential diagnosis of 916–919t
Blue nevus 377–378, 377–378f
Blue sclerae in osteogenesis imperfecta 618, 619f
BMD (burning mouth disorder) 868–869, 868b
BMPI (bite mark patterned injury) 899
saliva evidence from 905
serial pictures of 904–905
BMU (basic multicellular unit) 287–288, 288f
Bohn's nodules 25–27, 26f, 698

Bone(s)
in hyperparathyroidism 840, 841f
physical anthropologic examination of 885–888, 886t, 886f
Bone cavity, idiopathic 636–638, 637f
Bone cyst
aneurysmal 638–640, 639f
simple (traumatic, hemorrhagic, solitary, unicameral) 636–638, 637f
Stafne (latent, static) 23–25, 24–25f
Bone eburnation 626–627, 626f
Bone pathology 618–684
bone cyst as
aneurysmal 638–640, 639f
simple 636–638, 637f
cementoblastoma (true cementoma) as 659–661, 660–661f
central giant cell granuloma as 631–633, 632–633f
central xanthoma of jaws 640–641
cherubism as 634–635, 634–636f
chondroma as 661
chondrosarcoma as 669–671, 669f
mesenchymal 670–671, 671f
cleidocranial dysplasia (cleidocranial dysostosis) as 623–625, 623t, 624f
fibroma as
chondromyxoid 661–662, 662f
desmoplastic 663–665, 664f
ossifying 652–653, 652–653f
juvenile 653–655, 654–655f
fibro-osseous lesions of jaws as 641–674
cemento-osseous (osseous) dysplasia 645–650
familial gigantiform cementoma as 650–651, 651f
fibrous dysplasia as 641–645
juvenile ossifying fibroma as 653–655, 654–655f
ossifying fibroma as 652–653, 652–653f
fibrous xanthoma of bone 640–641
fibroxanthoma of bone 640–641
focal osteoporotic marrow defect as 625, 625f
giant cell tumor (“true giant cell tumor”) as 633, 633f
idiopathic osteosclerosis as 626–627, 626f
massive osteolysis as 627–628, 627–628f
metastatic tumors to jaws as 673–674, 673–674f
osteoblastoma as 658–659, 658–659f
osteogenesis imperfecta (“brittle bone disease”) as 618–620, 619f, 619t
osteoma as 655–656, 656f
giant osteoid (osteoid) 658–659, 658–659f
osteopetrosis as 620–623, 621–622f, 621t
osteosarcoma (osteogenic sarcoma) as 665–669
postirradiation 669
surface (juxtacortical) 668, 668f
Paget disease of bone (osteitis deformans) as 628–630, 629–630f
primary intraosseous xanthoma 640–641
primary xanthoma of bone 640–641
sarcoma as
Ewing 671–673, 672f
postirradiation bone 669
synovial chondromatosis (chondrometaplasia) as 662–663, 663f
Bone scar 141, 141f, 626–627, 626f
Bone sequestration, oral ulceration with 310, 310f
Bone whorl 626–627, 626f
Botryoid odontogenic cysts 699–700, 700f
Botryomycosis 193
Bourneville-Pringle syndrome See Tuberous sclerosis
Bowenoid actinic keratosis 397
BP180 (bullous pemphigoid antigen) 780
BP230 (bullous pemphigoid antigen) 780
Brachycephaly 41
Bradycardia in hypothyroidism 836
Branchial cleft cyst 35–36, 35–36f
Brandywine isolate 105
Braun, Eva 895
“Brittle bone disease” 618–620, 619f, 619t
Bronchiolitis obliterans in paraneoplastic pemphigus 775
BRONJ See Bisphosphonate-related osteonecrosis of the jaw (BRONJ)
Brown lesions, differential diagnosis of 916–919t
Brown tumor in hyperparathyroidism 840–841, 841f
Buccal bifurcation cyst(s) 704–705, 705f
cervical enamel extensions and 91
Buccal exostoses 19, 19f
Buccal mucosa, differential diagnosis of soft tissue masses of 922–925t
Bulky hyperkeratotic epithelial proliferation 388
Bulla, defined 914
Bull neck 178
Bullous impetigo 172
Bullous lichen planus 788
Bullous pemphigoid 771t, 779–781, 780f
Bullous pemphigoid antigens (BP180 and BP230) 780
Bundy, Ted 896
Burkitt lymphoma 606–607
African (endemic) 606
American (sporadic) 606
clinical and radiographic features of 606, 606f
defined 606
histopathologic features of 607, 607f
immunodeficiency-associated 606
treatment and prognosis for 607
Burn(s)
cotton roll 280, 280f
electrical and thermal 276–278
Burning mouth disorder (BMD) 868–869, 868b
Burning tongue syndrome 868–869, 868b

Enamel
development of 51
ectopic 90–92, 91f
mottled 57, 57f
Enamel defects, environmental 51–74
clinical and radiographic features of 51–58, 52–53f
dental fluorosis as 57–58, 57f
due to antineoplastic therapy 56, 56f
factors associated with 51, 52b
molar-incisor hypomineralization as 55
molar root-incisor malformation as 55–56, 55–56f
pathogenesis of 72
syphilitic hypoplasia as 58
timing of insult in 51
Turner hypoplasia as 53–54, 53f
Enamel hypoplasia
clinical and radiographic features of 51–58, 52–53f
defined 51–52
syphilitic 58
Turner 53–54, 53f
Enamel loss, differential diagnosis of 932–935t
Enameloid conglomerates 111, 111f
Enamel opacities 51–52
Enamel pearls
clinical and radiographic features of 90–91, 91f
defined 90
treatment and prognosis for 91–92
ENAM gene 99t, 100
Encephalotrigeminal angiomatosis 551–552, 551–552f
Enchondromas 661
Endocarditis, Libman-Sacks 798
Endocrine-candidiasis syndrome 202t, 206–207, 208f
and hypoparathyroidism 839
Endodontic-related amalgam implantation 298, 298f
Endophytic papilloma 362–363
Endophytic sinonasal papilloma 362–363, 362–363f
Enlargements, differential diagnosis of 922–925t
Enostosis 626–627, 626f
Enteric duplication cysts 33
Enteritis, regional 850–851, 850–851f
Enterocystomas 33
Enterovirus(es) 244–246
acute lymphonodular pharyngitis due to 245, 246f
classification of 244
clinical features of 244–245
diagnosis of 246
hand-foot-and-mouth disease due to 244–245, 245f
herpangina due to 244, 245f
histopathologic features of 245–246
treatment and prognosis for 246
Entropion in mucous membrane pemphigoid 776–777, 777f
Environmental alterations of teeth 51–74, 52b
environmental effects on tooth structure development as 51–58, 52b
localized disturbances in eruption as 71–74
postdevelopmental loss of tooth structure as 58–67
Environmental discoloration of teeth 67–71, 67b
clinical features of 67–70, 68f
extrinsic 67
clinical features of 67–70, 68f
due to bacterial stains 67–68
due to tobacco products, tea, or coffee 68, 68f
treatment and prognosis for 70–71
intrinsic 67
due to congenital erythropoietic porphyria 68–69, 68f
due to hyperbilirubinemia 69
due to lepromatous leprosy 69
due to medications 69–70
due to restorative materials 69, 70f
due to trauma 69
treatment and prognosis for 71

Eosinophilic granuloma See Langerhans cell histiocytosis
Eosinophilic, hyalinized change in pleomorphic adenoma 486, 486f
Eosinophilic ulcerations 273–274
  atypical 275, 275f
Ephelis 368–369, 371f
Epidemic parotitis 249–250, 250f
Epidermal inclusion cyst 31
Epidermoid cyst(s) 33
  in Gardner syndrome 31, 657, 657f
  of skin 31
    clinical features of 31, 31f
    histopathologic features of 32, 32f
Epidermolysis bullosa 766–769
  acquisita 766
    vs. mucous membrane pemphigoid 778–779
  categories of 766, 767t
  clinical features of 766–768, 767f
  defined 766
  dystrophic 766, 767t
    dominant 766–767, 767f, 767t
    recessive 767–768, 767f, 767t
  histopathologic features of 768, 768f
  junctional 767t, 768, 768f
  pathogenesis of 766
  simplex 767t, 768
  treatment and prognosis for 768
Epidermotropism 604
Epiloia See Tuberous sclerosis
Epithelial attachment apparatus 769, 770f
Epithelial dysplasia, in lichen planus 790
Epithelial inclusion cysts 698
Epithelial necrosis, chemotherapy-related 281f
Epithelial pathology 354–459
  acquired melanocytic nevus as 375–380
  actinic cheilosis as 395–396
  actinic keratosis as 396–397, 396–397f
  actinic lentigo as 369–370, 370f
  basal cell carcinoma as 430–432, 431–432f
  basaloid squamous carcinoma as 425, 425f
  benign HPV-associated lesions as 354–364, 355t
    condyloma acuminatum (venereal wart) as 358–360
    cylindrical cell papilloma as 363–364
    exophytic sinonasal papilloma as 361–362
    fungiform papilloma as 361–362, 362f
    inverted papilloma as 362–363
    multifocal epithelial hyperplasia as 360–361
    sinonasal papillomas as 361
    squamous papilloma as 361
  blue nevus as 377–378, 377–378f
  carcinoma of maxillary sinus as 426, 426f
  congenital melanocytic nevus as 377–378, 377–378f
  ephelis (freckle) as 368–369, 371f
  erythroplakia as 390–391, 390f
  keratoacanthoma as 398–401
  lentigo simplex as 370–371, 371f
  leukoplakia as 381–390
  melanoma as 434–442
  melasma as 371–372, 371f
  Merkel cell carcinoma as 432–434, 433f
  molluscum contagiosum as 364–365, 364–365f
  nasopharyngeal carcinoma as 428–430, 429f
  nicotine stomatitis as 397–398, 398f
  oral melanoacanthoma (melanoacanthosis) as 373–374, 374f
  oral melanotic macule (focal melanosis) as 372–373, 372–373f, 373b
  oral potentially malignant disorders 380–381, 380–381b
  oral submucous fibrosis as 393–395, 394f
  sebaceous hyperplasia as 368, 368–369f
  seborrheic keratosis as 366–368
  sinonasal undifferentiated carcinoma as 426–428, 427f
  spindle cell carcinoma as 423–424, 423–424f
  verruca vulgaris (common wart) as 357–358
  verruciform xanthoma as 365–366, 365–366f
  verrucous carcinoma as 421–423, 422–423f
Epithelial rests of Malassez in periapical granuloma 124–125
Epithelioid multinodular osteoblastoma 659
Epstein-Barr virus (EBV) 229
  infectious mononucleosis due to 241–242, 241f
Epstein-Barr virus (EBV)-associated lymphoproliferative disorders 601, 602f
Epstein's pearls 25–26, 26f, 698
Epulis
  congenital 546–547, 546f
  fissuratum (denture) 517–519
    clinical features of 517–518, 518f
    histopathologic features of 518–519, 519f
    treatment and prognosis for 519
  giant cell 527–529, 528f
  granulomatosa 526, 527f
  ossifying fibroid 529–530, 529–530f
Erethism 305
Erlenmeyer flask deformities 821
Erosion
  defined 914
  tooth wear due to
    clinical features of 59–60, 60–61f
    treatment and prognosis for 61–62
Erosive lichen planus
  clinical features of 788, 789–790f
  diagnosis of 791
  treatment and prognosis for 791–792, 792f
Eruption cyst 688–689, 689f
Eruption hematoma 688–689, 689f
Eruption sequestrum 72, 73f
Erysipelas 173–174, 174f
Erythema
  migrans 784–786
    clinical features of 784–785
      on sites other than tongue 785, 785f
      on tongue 785, 785f
    in diabetes mellitus 845–846
    epidemiology of 784
    etiopathogenesis of 784
    fissured tongue in 11–12, 11f, 785
    histopathologic features of 785–786, 785–786f
    and reactive arthritis 786
    treatment and prognosis for 786
  multiforme 230, 771t, 781–783
    clinical features of 781
    etiopathogenesis of 781
    histopathologic features of 782, 782f
    major 781, 782f
    minor 781, 781f
    treatment and prognosis for 782–783
  nodosum 328–329
Erythematous candidiasis 202–206, 202t, 203f
Erythroblastosis fetalis, tooth discoloration due to 69
Erythrocytosis, primary acquired 592
Erythroleukoplakia 384, 384f, 390
Erythromelalgia 592
Erythroplakia 384, 390–391
Erythroplasia of Queyrat 390–391
Erythropoietic porphyria, tooth discoloration due to congenital 68–69, 68f

Esophageal dysfunction in CREST syndrome 805
Esophageal webs 404
in Plummer-Vinson syndrome 830
Esthesioneuroblastoma 562–563, 562–563f
Ewing sarcoma 671–673, 672f
Exanthema subitum 229
Exclusion of identification evidence 883
Exfoliative cheilitis 294–296, 295f
Exophthalmos 837, 838f
Exophytic papilloma 361–362, 362f
Exostosis(es) 19–20
buccal 19, 19f
clinical and radiographic features of 19–20, 19–20f
histopathologic features of 20
in osteoarthritis 872
palatal 19–20, 20f
reactive subpontine 20, 20f
solitary 20
torus mandibularis as 21–23
clinical and radiographic features of 21–22, 22f
histopathologic features of 22, 22f
treatment and prognosis for 23
torus palatinus as 20–21, 21f
treatment and prognosis for 20
Expansive osseous dysplasia 650
Expert witnesses, dentists as 910
Extraabdominal desmoids 523
Extramedullary myeloid tumor 594
Extranodal extension 411
Extranodal marginal zone B-cell lymphoma, Sjögren syndrome and 476
Extranodal NK/T-cell lymphoma, nasal-type 607–609, 608f
Extrinsic factor malabsorption, pernicious anemia due to 831

Gorham disease 627–628, 627–628f
Gorham-Stout syndrome 627–628, 627–628f
Gorlin cyst See Calcifying odontogenic cyst
Gorlin sign 761–762, 762f
Gorlin syndrome See Nevoid basal cell carcinoma syndrome
Graft-versus-host disease (GVHD) 794–796, 795f
  acute 794
  chronic 794
  clinical features of 794–795, 795f
  cyclosporine-related nongingival hyperplasia in 157, 158f
  diagnosis of 795–796
  etiopathogenesis of 794

histopathologic features of 795
squamous cell carcinoma arising in 795
treatment and prognosis for 796
Graft-versus-leukemia effect 794
Grains in Darier disease 757
Granular cell ameloblastoma 711, 712f
Granular cell lesion, congenital 546
Granular cell odontogenic fibroma 734–735
Granular cell odontogenic tumor 734–735
Granular cell tumor 544–546, 545f
gingival, of newborn 546
Granulocytic sarcoma 594
Granuloma
calcifying fibroblastic 529–530, 529–530f
eosinophilic See Langerhans cell histiocytosis
giant cell
central 631–633, 632–633f
vs. brown tumor 841
odontogenic fibroma with 733, 733f
peripheral 527–529, 528f
gravidarum 526
midline lethal 607–609, 608f
periapical 123–125
clinical and radiographic features of 123–124, 124f
defined 123
etiology and pathogenesis of 123
histopathologic features of 124–125, 124f
treatment and prognosis for 125, 125f
pulse, in periapical cyst 129, 129f
pyogenic 525–527
clinical features of 525–526, 526f
gingival 148–149, 149f
histopathologic features of 526, 527f
during pregnancy 526, 527f
treatment and prognosis for 527
traumatic 273–274, 274f
Granulomatosis
interventions to rule out local causes of 330, 331t
Langerhans cell See Langerhans cell histiocytosis
lymphomatoid 608
orofacial 155, 330, 331f
clinical features of 330–332, 331–332f
in Crohn disease 850–851
diagnosis of 332–333
histopathologic features of 332, 332f
systemic evaluation of 330, 331t
treatment and prognosis for 333, 333–334f
with polyangiitis 333–336
Wegener 333–336
clinical features of 333–335, 334–335f
diagnosis of 335–336, 336b
generalized 333
histopathologic features of 335, 335f
limited 333–334
superficial 333–334
treatment and prognosis for 336
Granulomatous angiitis 240
Granulomatous arteritis 867–868
Grave's disease 837–838, 838f
Gray lesions, differential diagnosis of 916–919t
"Ground glass" radiopacities, differential diagnosis of 926–931t
Grzybowski syndrome 399
Guillain-Barré syndrome 861
Gum boil 130–131, 130–132f
Gumma 180–181
Günther disease, tooth discoloration due to 68–69, 68f
Gustatory lacrimation syndrome 862
Gustatory sweating and flushing 862–863, 863f
GVHD See Graft-versus-host disease (GVHD)

H

Hailey-Hailey disease 770
Hairy tongue 12–13
clinical features of 12–13, 12f
histopathologic features of 13, 13f
treatment and prognosis for 13
Halo nevus 379, 379f
Hamartoma(s)
intracranial, in tuberous sclerosis 763f, 764–765
in multiple hamartoma syndrome 765–766, 765–766f
odontogenic epithelial 733
odontomas as 729
Hamman's crunch 314
Hand-foot and-mouth disease 244–245, 245f
Hand-Schüller-Christian disease 596
Hansen disease See Leprosy
Hard palate, differential diagnosis of soft tissue masses of 922–925t
Hashimoto thyroiditis 836
HBID (hereditary benign intraepithelial dyskeratosis) 749–750, 750f
Headache disorders, primary 864b
Head and neck pain 863, 864b
due to burning mouth disorder 868–869, 868b
due to giant cell arteritis 867–868
due to glossopharyngeal neuralgia 866–867
due to trigeminal neuralgia 864–866, 865b
Health Insurance Portability and Accountability Act (HIPAA, 1996) 881
Heck disease360–361 See Multifocal epithelial hyperplasia

Hemangioendothelioma 563
juvenile 549
kaposiform 548
Hemangioma(s) 547–551
capillary 549, 550f
clinical and radiographic features of 547–548, 548f
congenital 547
defined 547
histopathologic features of 549–551, 550f
of infancy 547, 548f
juvenile (cellular) 549, 550f
lobular capillary See Pyogenic granuloma
in multiple hamartoma syndrome 765
in PHACE(S) syndrome 548
sclerosing 520–521, 521f
"strawberry" 547–548, 548f
treatment and prognosis for 550–551
tufted 548
Hemangiopericytoma 521
sinonasal-type 521
Hemarthrosis 580, 580f
Hematologic disorder(s) 578–617
agranulocytosis as 589
anemia as 582–583, 583b
aplastic 586–587, 587f
sickle cell 583–585, 584f
cyclic neutropenia (cyclic hematopoiesis) as 589–590, 590f
hemophilia as 579–581, 579t, 580f
Langerhans cell histiocytosis as 596–598
leukemia as 593–595, 594f
lymphoid hyperplasia as 578, 579f
lymphoma as
Burkitt 606–607
cutaneous T-cell 604–606
extranodal NK/T-cell, nasal-type 607–609, 608f
Hodgkin 579t, 598–600, 599f
non-Hodgkin 600–604
multiple myeloma as 609–611, 609–610f
mycosis fungoides as 604–606

neutropenia as 587–589
plasmacytoma as 611, 611f
plasminogen deficiency as 581–582, 582f
polycythemia vera as 592
thalassemia as 585–586, 585–586f
thrombocytopenia as 590–592, 591f
Hematoma 296, 297f, 591, 591f
eruption 688–689, 689f
Hematopoiesis, cyclic 589–590, 590f
Hematopoietic cell transplantation, nonmyeloablative allogenic 794
Hemiageusia 870
Hemiatrophy, progressive facial 38–39, 39f
Hemidesmosomes in bullous pemphigoid 780
Hemifacial hyperplasia 37
complex vs. simple 37
condylar hyperplasia vs. 16
macroglossia in 9
Hemifacial microsomia, condylar hypoplasia with 17
Hemihyperplasia 37–38, 37b, 38f
complex vs. simple 37
Hemihypertrophy 37–38, 37b, 38f
Hemimaxillofacial dysplasia 39–40, 40f
Hemochromatosis 586
Hemodialysis-associated amyloidosis 825
Hemoglobinopathies 583
Hemolytic anemia 583b
jaundice in autoimmune 823
Hemophilia 579–581
clinical features of 580, 580f
defined 579
dental care with 581
and HIV 581
most common forms of 579, 579t
pseudotumor of 580
treatment and prognosis for 580–581
Hemophilia A 579, 579t
Hemophilia B 579, 579t
Hemorrhage
due to antineoplastic therapy 281
submucosal 296–297, 296–297f
tooth discoloration due to gingival 68
Hemorrhagic bone cyst 636–638, 637f
Henderson-Paterson bodies 364, 365f
Hereditary angioedema with normal C1-INH (HAE-nC1-INH) 348–349
Hereditary benign intraepithelial dyskeratosis (HBID) 749–750, 750f
Hereditary hemorrhagic telangiectasia (HHT) 759–760, 759–760f
Hereditary hypophosphatemia 848–850, 849f
Hereditary mucoepithelial dysplasia 754–755, 754–755f
Hereditary opalescent dentin 105
Hereditary transthyretin amyloidosis 825–826
Heredofamilial amyloidosis 825–826
Herpangina 244, 245f
Herpes 229
Herpes barbae 232–233
Herpes gladiatorum 232–233
Herpes labialis 231–232, 232f
Herpes simplex virus (HSV) 229–235
acute herpetic gingivostomatitis due to 230, 231f
chronic infection with 232–233, 233f
clinical features of 230–233
diagnosis of 234
eczema herpeticum (Kaposi varicelliform eruption) due to 232–233
herpes barbae due to 232–233
herpes gladiatorum (scrumpox) due to 232–233
herpes labialis (“cold sore”, “fever blister”) due to 231–232, 232f
herpetic whitlow (herpetic paronychia) due to 232, 233f
histopathologic features of 233–234, 233–234f
HIV-associated 260, 260f
in immunocompromised host 233, 233f, 235
pathogenesis of 229
pharyngotonsillitis due to 231
primary infection with 229–230, 231f
recurrent (secondary, recrudescent) infection with 230, 232f
treatment and prognosis for 234–235
Herpes simplex virus type 1 (HSV-1) 229
Herpes simplex virus type 2 (HSV-2) 229
Herpes zoster 238–241, 238–239f
with HIV infection 260
Herpes zoster vaccine (Zostavax) 240–241
Herpetic paronychia 232, 233f
Herpetic whitlow 232, 233f
Herpetiform aphthous stomatitis 324–325, 324f
Herpetoviridae 229
Heterotopic oral gastrointestinal cysts 33
HHT (hereditary hemorrhagic telangiectasia) 759–760, 759–760f
HHVs See Human herpesvirus(es) (HHVs)
Hide-bound disease See Systemic sclerosis

panoramic radiographs in 892, 892f
postmortem examination in 893–894, 894f
presence and position of individual teeth in 889–890, 889f
requesting antemortem records for 893
exclusion evidence for 883
fingerprinting for 884–885
insufficient evidence for 883
morphometric means of 884–885
personal recognition for 883–884, 884f
physical anthropologic examination of bones and teeth for 885–888, 886t, 886f
positive 883
presumptive (possible) 883
serologic and genetic (DNA) comparison for 888–889
Idiopathic bone cavity 636–638, 637f
Idiopathic facial paralysis 861–862, 862f
Idiopathic midline destructive disease 607–609, 608f
Idiopathic osteolysis 627–628, 627–628f
Idiopathic osteosclerosis 626–627, 626f
vs. condensing osteitis 141
Idiopathic seventh nerve paralysis 861–862, 862f
IgG4-related disease 471–472
Ileitis, regional 850–851, 850–851f
Imidazole agents for candidiasis 209, 211t
Immune-mediated dermatologic disease(s) 768–769
chronic ulcerative stomatitis 792–794, 793–794f
CREST syndrome 805–806, 805–806f
erythema as
migrans 784–786
multiforme 781–783
evaluation of 768–769, 769f
graft-versus-host disease 794–796, 795f
immunopathologic features of 748f, 761t, 768–769
lichen planus as 787–792
lupus erythematosus as 798–801
pemphigoid as
bullous 779–781
mucous membrane 775–779
pemphigus as
paraneoplastic 774–775
vulgaris 769–773
psoriasis as 796–798, 796–797f
reactive arthritis (Reiter syndrome) as 786–787
Stevens-Johnson syndrome and toxic epidermal necrolysis as 783–784
systemic sclerosis as 801–805
Immune reconstitution syndrome 264
Immune thrombocytopenic purpura (ITP) 591
Immunobullous disease 769
Immunocompromised patients
herpes zoster in 240
HSV recurrence in 233, 233f
varicella in 237
Immunofluorescence techniques 769, 769f
Immunologic disease(s)
Behçet syndrome as 326–328
orofacial granulomatosis as 330–333
recurrent aphthous stomatitis as 321–326
sarcoidosis as 328–330
transient lingual papillitis as 321, 322f
Wegener granulomatosis as 333–336
Immunosuppression, and squamous cell carcinoma 406
Impaction, tooth 72–73, 73f
Impetiginized dermatitis 172
Impetigo 172–173
bullous (staphylococcal) 172
clinical features of 172, 173f
defined 172
diagnosis of 172
nonbullous (contagiosa) 172, 173f
treatment and prognosis for 172–173
Implantation cyst 31
Impressions of bite mark injury 905
IMRT (Intensity-modulated radiation therapy) 419
Incisive canal 27
Incisive canal cyst 27–30
clinical and radiographic features of 28, 28–29f
histopathologic features of 28–29, 29f
treatment and prognosis for 30
Incisive papilla, cysts of 28, 29f
Incisors
Hutchinson 58, 182, 182f
shovel-shaped 87, 87f
Incontinentia pigmenti 755–756, 755–756f

Periadenitis mucosa necrotica recurrens (PMNR) 323, 323–325f, 327f
Periapical abscess 129–132
  classification of 129–130
  clinical and radiographic features of 129–131, 130f
  with cutaneous sinus 130–131, 131f
  defined 129
  parulis (gum boil) as 130–131, 130–132f
  pathogenesis of 130
  periapical granuloma after 123
  phoenix 129
  treatment and prognosis for 132
Periapical cemental dysplasia 646–647, 647f
Periapical cementoma 646–647, 647f
Periapical cemento-osseous dysplasia 646–647, 647f
Periapical cyst 126–129
  clinical and radiographic features of 126–127, 126–128f
  defined 126
  etiology and pathogenesis of 126
  "globulomaxillary cyst" as 27, 31
  histopathologic features of 127–129, 128–129f
  periapical granuloma after 123
  pocket 126
  residual 127, 128f, 129
    carcinomatous transformation of 706
  treatment and prognosis for 129
  true 126
Periapical fibrous scars 125, 125f
Periapical granuloma 123–125
  clinical and radiographic features of 123–124, 124f
  defined 123
  etiology and pathogenesis of 123

histopathologic features of 124–125, 124f
treatment and prognosis for 125, 125f
Periapical osteopetrosis, focal 626–627, 626f
Periapical radiolucency, differential diagnosis of 926–931t
Pericoronal radiolucency, differential diagnosis of 926–931t
Pericoronitis 165, 165f
treatment and prognosis for 166–167
Peri-implant diseases 167
Peri-implantitis 167, 167f
Peri-implant mucositis 147, 167
Perineural invasion 416
by adenoid cystic carcinoma 503, 503f
by polymorphous low-grade adenocarcinoma 503–505, 504f
Periodontal abscess 164–165, 164–165f
treatment and prognosis for 166
Periodontal cysts
apical See Periapical cyst
lateral See Lateral periodontal cyst(s)
Periodontal disease(s) 147–171
COVID-19 as 265–266, 266f
gingival fibromatosis as 158–160
gingival hyperplasia as
drug-related 156–158
localized juvenile spongiotic 150–151
spongiotic 150–151, 150f
gingivitis as 147–150
desquamative 155
foreign body 154–155
localized juvenile spongiotic 150–151
necrotizing ulcerative 151–152, 152f
plasma cell 152–154, 153f
spongiotic 150–151, 150f
HIV-associated 257–258, 258f
Papillon-Lefèvre syndrome as 167–169, 168f
periodontitis as 160–167
Periodontal ligament, differential diagnosis of thickened 932–935t
Periodontal ligament space in systemic sclerosis 803, 803f
Periodontitis 160–167
acute apical 123, 129
aggressive 161
associated with systemic disease 161, 161b
chronic 161, 162f
apical See Periapical granuloma
classification of 161
clinical and radiographic features of 161–165
defined 160
histopathologic features of 165
HIV-associated 257, 258f
necrotizing 161, 163–164
treatment and prognosis for 166
necrotizing ulcerative 151–152
HIV-associated 257, 258f
pathogenesis of 161
refractory 166
treatment and prognosis for 166–167
Perioral dermatitis 343–344, 344f
Periorificial dermatitis 343–344, 344f
Periosteal chondromas 661
Periosteal osteosarcoma 668, 668f
Periostitis
ossificans 141–143, 142–143f
osteomyelitis with proliferative 141–143, 142–143f
Peripheral fibroameloblastic dentinoma 733
Peripheral fibroma with calcification 529–530, 529–530f
Peripheral giant cell granuloma 527–529, 528f
histopathologic features of 526, 527f
treatment and prognosis for 527
Peripheral nerve sheath tumor, malignant 562
in neurofibromatosis type I 539, 539f
Peripheral ossifying fibroma 529–530, 529–530f
Peripheral vascular disease due to diabetes mellitus 844
Periungual fibromas in tuberous sclerosis 763, 763f
Perlèche 202t, 204–205, 204f
Pernicious anemia 831–833, 832f
Persistent generalized lymphadenopathy (PGL), HIV-associated 256, 256f
Personal injury 910
Personal recognition 883–884, 884f
Petechiae 296, 296f, 591
defined 914
differential diagnosis of 916–919t
Peutz-Jeghers syndrome 758–759, 758f
PGL (persistent generalized lymphadenopathy), HIV-associated 256, 256f
PHACE(S) syndrome 548
Phantom bone disease 627–628, 627–628f
Phantom taste 869–871, 870b, 871t
Pharyngitis
acute lymphonodular 245, 246f
streptococcal 174–175, 174f
Pharyngotonsillitis 231
Phenol, chemical injury due to 279, 279f
Phenolphthalein, oral mucosal discoloration due to 308
Phenytoin-related gingival hyperplasia 157, 157f
Pheochromocytomas in multiple endocrine neoplasia type 2B 541
PHI (protected health information) 881
Philadelphia chromosome 593
Phlebolith 14
Phoenix abscess 123, 129
Phosphate-regulating gene with endopeptidase activity on the X chromosome (PHEX) 849
Photography
alternative light source (alternate light imaging, fluorescent) 905
of bite marks 903–905, 904t, 904f
infrared 904
reflective ultraviolet 904
Phycomycosis 219–221
clinical features of 219–220, 220f
diagnosis of 220
histopathologic features of 220, 220f
pathogenesis of 219
radiographic features of 219–220, 220f
treatment and prognosis for 220–221
Physical anthropologic examination of bones and teeth 885–888, 886t, 886f
Physical injury(ies) 272–320
anesthetic necrosis as 294, 294f
antral pseudocysts due to 310–312, 311–312f
cervicofacial emphysema due to 314–315, 314f
drug-related discolorations of oral mucosa as 307–309, 308–309f
due to amalgam tattoo and other localized exogenous pigmentations 298–300
due to antineoplastic therapy 280–286
due to chemicals 278–280, 278f
due to cosmetic fillers 302–304, 303f
due to drug abuse 292–294, 293f
due to endodontic materials 279–280, 279f
due to oral piercings and other body modifications 300–302, 301–302f
due to sexual practices 297–298, 297–298f
due to systemic metallic intoxication 304–306
electrical and thermal burns as 276–278, 277–278f
exfoliative cheilitis as 294–296, 295f
linea alba as 272, 273f
medication-related osteonecrosis of jaw as 286–292

morsicatio mucosae oris as 272–273, 273f
myospherulosis as 315, 315f
oral ulceration with bone sequestration as 310, 310f
reactive osseous and chondromatous metaplasia (Cutright lesion) as 309–310, 309f
smoker's melanosis as 306–307, 307f
submucosal hemorrhage due to 296–297, 296–297f
traumatic ulcerations as 273–275
true cysts of sinuses due to 312–313, 313f
PID (pelvic inflammatory disease) 184
Piercings 300–302, 301–302f
Pierre Robin sequence, orofacial clefts in 3, 3f
Pigmented ameloblastoma 541–543, 542f
Pigmented basal cell carcinoma 431
Pilar cyst 31
clinical features of 31, 31f
Pindborg tumor 720–722
clinical and radiographic features of 721, 721f
epidemiology of 720–721
histopathologic features of 721–722, 722f
pathogenesis of 720–721
relative distribution of 721, 721f
treatment and prognosis for 722
Pink disease 305
Pink tooth of Mummery 62–63, 63f
Pituitary dwarfism 833–834
Plantar pits in nevoid basal cell carcinoma syndrome 694–695, 695f
Plaque, defined 914
Plasma cell gingivitis 152–154, 153f
vs. contact stomatitis from artificial cinnamon flavoring 344
Plasmacytoma 611, 611f
extramedullary 611
Plasminogen deficiency 581–582, 582f
Plass Data DVI System International software 895
Platelet destruction, increased 590–591
Platelet production, reduced 590
Pleomorphic adenoma 483–487
carcinoma ex 499–501
clinical features of 499–500, 500f
histopathologic features of 500–501, 500f
intracapsular 501
treatment and prognosis for 501
clinical and radiographic features of 483–485, 484f
of deep lobe of parotid gland 485, 485f
epidemiology of 483
histopathologic features of 485–487, 486f
chondroid appearance as 486, 486f
eosinophilic, hyalinized change as 486, 486f
myoepithelial cells as 486, 486f
myxomatous background as 486, 486f
of palate 485, 485f
pathogenesis of 483
treatment and prognosis for 487
Pleomorphic lipoma 531
Pleomorphic liposarcoma 561
Plumbism 304–306
Plummer-Vinson syndrome 404, 830–831, 831f
Plunging ranula 463f
PMNR (periadenitis mucosa necrotica recurrens) 323, 323–325f, 327f
Pneumoparotid 314
Polyarthralgia 873
Polycythemia vera (primary, rubra vera) 592
Polydipsia in diabetes mellitus 845
Polyethylene agents for candidiasis 209, 211t
Poly-L-lactic acid (Sculptra), oral lesions associated with 302
Polymerase chain reaction (PCR) 888
Polymethylmethacrylate (Artecoll, ArteFill), oral lesions associated with 302, 303f
Polymorphic reticulosis 607–609, 608f
Polymorphous low-grade adenocarcinoma 503–505
clinical features of 504, 504f
histopathologic features of 504–505, 504–505f
treatment and prognosis for 505
Polymyalgia rheumatica 867
Polyp
fibroepithelial 517–518, 518f
pulp
clinical features of 118
histopathologic features of 118–119
treatment and prognosis for 119
Polyphagia in diabetes mellitus 845
Polypoid squamous cell carcinoma 423–424, 423–424f
Polyuria in diabetes mellitus 845
Poorly defined borders, differential diagnosis of radiolucencies with 926–931t
Poorly demarcated borders
differential diagnosis of mixed radiolucent/radiopaque lesions with 926–931t
differential diagnosis of radiopacities with 926–931t
Popliteal pterygium syndrome 5
Porphyria, tooth discoloration due to congenital erythropoietic 68–69, 68f
Port wine stain 551–552, 551f
Posaconazole for candidiasis 210
Positive identification 883
Possible identification 883
Postherpetic neuralgia 240
Postirradiation bone sarcoma 669
Postmortem examination 893–894, 894f
Postmortem records, comparison of antemortem and 894–895, 894t, 895f
Postoperative maxillary cyst 312–313, 313f
Potentially malignant disorder 381
Pregnancy
mask of 371–372, 371f
pyogenic granuloma during 526, 527f
Pregnancy tumor 526, 527f
Presumptive identification 883
Prevotella intermedia 191
Primary cutaneous CD30+ lymphoproliferative disorder 274
Primary palate 1, 27
Primordial cyst 689, 689f
Primordial odontogenic tumor 731
clinical and radiographic features of 731, 731f
histopathologic features of 731, 731f
treatment and prognosis for 731
Privacy Rule 881
Progeria 120
Prognastic staging classification
for oral cavity carcinoma and cutaneous carcinoma, of head and neck 415t
for oropharyngeal carcinoma 415–416t
Progonoma, melanotic 541–543, 542f
Progressive facial hemiatrophy 38–39, 39f
Progressive hemifacial atrophy 38–39, 39f
Progressive systemic sclerosis. See Systemic sclerosis
Proliferative periostitis, osteomyelitis with 141–143, 142–143f
Proliferative verrucous leukoplakia (PVL) 149–150, 384, 385f, 788
Proptosis 837, 838f
ProQuad (measles, mumps, rubella, and varicella virus vaccine) 238
Prosoplasia 127–129
Protease inhibitors 264
Protected health information (PHI) 881
Proteinosis, lipoid 822–823, 822–823f

Proteus-like syndrome, multiple hamartoma syndrome and 765
Proteus syndrome 539
Protostylid 85
Protozoal disease(s)
  leishmaniasis as 224–225, 224f
  toxoplasmosis as 222–224, 223f
Pseudoacanthosis nigricans 806
Pseudocarcinoma. See Keratoacanthoma
Pseudocarcinomatous hyperplasia 215

  acinic cell carcinoma as 497–498, 497–498f
  adenoid cystic carcinoma as 501–503
  basal cell adenoma as 491–492, 492f
  canalicular adenoma as 490–491, 490f
  carcinoma ex pleomorphic adenoma as 499–501
  carcinosarcoma as 499–501
  classification of 479
  ductal papillomas as 492–493
  frequency of malignancy by site for 479, 480t
  general considerations with 479–482
  incidence of 479
  intraosseous mucoepidermoid carcinoma (central mucoepidermoid carcinoma) as 496, 497f
  labial 481, 483t
  malignant mixed tumors as 499–501, 500f
  mammary analogue secretory carcinoma as 498–499, 498f
  metastasizing mixed tumor as 499–501
  of minor salivary glands 481, 484t
    location of 481, 483t
    percentage malignant by site of 484t
  monomorphic adenoma as 490
  mucoepidermoid carcinoma as 493–496
  oncocytoma (oxyphilic adenoma) as 487–488, 487f
  palatal 483t
  parotid 479, 480t
  pleomorphic adenoma (benign mixed tumor) as 483–487
  polymorphous low-grade adenocarcinoma as 503–505
  salivary adenocarcinoma, not otherwise specified as 505–506, 505–506f
  sites of 479, 480t
  sublingual 481
  submandibular 479–481, 481t
  Warthin tumor (papillary cystadenoma lymphomatosum) as 488–490, 489f
Salivary stones. See Sialolithiasis
Salivation, excessive 469–470
Sanfilippo-A disease 820t
Sanfilippo-B disease 820t
Sanguinaria-associated keratosis 381–382, 382f

San Joaquin Valley fever 217, 217f
SAPHO syndrome 138
  clinical and radiographic features of 139–140
  histopathologic features of 140
  treatment and prognosis for 140–141
Sarcoidosis 328–330
  clinical features of 328–329, 329f
  histopathologic features of 329, 330f
  treatment and prognosis for 330
Sarcoma(s)
  alveolar soft-part 568–569, 569f

  chronic 467–468, 467f
    sclerosing 468, 468f
  clinical and radiographic features of 467–468, 467f
  defined 467
  etiology and pathogenesis of 467
  histopathologic features of 468, 468f
  juvenile recurrent parotitis as 468
  myoepithelial 475, 475f
  subacute necrotizing 468
  treatment and prognosis for 468
Sialadenoma papilliferum 492–493
  clinical features of 492, 492–493f
  histopathologic features of 492–493, 493f
  treatment and prognosis for 493
Sialadenosis 476–477, 477f
  diabetic 845–846
Sialocyst 463–465, 464f
Sialolipoma 531
Sialolithiasis 465–467
  clinical features of 465, 465–466f
  defined 465
  histopathologic features of 465–466, 466f
  of minor salivary gland 465, 466f
  pathogenesis of 465
  radiographic features of 465, 465–466f
  treatment and prognosis for 466–467
Sialometaplasia, necrotizing 477–479, 478f
Sialo-odontogenic cyst 703–704, 704f
Sialorrhea 469–470
Sialosis 476–477, 477f
Sicca syndrome 472
Sickle cell anemia 583–585, 584f
  jaundice in 823
Sickle cell crisis 583
Sickle cell disease 583
Sickle cell trait 583
Sideropenic dysphagia 830–831, 831f
Silver intoxication 304–305, 306f
Silver nitrate, chemical injury due to 279
Simple bone cyst 636–638, 637f
Simvastatin, allergic mucosal reaction to 340f
Sinonasal papillomas 361

Sinonasal-type hemangiopericytoma 521
Sinonasal undifferentiated carcinoma (SNUC) 426–428, 427f
Sinusitis 196–198, 196f, 198f
  allergic fungal 221
Sinus mucocele 312–313, 313f
Sinus retention cyst 312–313
Sixth disease 229
Sjögren syndrome 472–476, 869
  classification of 472
  clinical and radiographic features of 473–474, 474f
  defined 472
  etiology and pathogenesis of 472
  histopathologic features of 475–476, 475–476f
  keratoconjunctivitis sicca in 472
  laboratory values in 474–475
  and lymphoma 476
  primary 472
  secondary 472
  treatment and prognosis for 476
Skeletal anomalies in nevoid basal cell carcinoma syndrome 695, 695f
Skeletal anthropologic variations 885–888, 886t, 886f
Skin
  clinical features of 31–32, 31–32f
  epidermoid cyst of 31
    clinical features of 31, 31–32f
    histopathologic features of 32, 32f
  follicular cysts of 31–32
    histopathologic features of 32, 32f
    treatment and prognosis for 32
Skull, physical anthropologic examination of 885–888, 886t, 886f
SLE (systemic lupus erythematosus), clinical features of 798, 798f, 799t
Small cell carcinoma of skin 432–434, 433f
Smokeless tobacco and squamous cell carcinoma 402–403
Smokeless tobacco keratosis 391–393
  clinical features of 391–392, 391f
  defined 381
  histopathologic features of 392–393, 392f
  treatment and prognosis for 393, 393f
Smokeless tobacco–related gingival recession 391, 391f
Smokeless tobacco use
  epidemiology 391
  types of 391
Smoker's melanosis 306–307, 307f
Smoker's palate 397–398, 398f
SNUC (sinonasal undifferentiated carcinoma) 426–428, 427f
Snuff dipper's cancer 393, 421–423, 422–423f
Snuff dipper's lesion. See Smokeless tobacco keratosis
Snuff pouch 391
Soft palate, differential diagnosis of soft tissue masses of 922–925t
Soft palate fistulas, lateral 15, 15f
Soft tissue chondromas 559
Soft tissue masses, differential diagnosis of 922–925t
Soft tissue osteomas 559
Soft tissue pathology, differential diagnosis of
  with color changes 916–919t
  with masses or enlargements 922–925t
  with surface alterations 920–921t
Soft tissue radiopacities, differential diagnosis of 926–931t
Soft tissue sarcoma(s) 559
  alveolar soft-part sarcoma as 568–569, 569f
  angiosarcoma as 563–564, 563f
  ectomesenchymal chondromyxoid tumor as 558
  fibrosarcoma 559–560, 560f
  Kaposi sarcoma as 564–565
  leiomyosarcoma as 565–566, 565–566f
  liposarcoma as 561, 561f
  malignant peripheral nerve sheath tumor as 562
  olfactory neuroblastoma (esthesioneuroblastoma) as 562–563, 562–563f
  rhabdomyosarcoma as 566–567
  synovial sarcoma as 567–568, 568f
  undifferentiated pleomorphic sarcoma (malignant fibrous histiocytoma) as 560–561, 561f
Soft tissue tumor(s) 514–577
  congenital epulis as 546–547, 546f
  epulis fissuratum as 517–519
  fibroma as 514
    giant cell 514–517
    irritation (traumatic) 514
    peripheral ossifying 529–530, 529–530f
  fibromatosis as 523, 523f
  fibrous histiocytoma as 520–521, 521f
  genetic abnormalities of various 515t
  granular cell tumor as 544–546
  hemangioma and vascular malformations as 547–551
  inflammatory papillary hyperplasia (denture papillomatosis) as 519–520, 519–520f
  leiomyoma as 555–557
  lipoma as 530–531
  lymphatic malformations as 553–555
  melanotic neuroectodermal tumor of infancy as 541–543
  metastases as 569–570
  multiple endocrine neoplasia type 2B as 540–541
  myofibromatosis as 523–524, 524f
  nasopharyngeal angiofibroma as 552–553, 553f
  neurofibroma as 534–537, 536–537f
  neurofibromatosis type I (von Recklinghausen disease of the skin) as 537–539
  neuroma as
    palisaded encapsulated (solitary circumscribed) 533–534, 533–534f
    traumatic (amputation) 531f, 532, 533f
  oral focal mucinosis as 524–525, 525f
  osseous and cartilaginous choristomas as 559, 559f
  paraganglioma as 543–544, 543–544f
  peripheral giant cell granuloma (giant cell epulis) as 527–529, 528f
  pyogenic granuloma (lobular capillary hemangioma) as 525–527
  rhabdomyoma as 557–558
  sarcomas as See Soft tissue sarcoma(s)
  schwannoma (neurilemoma) 534, 535t, 536f
  solitary fibrous tumor (hemangiopericytoma) as 521–522, 522f
  Sturge-Weber syndrome as 551–552, 551–552f
Solar cheilosis 395–396
Solar elastosis 395, 397, 431–432
Solar keratosis 396–397, 396–397f
  in xeroderma pigmentosum 753
Solar lentigo 369–370, 370f
Solid variant of adenoid cystic carcinoma 502–503
Solitary bone cyst 636–638, 637f
Solitary circumscribed neuroma 533–534, 533–534f
Solitary exostoses 20
Solitary fibrous tumor 521–522, 522f
South American blastomycosis 216–217, 216f
Speckled leukoplakia 384, 384f
Spindle and epithelioid cell nevus 378–379
Spindle cell carcinoma 423–424, 423–424f
Spindle cell lipoma 531
Spindle torus 21

Spit tobacco keratosis. See Smokeless tobacco keratosis
Spitz (spindle and epithelioid) 378–379
Spitz nevus 378–379
Spleen, sequestration in 591–592
Split papules 179–180, 180f
Split tongue 300–301
Spongiotic gingival hyperplasia 150–151, 150f
Squamous cell carcinoma 398–421
  adenosquamous 424–425
  arising in graft-versus-host disease 795, 795f
  basal cell 430–432, 431–432f
  basaloid 425, 425f
  clinical and radiographic features of 406–410
    intraoral cacinoma 407f, 408–410, 409–410f
    lip vermilion carcinoma 408, 408f
    metastasis 408–410, 411f
    oral cavity carcinoma 406–408, 406–408f
    oropharyngeal carcinoma 408–410, 410–411f
  epidermolysis bullosa and 768
  etiology of 402–406
    due to alcohol 403
    due to bacteria 404
    due to betel quid 403
    due to Candida 404
    due to chronic trauma or irritation 406
    due to dietary factors 404
    due to immunosuppression 406
    due to occupational exposures and environmental pollutants 403
    due to oncogenes and tumor suppressor genes 406
    due to oncogenic viruses 404–406
    due to radiation 403–404
    due to smokeless tobacco 402–403
    due to tobacco smoking 402
    due to vitamin/mineral deficiencies 404
  histopathologic features of 416–418, 417–418f
  histopathologic grading of 417
  HIV-associated 263, 263f
  keratinizing 429
  malignant transformation of dentigerous cyst to 688

Sample Exam Questions

CHAPTER 1: DEVELOPMENTAL DEFECTS OF THE ORAL AND MAXILLOFACIAL REGION

1. Which one of the following statements about leukoedema is true?
   A. Lesions are seen most commonly on the lateral surface of the tongue.
   B. Leukoedema is caused by Epstein-Barr virus.
   C. Malignant transformation occurs in 10% of cases.
   D. The condition is most common in whites.
   E. The white appearance disappears when the lesion is stretched.

   ANS: E

2. The branchial cleft cyst is also known as:
   A. cervical lymphoepithelial cyst.
   B. cystic teratoma.
   C. dermoid cyst.
   D. epidermoid cyst.
   E. thyroglossal duct cyst.

   ANS: A

3. The favored treatment for Fordyce granules is:
   A. conservative excision.
   B. laser ablation.
   C. tetracycline rinses.
   D. topical corticosteroid therapy.
   E. no treatment is necessary.

   ANS: E

4. Macroglossia is most likely to be associated with which endocrine problem?
   A. Diabetes mellitus
   B. Hyperparathyroidism
   C. Hyperthyroidism
   D. Hypoparathyroidism
   E. Hypothyroidism

   ANS: E

5. Fordyce granules are:
   A. hair follicles.
   B. minor salivary glands.
   C. sebaceous glands.
   D. sweat glands.
   E. tiny epidermoid cysts.

   ANS: C

6. Which one of the following sites is the most common location for a caliber-persistent artery?
   A. Buccal mucosa
   B. Gingiva
   C. Lateral soft palate
   D. Upper labial mucosa
   E. Ventral surface of tongue

   ANS: D

7. Which one of the following developmental cysts of the oral cavity is most common?
   A. Dermoid cyst
   B. Globulomaxillary cyst
   C. Median palatal cyst
   D. Nasolabial cyst
   E. Nasopalatine duct cyst

   ANS: E

8. Which one of the following anomalies occurs in approximately 80% of the population?
   A. Commissural lip pits
   B. Epidermoid cysts of the skin
   C. Fordyce granules
   D. Hypodontia of one of the third molars
   E. Torus palatinus or torus mandibularis

   ANS: C

9. The most commonly purported cause of hairy tongue is:
   A. cigarette smoking.
   B. human immunodeficiency syndrome infection.
   C. long-standing geographic tongue (erythema migrans).
   D. misplaced follicular progenitor cells from the first and second branchial arches.
   E. mouth-breathing associated with a high-arched palate.

   ANS: A

10. The most common presenting symptom of coronoid hyperplasia is:
    A. increasing anterior open bite.
    B. restriction of mandibular opening.
    C. subluxation of the temporomandibular joint.
    D. temporal headaches.
    E. unilateral cross-bite.

    ANS: B

dentlearn.ir

11. The least likely site for an oral lymphoepithelial cyst is:
    A. floor of mouth.
    B. palatine tonsil.
    C. posterior lateral border of tongue.
    D. tip of tongue.

    ANS: D

12. The microscopic appearance of a branchial cleft cyst is most similar to:
    A. dermoid cyst.
    B. epidermoid cyst.
    C. nasolabial cyst.
    D. nasopalatine duct cyst.
    E. oral lymphoepithelial cyst.

    ANS: E

13. Which one of the following statements about the Stafne defect is NOT true?
    A. No treatment is recommended for the Stafne defect.
    B. The Stafne defect also has been known as a static bone cyst.
    C. The Stafne defect is lined by stratified squamous epithelium.
    D. The Stafne defect is located beneath the mandibular canal.
    E. The Stafne defect occurs more commonly in males.

    ANS: C

14. The most common location for an oral dermoid cyst is:
    A. floor of the mouth.
    B. lateral aspect of the upper lip.
    C. midline of the hard palate.
    D. posterior buccal mucosa.
    E. posterior lateral tongue.

    ANS: A

15. Torus palatinus and torus mandibularis are best considered as types of:
    A. choristoma.
    B. exostosis.
    C. hamartoma.
    D. osteoma.
    E. all of the above.

    ANS: B

16. Which one of the following conditions occurs more commonly in blacks?
    A. Commissural lip pits
    B. Fordyce granules
    C. Leukoedema
    D. Stafne defects
    E. Torus mandibularis

    ANS: C

17. Which one of the following developmental anomalies is most likely to be associated with cleft palate?
    A. Bifid condyles
    B. Condylar hyperplasia
    C. Lingual thyroid
    D. Nasopalatine duct cyst
    E. Paramedian lip pits

    ANS: E

18. By definition, a cyst:
    A. is caused by infection.
    B. is filled with keratin.
    C. is lined by epithelium.
    D. occurs within bone.
    E. will resolve by itself.

    ANS: C

19. A Stafne defect is created by:
    A. aberrant thyroid tissue.
    B. elongation of the stylohyoid ligament.
    C. hyperplasia of the coronoid process of the mandible.
    D. secondary inflammation of the cervical lymph nodes.
    E. submandibular gland.

    ANS: E

20. A simple diagnostic test for leukoedema is everting the cheek. When this is done, the leukoedema will:
    A. become whiter.
    B. disappear.
    C. form multiple vesicles.
    D. peel off.
    E. release milky fluid.

    ANS: B

21. Fissured tongue is often seen associated with what other tongue condition?
    A. Ankyloglossia
    B. Geographic tongue
    C. Hairy tongue
    D. Lingual thyroid
    E. Lingual varicosities

    ANS: B

dentlearn.ir

Sample Exam Questions

CHAPTER 2: ABNORMALITIES OF TEETH

1. A Turner tooth may be caused by:
   A. excess fluoride in the water supply.
   B. syphilis.
   C. too little fluoride in the water supply.
   D. trauma to the primary dentition.
   E. viral infection.

   ANS: D

2. Hypodontia may be a feature of which syndrome?
   A. Gardner syndrome
   B. Hypohidrotic ectodermal dysplasia
   C. McCune-Albright syndrome
   D. Neurofibromatosis
   E. Peutz-Jeghers syndrome

   ANS: B

3. Dens in dente occurs most frequently in which tooth?
   A. Mandibular central incisor
   B. Mandibular cuspid
   C. Mandibular molars
   D. Maxillary bicuspid
   E. Maxillary lateral incisor

   ANS: E

4. Which one of the following is the most common supernumerary tooth?
   A. Mandibular premolar
   B. Mandibular third molar
   C. Maxillary canine
   D. Maxillary third molar
   E. Mesiodens

   ANS: E

5. Which one of the following tooth anomalies is characterized by a tendency for the enamel to fracture away from the dentin?
   A. Dentin dysplasia type I
   B. Dentinogenesis imperfecta
   C. Hypoplastic amelogenesis imperfecta
   D. Regional odontodysplasia
   E. All of the above

   ANS: B

6. Which one of the following is the most common developmentally missing tooth?
   A. Central incisor
   B. First bicuspid
   C. First molar
   D. Lateral incisor
   E. Third molar

   ANS: E

7. Shell teeth represent a clinical variant of:
   A. amelogenesis imperfecta.
   B. dentin dysplasia type II.
   C. dentinogenesis imperfecta.
   D. fluorosis.
   E. regional odontodysplasia.

   ANS: C

8. Which one of the following tooth problems may be associated with bulimia?
   A. Dilaceration
   B. Enamel hypoplasia
   C. Erosion
   D. External resorption
   E. Internal resorption

   ANS: C

9. All of the following causes of tooth discoloration are classified as intrinsic stains EXCEPT:
   A. chlorhexidine therapy.
   B. erythroblastosis fetalis.
   C. hyperbilirubinemia.
   D. porphyria.
   E. tetracycline therapy.

   ANS: A

10. The union of the roots of two adjacent teeth by excess cementum is termed:
    A. abfraction.
    B. concrescence.
    C. dilaceration.
    D. fusion.
    E. gemination.

    ANS: B

dentlearn.ir

11. Which one of the following conditions is characterized by multiple unerupted and supernumerary teeth?
    A. Cleidocranial dysplasia
    B. Crouzon syndrome
    C. Ectodermal dysplasia
    D. Taurodontism
    E. van der Woude syndrome

    ANS: A

12. "Snow-capped teeth" is an example of:
    A. amelogenesis imperfecta.
    B. dens evaginatus.
    C. dentinogenesis imperfecta.
    D. the Lyon hypothesis.
    E. Turner's hypoplasia.

    ANS: A

13. Macrodontia can be a clinical feature of:
    A. Ascher syndrome.
    B. hemihyperplasia.
    C. juvenile diabetes mellitus.
    D. Pierre Robin sequence.
    E. radiation therapy during tooth development.

    ANS: B

14. Which one of the following dental anomalies is inherited as an autosomal dominant trait?
    A. Dens invaginatus
    B. Dentinogenesis imperfecta
    C. Dilaceration
    D. Gemination
    E. Regional odontodysplasia

    ANS: B

15. The most common problem associated with concrescence is:
    A. difficulty in extraction.
    B. frequent association with Paget's disease of bone.
    C. high frequency of pulpal necrosis.
    D. high incidence of pulp stones.
    E. lack of room for eruption of all of the teeth.

    ANS: A

16. Which one of the following dental anomalies is found most frequently in patients of Asian heritage?
    A. Dens evaginatus
    B. Dilaceration
    C. Enamel pearls
    D. Hypercementosis
    E. Taurodontism

    ANS: A

17. Obliteration of the pulp chambers by excess dentin formation is a feature of:
    A. dentinogenesis imperfecta.
    B. Gardner syndrome.
    C. late taurodontism.
    D. regional odontodysplasia.
    E. secondary hyperparathyroidism.

    ANS: A

18. Mulberry molars might be seen in a child who also exhibits:
    A. dens evaginatus.
    B. Hutchinson incisors.
    C. osteogenesis imperfecta.
    D. talon cusps.
    E. taurodontism.

    ANS: B

19. Riga-Fede disease refers to ulceration of the tongue associated with:
    A. elongation of the styloid process.
    B. large mandibular tori.
    C. lingual thyroid.
    D. natal or neonatal teeth.
    E. persistent ankyloglossia.

    ANS: D

20. Talon cusps occur most often on which tooth?
    A. Mandibular canine
    B. Mandibular premolar
    C. Mandibular third molar
    D. Maxillary first molar
    E. Maxillary lateral incisor

    ANS: E

21. Which one of the following conditions often results in the development of nonvital teeth?
    A. Dentin dysplasia type I
    B. Fluorosis
    C. Gemination
    D. Hereditary hypohidrotic ectodermal dysplasia
    E. Taurodontism

    ANS: A

dentlearn.ir

Sample Exam Questions

CHAPTER 3: PULPAL AND PERIAPICAL DISEASE

1. Which of the following is NOT true about chronic hyperplastic pulpitis?
   A. Associated with grossly carious tooth
   B. Because the pulp is still vital, root canal therapy (or extraction) is not necessary.
   C. Granulation tissue grows out of the pulp to fill the carious defect.
   D. The tooth is often asymptomatic.
   E. Usually occurs in children and young adults

   ANS: B

2. The most likely source of the epithelium for the periapical cyst is:
   A. crevicular epithelium.
   B. oral mucosa.
   C. rests of Malassez.
   D. sinus mucosa.
   E. vascular endothelium.

   ANS: C

3. Which one of the following lesions may contain Rushton bodies?
   A. Chronic osteomyelitis
   B. Parulis
   C. Periapical abscess
   D. Periapical cyst
   E. Pulp stones

   ANS: D

4. The site of a draining abscess on the gingival/alveolar mucosa is termed:
   A. ephelis.
   B. epulis.
   C. Ludwig's angina.
   D. nevus.
   E. parulis.

   ANS: E

5. A tooth that is sensitive to cold after having a restoration placed recently would probably represent an example of:
   A. acute pulpitis.
   B. chronic hyperplastic pulpitis.
   C. chronic pulpitis.
   D. pulpal necrosis.
   E. reversible pulpitis.

   ANS: E

6. Which one of the following histopathologic patterns best characterizes the periapical granuloma?
   A. Caseous necrosis
   B. Epithelium-lined cavity
   C. Fibrous scar tissue
   D. Granulation tissue
   E. Periosteal bone production

   ANS: D

7. Which one of the following infections is an example of a cellulitis?
   A. Ludwig's angina
   B. Primary syphilis
   C. Pyogenic granuloma
   D. Sarcoidosis
   E. Scarlet fever

   ANS: A

8. A piece of dead bone in a case of osteomyelitis is best termed a(n):
   A. cementoma.
   B. exostosis.
   C. osteoma.
   D. Russell body.
   E. sequestrum.

   ANS: E

9. The characteristic radiographic pattern seen in proliferative periostitis is:
   A. "Cobweb" trabeculation.
   B. "cotton-wool" bone.
   C. "ground-glass" bone.
   D. "onionskin" laminations.
   E. widened periodontal ligament spaces.

   ANS: D

10. The predominant inflammatory cell in an abscess is the:
    A. histiocyte.
    B. Langerhans cell.
    C. neutrophil.
    D. plasma cell.
    E. T-lymphocyte.

    ANS: C

dentlearn.ir

Sample Exam Questions

CHAPTER 4: PERIODONTAL DISEASES

1. Which one of the following drugs has NOT been associated with gingival hyperplasia?
   A. Amoxicillin
   B. Cyclosporine
   C. Dilantin
   D. Nifedipine
   E. Phenytoin

   ANS: A

2. Hyperkeratosis of the palms and soles is a feature of:
   A. Apert syndrome.
   B. Crouzon syndrome.
   C. Papillon-Lefèvre syndrome.
   D. Treacher Collins syndrome.
   E. tricho-dento-osseous syndrome.

   ANS: C

3. Hypertrichosis (excess body hair) can be associated with:
   A. aggressive periodontitis.
   B. granulomatous gingivitis.
   C. hereditary gingival fibromatosis.
   D. necrotizing ulcerative gingivitis.
   E. plasma cell gingivitis.

   ANS: C

4. A 25-year-old white male presents to you with classic necrotizing ulcerative gingivitis. Which of the following underlying conditions should be considered?
   A. Acquired immune deficiency syndrome
   B. Parkinson's disease
   C. Patent ductus arteriosus
   D. Posttraumatic stress syndrome
   E. Tetralogy of Fallot

   ANS: A

5. Desquamative gingivitis is a clinical term used to describe the vesiculoerosive lesions of the gingiva that occur in association with dermatologic disorders. Which one of the following conditions would NOT be expected to present in the mouth as a desquamative gingivitis?
   A. Erosive lichen planus
   B. Pemphigoid
   C. Pemphigus
   D. Psoriasis

   ANS: D

6. "Desquamative gingivitis" is most likely to occur in a:
   A. 15-year-old female.
   B. 25-year-old male.
   C. 35-year-old female.
   D. 45-year-old male.
   E. 55-year-old female.

   ANS: E

7. Aggressive periodontitis in young persons most frequently involves:
   A. bicuspids.
   B. cuspids.
   C. incisors and first molars.
   D. third molars.
   E. unerupted teeth.

   ANS: C

8. Which of the following is the inheritance pattern of Papillon-Lefèvre syndrome?
   A. Autosomal dominant
   B. Autosomal recessive
   C. Multifactorial
   D. X-linked dominant
   E. X-linked recessive

   ANS: B

dentlearn.ir

Sample Exam Questions

CHAPTER 5: BACTERIAL INFECTIONS

1. Scrofula refers to a form of:
   A. cat-scratch disease.
   B. gonorrhea.
   C. lymphoma.
   D. syphilis.
   E. tuberculosis.

   ANS: E

2. Which one of the following infections is NOT caused by a fungus?
   A. Actinomycosis
   B. Blastomycosis
   C. Candidiasis
   D. Histoplasmosis
   E. Phycomycosis

   ANS: A

3. Tuberculosis is classically characterized by which type of necrosis?
   A. Aspiration necrosis
   B. Caseous necrosis
   C. Coagulative necrosis
   D. Fat necrosis
   E. Liquefactive necrosis

   ANS: B

4. Most intraoral lesions of tuberculosis are thought to be secondary to:
   A. dental treatment with infected instruments.
   B. kissing a person with active tuberculosis.
   C. lupus vulgaris.
   D. pulmonary tuberculosis.
   E. scrofula.

   ANS: D

5. Which one of the following infections is caused by an acid-fast mycobacterium?
   A. Cat-scratch disease
   B. Leprosy
   C. Noma
   D. Scarlet fever
   E. Syphilis

   ANS: B

6. Which one of the following infections often affects nerves resulting in loss of sensation?
   A. Actinomycosis
   B. Leprosy
   C. Primary syphilis
   D. Sarcoidosis
   E. Scarlet fever

   ANS: B

7. "Split papules" at the commissures may be seen in patients with:
   A. actinomycosis.
   B. erysipelas.
   C. impetigo.
   D. noma.
   E. secondary syphilis.

   ANS: E

8. Which one of the following is a characteristic oral lesion that has been described in patients with scarlet fever?
   A. Chancre
   B. Gumma
   C. Mucous patch
   D. Strawberry tongue
   E. Sulfur granules

   ANS: D

9. Many examples of noma represent a progression of which infection?
   A. Necrotizing ulcerative gingivitis
   B. Primary herpetic gingivostomatitis
   C. Pyogenic granuloma
   D. Scarlet fever
   E. Syphilis

   ANS: A

10. Hutchinson incisors are associated with:
    A. congenital syphilis.
    B. diphtheria.
    C. gonorrhea during pregnancy.
    D. multibacillary leprosy.
    E. oral cat-scratch disease.

    ANS: A

dentlearn.ir

Sample Exam Questions

CHAPTER 6: FUNGAL AND PROTOZOAL DISEASES

1. The most common fungal infection of the oral cavity is:
   A. actinomycosis.
   B. blastomycosis.
   C. candidiasis.
   D. histoplasmosis.
   E. zygomycosis.

   ANS: C

2. Candidiasis infections are often associated with patients taking which of the following drugs?
   A. Antibiotics
   B. Anticoagulants
   C. Antihistamines
   D. Calcium-channel blockers
   E. Diet pills

   ANS: A

3. Median rhomboid glossitis actually represents what lesion microscopically?
   A. Arteriovenous malformation
   B. Candidiasis
   C. Erythema migrans
   D. Erythroplakia
   E. Remnants of lingual thyroid tissue

   ANS: B

4. Rhinocerebral mucormycosis infections are classically associated with:
   A. cocaine abuse.
   B. ipsilateral herpes zoster.
   C. overfilled canals during root canal therapy.
   D. uncontrolled diabetes.
   E. none of the above.

   ANS: D

5. Which one of the following infections classically presents with white lesions of the oral mucosa that can be rubbed off?
   A. Actinomycosis
   B. Candidiasis
   C. Histoplasmosis
   D. Primary herpetic gingivostomatitis
   E. Primary syphilis

   ANS: B

6. Which one of the following infections is considered to be endemic in the regions drained by the Ohio and Mississippi Rivers?
   A. Coccidioidomycosis
   B. Cryptococcosis
   C. Histoplasmosis
   D. Mucormycosis
   E. Paracoccidioidomycosis

   ANS: C

7. Mucormycosis infections would most likely occur in which location?
   A. Floor of mouth
   B. Liver
   C. Maxillary sinus
   D. Submandibular gland
   E. Tongue

   ANS: C

8. Which animal is the most common host for toxoplasmosis?
   A. Armadillo
   B. Bird
   C. Cat
   D. Dog
   E. Elephant

   ANS: C

9. Allergic fungal sinusitis is related to which organism?
   A. Aspergillus
   B. Blastomyces
   C. Candida
   D. Histoplasma
   E. Mucor

   ANS: A

10. Which one of the following organisms often is related to angular cheilitis?
    A. Herpes simplex, type 1
    B. Candida albicans
    C. Streptococcus mutans
    D. Actinomyces israelii
    E. Tinea versicolor

    ANS: B

dentlearn.ir

Sample Exam Questions

CHAPTER 7: VIRAL INFECTIONS

1. "Ballooning degeneration" of the nuclei of epithelial cells is a characteristic microscopic finding in:
   A. herpangina.
   B. herpes simplex infections.
   C. infectious mononucleosis.
   D. measles.
   E. mumps.

   ANS: B

2. The most common site for recurrent intraoral herpes infections is:
   A. buccal mucosa.
   B. dorsal tongue.
   C. floor of mouth.
   D. hard palate.
   E. soft palate.

   ANS: D

3. Orchitis (testicular inflammation) is a well-known complication of:
   A. lymphonodular pharyngitis.
   B. mumps.
   C. rubella.
   D. rubeola.
   E. all of the above.

   ANS: B

4. Oral hairy leukoplakia is caused by:
   A. candidiasis.
   B. cytomegalovirus (CMV).
   C. Epstein-Barr virus.
   D. smoking.
   E. tongue-biting.

   ANS: C

5. The most common oral infection associated with acquired immune deficiency syndrome (AIDS) is:
   A. acute herpetic gingivostomatitis.
   B. blastomycosis.
   C. candidiasis.
   D. CMV.
   E. human papillomavirus.

   ANS: C

6. Which one of the following presentations of herpes simplex infection is most common?
   A. Herpes labialis
   B. Herpetic whitlow
   C. Neonatal herpes
   D. Primary herpetic gingivostomatitis
   E. Recurrent intraoral herpes

   ANS: A

7. Which one of the following can be an early oral sign in patients with infectious mononucleosis?
   A. Enlargement of the fungiform papillae
   B. Forchheimer sign
   C. Fordyce spots
   D. Koplik spots
   E. Palatal petechiae

   ANS: E

8. A unilateral distribution of skin lesions would be most suggestive of:
   A. CMV dermatitis.
   B. eczema herpeticum.
   C. German measles.
   D. hand-foot-and-mouth disease.
   E. herpes zoster.

   ANS: E

9. Kaposi sarcoma is believed to be caused by:
   A. cryptococcus neoformans.
   B. CMV.
   C. Epstein-Barr virus.
   D. human herpesvirus type 2.
   E. human herpesvirus type 8.

   ANS: E

10. The most common location for Kaposi sarcoma in the mouth is:
    A. buccal mucosa.
    B. hard palate.
    C. lower lip.
    D. tongue.
    E. upper lip.

    ANS: B

dentlearn.ir

11. In addition to Kaposi sarcoma, which one of the following tumors has the most significantly increased risk in patients with AIDS?
    A. Breast cancer
    B. Hepatocellular carcinoma
    C. Lymphoma
    D. Nasopharyngeal carcinoma
    E. Prostate cancer

    ANS: C

12. For both herpes simplex and varicella-zoster virus, the organism may remain dormant in the body for many years, and later give rise to a recurrence. The most common site for the virus to remain dormant is:
    A. bone marrow.
    B. circumvallate papillae.
    C. liver.
    D. nerve ganglia.
    E. sinus mucosa.

    ANS: D

13. Oral hairy leukoplakia is often associated with:
    A. CMV.
    B. human immunodeficiency virus infection.
    C. increased risk for squamous cell carcinoma.
    D. smoking.
    E. all of the above.

    ANS: B

14. The "whitlow" phenomenon is an infection of the finger or nail bed caused by which virus?
    A. CMV
    B. Herpes simplex
    C. Human papillomavirus
    D. Pox virus
    E. Varicella-zoster

    ANS: B

dentlearn.ir

Sample Exam Questions

CHAPTER 8: PHYSICAL AND CHEMICAL INJURIES

1. Which of the following is not typically an oral complication of antineoplastic therapy?
   A. Cervicofacial emphysema
   B. Hypogeusia
   C. Mucositis
   D. Osteoradionecrosis
   E. Xerostomia

   ANS: A

2. Which one of the following drugs may stain bone and result in blue-gray discoloration of the alveolar mucosa adjacent to the teeth?
   A. Amphotericin B
   B. Clotrimazole
   C. Fluconazole
   D. Fluocinonide
   E. Minocycline

   ANS: E

3. Which one of the following drugs has been known to result in palatal hyperpigmentation?
   A. Accutane
   B. Botox
   C. Chloroquine
   D. Dilantin
   E. Ephedrine

   ANS: C

4. The most common location for the traumatic granuloma (traumatic ulcerative granuloma with stromal eosinophilia) is:
   A. buccal mucosa.
   B. gingiva.
   C. hard palate.
   D. lower lip.
   E. tongue.

   ANS: E

5. Minute, pinpoint areas of hemorrhage on the skin or mucosa are best termed:
   A. ecchymoses.
   B. hematomas.
   C. petechiae.
   D. purpura.
   E. vesicles.

   ANS: C

6. Susceptibility to dental caries in a patient with a history of radiation therapy to the head and neck is mostly related to:
   A. decreased ability of the patient to brush and floss the teeth.
   B. direct radiation damage to the hydroxyapatite crystal structure of tooth enamel.
   C. direct resorption of tooth structure by cancerous cells.
   D. radiation-induced mutations to caries-causing bacteria (*Streptococcus mutans*).
   E. secondary xerostomia due to damage to salivary glands in the field of radiation.

   ANS: E

7. A pseudocyst of the maxillary sinus will classically appear as:
   A. a cavity lined by pseudostratified columnar epithelium.
   B. a cavity lined by stratified squamous epithelium.
   C. a dome-shaped radiopacity arising from the floor of the sinus.
   D. a well-defined radiolucency located between the roots of the maxillary teeth.
   E. total opacification of the sinus with evidence of peripheral bone resorption.

   ANS: C

8. Bisphosphonate medications work by:
   A. causing renal phosphate excretion.
   B. decreasing serum calcium levels.
   C. inhibiting calcitonin activity.
   D. inhibiting resorptive activity by osteoclasts.
   E. promoting the action of parathyroid hormone.

   ANS: D

9. Which one of the following drugs may be used for the treatment of xerostomia?
   A. Chlorpromazine
   B. Methamphetamines
   C. Pamidronate
   D. Pilocarpine
   E. Zoledronic acid

   ANS: D

dentlearn.ir

Sample Exam Questions

CHAPTER 9: ALLERGIES AND IMMUNOLOGIC DISEASES

1. The least likely location for an aphthous ulcer is:
   A. buccal mucosa.
   B. hard palate.
   C. labial mucosa.
   D. lateral tongue.
   E. soft palate.

   ANS: B

2. Which one of the following is a typical feature of an aphthous ulcer?
   A. Caused by herpes simplex
   B. Grayish yellow ulcer located on the maxillary gingiva
   C. Painful ulcer surrounded by a red halo
   D. Starts as a fluid-filled blister that ruptures
   E. Usually associated with inflammatory bowel disease

   ANS: C

3. "Strawberry gingivitis" is a characteristic oral presentation of:
   A. aspergillosis.
   B. histoplasmosis.
   C. scarlet fever.
   D. tertiary syphilis.
   E. Wegener granulomatosis.

   ANS: E

4. Which of the following conditions is NOT associated with granulomatous inflammation?
   A. Cheilitis granulomatosa
   B. Leprosy
   C. Recurrent aphthous stomatitis
   D. Sarcoidosis
   E. Tuberculosis

   ANS: C

5. The clinical appearance of contact stomatitis on the lateral tongue from chewing cinnamon-flavored gum is most likely to resemble which of the following?
   A. Black hairy tongue
   B. Erythema migrans (geographic tongue)
   C. Fissured tongue
   D. Leukoedema
   E. Oral hairy leukoplakia

   ANS: E

6. Oral mucosal contact reactions to dental materials, such as amalgam, may appear clinically and histopathologically similar to:
   A. candidiasis.
   B. lichen planus.
   C. morsicatio buccarum.
   D. orofacial granulomatosis.
   E. pemphigus vulgaris.

   ANS: B

7. Which one of the following classes of drugs is most likely to produce a severe form of angioedema?
   A. Angiotensin-converting-enzyme inhibitors
   B. Antifungals
   C. Calcium-channel blockers
   D. Nonsteroidal antiinflammatory drugs
   E. Statins

   ANS: A

8. Which one of the following oral lesions is classically associated with Behçet syndrome?
   A. Aphthous ulcers
   B. Diffuse enlargement of the upper lip
   C. Fissured tongue
   D. Superficial peeling of the oral mucosa
   E. White plaques that do not rub off

   ANS: A

dentlearn.ir

Sample Exam Questions

CHAPTER 10: EPITHELIAL PATHOLOGY

1. Which one of the following is NOT caused by one of the human papillomaviruses (HPV)?
   A. Condyloma acuminatum
   B. Focal epithelial hyperplasia
   C. Molluscum contagiosum
   D. Squamous papilloma
   E. Verruca vulgaris

   ANS: C

2. Oral mucosal melanoma most commonly arises on the:
   A. buccal mucosa and upper labial mucosa.
   B. hard palate and maxillary alveolar mucosa.
   C. mandibular alveolar ridge and floor of mouth.
   D. soft palate and buccal mucosa.
   E. ventrolateral tongue and floor of mouth.

   ANS: B

3. Which one of the following lesions typically shows squamous metaplasia of the minor salivary gland ducts on microscopic examination?
   A. Nicotine stomatitis
   B. Seborrheic keratosis
   C. Squamous papilloma
   D. Tobacco pouch keratosis
   E. Traumatic neuroma

   ANS: A

4. Squamous cell carcinoma represents approximately what percentage of all oral cancer?
   A. 10%
   B. 30%
   C. 50%
   D. 70%
   E. 90%

   ANS: E

5. HPV would most likely be involved in the pathogenesis of a squamous cell carcinoma in which one of the following locations?
   A. Floor of mouth
   B. Gingiva
   C. Lateral tongue
   D. Palatine tonsil
   E. Upper lip vermilion

   ANS: D

6. Which one of the following lesions is LEAST likely to transform into a carcinoma?
   A. Actinic keratosis
   B. Erythroplakia
   C. Proliferative verrucous leukoplakia
   D. Seborrheic keratosis
   E. Speckled leukoplakia

   ANS: D

7. Which of the following is the most common site for the melanotic macule?
   A. Buccal mucosa
   B. Gingiva
   C. Hard palate
   D. Lower lip vermilion
   E. Tongue

   ANS: D

8. Which strain of HPV has most often been associated with an increased risk of oropharyngeal cancer?
   A. HPV-1
   B. HPV-2
   C. HPV-6
   D. HPV-11
   E. HPV-16

   ANS: E

9. A 59-year-old white male presents with a 3×3 cm^2 ulcerated carcinoma of the buccal mucosa. No evidence of regional or distant metastasis can be identified clinically or radiographically. This lesion is best classified as:
   A. grade I.
   B. stage I.
   C. stage II.
   D. stage III.
   E. stage IV.

   ANS: C

10. Which one of the following lesions would be most likely to show malignant or dysplastic changes?
    A. Erythroplakia of the floor of the mouth
    B. Leukoplakia of the floor of the mouth
    C. Leukoplakia of the lateral border of the tongue
    D. Nicotine stomatitis
    E. Snuff pouch

    ANS: A

dentlearn.ir

11. Which one of the following benign dermatologic lesions classically presents as a brown, scaly, greasy plaque that appears to be "stuck onto" the skin surface?
    A. Ephelis
    B. Lentigo maligna
    C. Lentigo simplex
    D. Seborrheic keratosis
    E. Verruciform xanthoma

    ANS: D

12. Which one of the following is the most common site for intraoral cancer?
    A. Buccal mucosa
    B. Floor of mouth
    C. Gingiva
    D. Hard palate
    E. Lateral border of tongue

    ANS: E

13. By definition, carcinoma *in situ* is characterized by:
    A. dysplasia involving the entire epithelial thickness, but without invasion.
    B. metastasis.
    C. parakeratin production.
    D. proliferative verrucous leukoplakia.
    E. tripolar mitoses.

    ANS: A

14. In the ABCDE warning signs for melanoma, the "A" stands for:
    A. acral.
    B. amelanotic.
    C. anteverted.
    D. aplastic.
    E. asymmetry.

    ANS: E

15. The most common form of melanoma is:
    A. acral lentiginous.
    B. lentigo maligna.
    C. nodular.
    D. oral.
    E. superficial spreading.

    ANS: E

16. Which of the following locations would be the LEAST likely site for squamous cell carcinoma?
    A. Floor of mouth
    B. Lateral soft palate/palatine tonsil
    C. Lateral surface of tongue
    D. Lower lip vermilion
    E. Midline dorsal surface of tongue

    ANS: E

17. The so-called liver spot on the skin is better known as a(n):
    A. actinic lentigo.
    B. ephelis.
    C. epulis.
    D. melanoacanthosis.
    E. melanotic macule.

    ANS: A

18. Which one of the following clinical lesions is most likely to become an invasive squamous cell carcinoma?
    A. A 1×1 cm^2 leukoplakia in the floor of the mouth
    B. A 4×2 cm^2 wrinkled tobacco pouch keratosis in the lower vestibule
    C. A 5×5 mm^2 squamous papilloma of the lateral soft palate
    D. Generalized nicotine stomatitis involving the entire posterior hard palate
    E. Long-standing inflammatory papillary hyperplasia of the midline vault of the hard palate

    ANS: A

19. Oral squamous cell carcinoma is more common in men. In which of the following locations does squamous cell carcinoma show the most striking male predilection?
    A. Buccal mucosa
    B. Floor of mouth
    C. Lower lip vermilion
    D. Palate
    E. Tongue

    ANS: C

20. An increase in thickness of the spinous layer of the epithelium is termed:
    A. acanthosis.
    B. dyskeratosis.
    C. hyperparakeratosis.
    D. leukoplakia.
    E. polarity.

    ANS: A

21. Select the tumor with the worst prognosis.
    A. Intraoral melanoma
    B. Junctional nevus
    C. Lentigo maligna melanoma of the face
    D. Superficial spreading melanoma of the back
    E. Verrucous carcinoma

    ANS: A

22. Nicotine stomatitis is most often associated with:
    A. cigar smoking.
    B. cigarette smoking.
    C. nicotine gum.
    D. pipe smoking.
    E. snuff dipping.

    ANS: D

dentlearn.ir

23. Which one of the following clinical features would be a warning sign for a possible malignant alteration in a pigmented lesion?
    A. A blue lesion that blanches under direct pressure
    B. A blue-pigmented lesion
    C. A lesion with multiple different colors
    D. A uniform brown color
    E. A uniform dark black color

    ANS: C

24. The prognosis of melanoma of the skin is most closely related to:
    A. age of the patient.
    B. asymmetry of the borders.
    C. degree of melanin produced.
    D. depth of invasion.
    E. diameter of the tumor.

    ANS: D

25. Compared to melanoma of the skin, the overall prognosis for oral melanoma is:
    A. much better
    B. slightly better
    C. the same
    D. slightly worse
    E. much worse

    ANS: E

dentlearn.ir

Sample Exam Questions

CHAPTER 11: SALIVARY GLAND PATHOLOGY

1. Which of the following is the most common intrabony salivary gland tumor?
   A. Adenoid cystic carcinoma
   B. Malignant pleomorphic adenoma
   C. Mucoepidermoid carcinoma
   D. Oncocytoma
   E. Papillary cystadenoma lymphomatosum

   ANS: C

2. Which one of the following locations is the LEAST common site for mucoceles?
   A. Buccal mucosa
   B. Floor of mouth
   C. Lower lip
   D. Upper lip
   E. Ventral tongue

   ANS: D

3. Patients with Sjögren syndrome have a higher risk of developing which tumor?
   A. Acinic cell adenocarcinoma
   B. Hepatocellular carcinoma
   C. Kaposi's sarcoma
   D. Lymphoma
   E. Melanoma

   ANS: D

4. Which one of the following tumors is the most common malignancy arising in minor salivary glands?
   A. Acinic cell adenocarcinoma
   B. Adenoid cystic carcinoma
   C. Mucoepidermoid carcinoma
   D. Polymorphous low-grade adenocarcinoma
   E. Warthin tumor

   ANS: C

5. The most common site for necrotizing sialometaplasia is:
   A. anterior tongue.
   B. lower lip.
   C. posterior hard palate.
   D. posterior lateral tongue
   E. upper lip.

   ANS: C

6. Which one of the following features would NOT be associated with Sjögren syndrome?
   A. Benign lymphoepithelial lesion
   B. Elevated antinuclear antibodies
   C. Female predominance
   D. Keratoconjunctivitis sicca
   E. Sialorrhea

   ANS: E

7. Sialadenosis is often associated with:
   A. bulimia.
   B. chewing cinnamon-flavored gum.
   C. history of recent tooth extraction.
   D. postsurgical mumps.
   E. none of the above.

   ANS: A

8. The most common salivary gland tumor is:
   A. adenoid cystic carcinoma.
   B. basal cell adenoma.
   C. canalicular adenoma.
   D. mucoepidermoid carcinoma.
   E. pleomorphic adenoma.

   ANS: E

9. Perineural invasion is most likely to occur in which tumor?
   A. Acinic cell adenocarcinoma
   B. Adenoid cystic carcinoma
   C. Mucoepidermoid carcinoma
   D. Pleomorphic adenoma
   E. Warthin tumor

   ANS: B

10. In which one of the following locations is a salivary gland tumor most likely to be malignant?
    A. Hard palate
    B. Lower lip
    C. Parotid gland
    D. Submandibular gland
    E. Upper lip

    ANS: B

dentlearn.ir

11. The salivary gland neoplasm most closely correlated with cigarette smoking is:
    A. adenoid cystic carcinoma.
    B. mucoepidermoid carcinoma.
    C. pleomorphic adenoma.
    D. polymorphous low-grade adenocarcinoma.
    E. Warthin tumor.

    ANS: E

12. The canalicular adenoma most commonly occurs in which location?
    A. Lower labial mucosa
    B. Palate
    C. Parotid gland
    D. Submandibular gland
    E. Upper labial mucosa

    ANS: E

13. Minor salivary gland tumors are most common in which location?
    A. Buccal mucosa
    B. Floor of mouth
    C. Lower lip
    D. Posterior lateral hard palate
    E. Upper lip

    ANS: D

14. The best treatment for mucoceles is:
    A. aspiration of spilled mucin with a small gauge needle.
    B. incision and drainage.
    C. injection with a sclerosing agent.
    D. surgical excision along with the "feeder" gland.
    E. no treatment is needed because it is a benign condition.

    ANS: D

15. Which of the following lesions typically has the worst prognosis?
    A. Adenoid cystic carcinoma
    B. Canalicular adenoma
    C. Necrotizing sialometaplasia
    D. Pleomorphic adenoma
    E. Polymorphous low-grade adenocarcinoma

    ANS: A

16. Which of the following is NOT commonly a cause of xerostomia?
    A. Adenomatoid hyperplasia
    B. Dehydration
    C. Medications
    D. Radiation therapy to the head and neck
    E. Sjögren syndrome

    ANS: A

17. The most common site for the Warthin tumor is:
    A. lower lip.
    B. palate.
    C. parotid gland.
    D. submandibular gland.
    E. tongue.

    ANS: C

18. Another name for the pleomorphic adenoma is:
    A. benign lymphoepithelial lesion.
    B. benign mixed tumor.
    C. Donath-Seifert tumor.
    D. monomorphic adenoma.
    E. Warthin tumor.

    ANS: B

19. Sialoliths occur most frequently in the:
    A. minor salivary gland ducts.
    B. nasopalatine duct.
    C. parotid duct.
    D. submandibular duct.
    E. Donald duct.

    ANS: D

20. Which one of the following salivary gland tumors has the best prognosis?
    A. acinic cell adenocarcinoma
    B. adenoid cystic carcinoma
    C. mucoepidermoid carcinoma
    D. pleomorphic adenoma
    E. polymorphous adenocarcinoma

    ANS: D

dentlearn.ir

Sample Exam Questions

CHAPTER 12: SOFT TISSUE TUMORS

1. The microscopic appearance of the congenital epulis most closely resembles:
   A. congenital melanocytic nevus.
   B. epulis fissuratum.
   C. granular cell tumor.
   D. peripheral giant cell granuloma.
   E. pyogenic granuloma.

   ANS: C

2. The cystic hygroma is a type of:
   A. leiomyoma.
   B. leukoplakia.
   C. lymphangioma.
   D. lymphoepithelial cyst.
   E. lymphoma.

   ANS: C

3. Medullary thyroid carcinoma is a common feature of which condition?
   A. Graves' disease
   B. Multiple endocrine neoplasia type 2B
   C. Neurofibromatosis type I
   D. Nevoid basal cell carcinoma syndrome
   E. PHACES syndrome

   ANS: B

4. Epilepsy is frequently a feature associated with:
   A. bisphosphonate-related osteonecrosis of the jaws.
   B. multiple endocrine neoplasia type 2B.
   C. primary herpetic gingivostomatitis.
   D. primary syphilis.
   E. Sturge-Weber syndrome.

   ANS: E

5. Lisch nodules are associated with:
   A. embryonal rhabdomyosarcoma.
   B. granular cell tumor.
   C. Kaposi sarcoma.
   D. Neurofibromatosis type I.
   E. Sturge-Weber syndrome.

   ANS: D

6. The oral cavity is the most common location in the body for which one of the following tumors?
   A. Granular cell tumor
   B. Kaposi sarcoma
   C. Leiomyoma
   D. Lipoma
   E. Schwannoma

   ANS: A

7. Which one of the following is one of the diagnostic criteria for neurofibromatosis type I?
   A. Axillary freckling
   B. Complex seizure disorder
   C. Mental retardation
   D. Merrick sign
   E. Schwannoma

   ANS: A

8. Which one of the following is the most common site for the granular cell tumor?
   A. Buccal mucosa
   B. Gingiva
   C. Hard palate
   D. Lower lip
   E. Tongue

   ANS: E

9. A peripheral giant cell granuloma is most likely to mimic what other lesion clinically?
   A. Epulis fissuratum
   B. Inflammatory papillary hyperplasia
   C. Lymphangioma
   D. Pyogenic granuloma
   E. Schwannoma

   ANS: D

10. Which one of the following lesions is often associated with pregnancy?
    A. Non-Hodgkin lymphoma
    B. Oral papillomas
    C. Peripheral giant cell granuloma
    D. Proliferative verrucous leukoplakia
    E. Pyogenic granuloma

    ANS: E

dentlearn.ir

11. The most common site for metastatic tumors to the oral cavity is:
    A. buccal mucosa.
    B. gingiva.
    C. hard palate.
    D. lower lip.
    E. upper lip.

    ANS: B

12. Which one of the following tumors is often painful?
    A. Irritation fibroma
    B. Neurofibroma
    C. Pleomorphic adenoma
    D. Pyogenic granuloma
    E. Traumatic neuroma

    ANS: E

13. Which one of the following tumors has the most striking predilection for males?
    A. Congenital epulis
    B. Kaposi sarcoma
    C. Nasopharyngeal angiofibroma
    D. Peripheral ossifying fibroma
    E. Pyogenic granuloma

    ANS: C

14. Which one of the following malignancies would most likely develop secondary to immunosuppressive therapy used to prevent rejection of an organ transplant?
    A. Carcinoma ex pleomorphic adenoma
    B. Embryonal rhabdomyosarcoma
    C. Kaposi sarcoma
    D. Lentigo maligna melanoma
    E. Malignant peripheral nerve sheath tumor

    ANS: C

15. What is the inheritance pattern for neurofibromatosis type I?
    A. Autosomal dominant
    B. Autosomal recessive
    C. Multifactorial
    D. X-linked dominant
    E. X-linked recessive

    ANS: A

16. The port wine nevus is:
    A. a capillary vascular malformation.
    B. a congenital malformation of melanocytes limited to the left side of the body.
    C. a congenital melanocytic nevus that occurs in a patient with partial albinism.
    D. a form of congenital melanocytic nevus with a high malignant transformation rate.
    E. a rare, congenital form of blue nevus.

    ANS: A

17. Which tumor is characterized by Antoni A tissue with Verocay bodies?
    A. Blue nevus
    B. Congenital epulis
    C. Fibrous histiocytoma
    D. Peripheral giant cell granuloma
    E. Schwannoma

    ANS: E

18. What is the inheritance pattern for multiple endocrine neoplasia type 2B?
    A. Autosomal dominant
    B. Autosomal recessive
    C. Multifactorial
    D. X-linked dominant
    E. X-linked recessive

    ANS: A

19. In classic Kaposi sarcoma, the lesions usually begin to develop in which location?
    A. Chest wall
    B. Inguinal region
    C. Lower extremities
    D. Neck
    E. Scalp

    ANS: C

20. Which of the following conditions is often associated with intellectual disability?
    A. Dermatosis papulosa nigra
    B. Multiple endocrine neoplasia type 2B
    C. Sialadenosis
    D. Sturge-Weber syndrome
    E. All of the above

    ANS: D

21. By definition, an epulis refers to a tumor or growth that:
    A. develops on the gingiva or along the alveolar ridge.
    B. has a rough, pebbly surface.
    C. is associated with an ill-fitting denture.
    D. is composed of epithelium.
    E. is related to an underlying infection.

    ANS: A

22. Which one of the following tumors shows a striking predilection for females?
    A. Congenital epulis
    B. Granular cell tumor
    C. Inverted papilloma
    D. Lymphangioma
    E. Schwannoma

    ANS: A

dentlearn.ir

23. Kaposi sarcoma is believed to be caused by which of the following?
    A. Arthropod bites
    B. Chronic ultraviolet light exposure
    C. Epstein-Barr virus
    D. Hepatitis C virus
    E. Human herpes virus, type 8

    ANS: E

24. The most common site for angiosarcoma is:
    A. scalp.
    B. upper lip.
    C. lower lip.
    D. neck.
    E. back.

    ANS: A

dentlearn.ir

Sample Exam Questions

CHAPTER 13: HEMATOLOGIC DISORDERS

1. Which one of the following would be a common feature in a patient with leukemia?
   A. Elevated hematocrit
   B. Elevated hemoglobin
   C. Polycythemia
   D. Thrombocytopenia
   E. All of the above

   ANS: D

2. Which one of the following malignancies is derived from T-lymphocytes?
   A. Acute myeloid leukemia
   B. Burkitt lymphoma
   C. Hodgkin lymphoma
   D. Multiple myeloma
   E. Mycosis fungoides

   ANS: E

3. Which one of the following is the most common site for oral lymphomas?
   A. Buccal mucosa
   B. Floor of mouth
   C. Lower lip
   D. Palate
   E. Upper lip

   ANS: D

4. All of the following are true concerning multiple myeloma EXCEPT:
   A. the disease has a relatively good prognosis using local radiation therapy.
   B. it is a neoplasm of plasma cells.
   C. it occurs most commonly in middle-aged and older patients.
   D. it may be associated with amyloidosis.
   E. tumors characteristically occur in bones.

   ANS: A

5. The most common leukemia of childhood is:
   A. acute lymphoblastic leukemia.
   B. acute myeloid leukemia.
   C. chronic lymphocytic leukemia.
   D. chronic myeloid leukemia.
   E. hairy cell leukemia.

   ANS: A

6. The most common leukemia of older adults is:
   A. acute lymphoblastic leukemia.
   B. acute myeloid leukemia.
   C. chronic lymphocytic leukemia.
   D. chronic myeloid leukemia.
   E. hairy cell leukemia.

   ANS: C

7. Which one of the following conditions should be considered in a child who presents with unexplained severe bone loss around the roots of multiple teeth resembling aggressive periodontitis?
   A. Hand, foot, and mouth disease
   B. Impetigo
   C. Langerhans cell histiocytosis
   D. Myospherulosis
   E. Primary herpetic gingivostomatitis

   ANS: C

8. Which one of the following hematologic conditions is associated with an increased risk of leukemia?
   A. Cyclic neutropenia
   B. Hemophilia B
   C. Idiopathic thrombocytopenic purpura
   D. Polycythemia vera
   E. Sickle cell trait

   ANS: D

9. Birbeck bodies are a characteristic ultrastructural finding of:
   A. eosinophils.
   B. Langerhans cells.
   C. lymphocytes.
   D. plasma cells.
   E. polymorphonuclear leukocytes.

   ANS: B

10. Amyloidosis is a common secondary manifestation of:
    A. acute lymphocytic leukemia.
    B. Burkitt lymphoma.
    C. multiple myeloma.
    D. mycosis fungoides.
    E. polycythemia vera.

    ANS: C

dentlearn.ir

11. An elevated hematocrit would be observed in patients with:
    A. chronic lymphocytic leukemia.
    B. cyclic neutropenia.
    C. myelogenous leukemia.
    D. pernicious anemia.
    E. polycythemia vera.

    ANS: E

12. Bisphosphonate medications are often used in the clinical management of:
    A. acute myeloid leukemia.
    B. Burkitt lymphoma.
    C. chronic lymphocytic leukemia.
    D. Hodgkin lymphoma.
    E. multiple myeloma.

    ANS: E

13. The neoplastic cell of the so-called eosinophilic granuloma of bone is:
    A. eosinophil.
    B. Langerhans cell.
    C. natural killer cell.
    D. T4 lymphocyte.
    E. T8 lymphocyte.

    ANS: B

14. Endemic Burkitt lymphoma has been pathogenetically related to:
    A. advancing age.
    B. chemical exposure.
    C. Epstein-Barr virus.
    D. human papillomaviruses types 16 and 18.
    E. PUVA therapy.

    ANS: C

15. Which one of the following conditions may result in jaw enlargement with a "chipmunk" facies?
    A. Cyclic neutropenia
    B. Hemophilia A
    C. Hemophilia B
    D. Polycythemia vera
    E. Thalassemia major

    ANS: E

dentlearn.ir

Sample Exam Questions

CHAPTER 14: BONE PATHOLOGY

1. Which one of the following is not a true cyst because it is not lined by epithelium?
   A. Epidermoid cyst
   B. Nasopalatine duct cyst
   C. Oral lymphoepithelial cyst
   D. Periapical cyst
   E. Simple (traumatic) bone cyst

   ANS: E

2. Failure of eruption of the permanent teeth is a clinical feature of:
   A. cleidocranial dysplasia.
   B. Gardner syndrome.
   C. hemifacial hyperplasia.
   D. multiple endocrine neoplasia type 2B.
   E. thalassemia.

   ANS: A

3. A patient with a jaw tumor diagnosed as a central giant cell granuloma should be evaluated to rule out the possibility of:
   A. hyperparathyroidism.
   B. multiple sclerosis.
   C. stomach cancer.
   D. systemic lupus erythematosus.
   E. ulcerative colitis.

   ANS: A

4. What is the inheritance pattern of cherubism?
   A. Autosomal dominant
   B. Autosomal recessive
   C. X-linked dominant
   D. X-linked recessive
   E. It is not hereditary

   ANS: A

5. Which of the following types of fibro-osseous lesions of the jaws is most often encountered by dental practitioners?
   A. Cemento-osseous dysplasia
   B. Familial gigantiform cementoma
   C. Fibrous dysplasia
   D. Juvenile active ossifying fibroma
   E. Ossifying fibroma

   ANS: A

6. *Café au lait* pigmentation may be associated with which one of the following conditions?
   A. Cherubism
   B. Hypohidrotic ectodermal dysplasia
   C. Polyostotic fibrous dysplasia
   D. Secondary hyperparathyroidism
   E. Sickle cell trait

   ANS: C

7. Which one of the following is NOT associated with Paget's disease of bone?
   A. Autosomal dominant or X-linked recessive inheritance pattern
   B. Bone pain
   C. Bony enlargement
   D. "Cotton-wool" radiographic pattern
   E. Increased risk of osteosarcoma

   ANS: A

8. Precocious puberty may be a feature of:
   A. cleidocranial dysplasia.
   B. florid cemento-osseous dysplasia.
   C. Gardner syndrome.
   D. McCune-Albright syndrome.
   E. osteopetrosis.

   ANS: D

9. Which one of the following conditions occurs most frequently in black women?
   A. Chronic myelogenous leukemia
   B. Paget's disease
   C. Periapical cemento-osseous dysplasia
   D. Polycythemia vera
   E. Polyostotic fibrous dysplasia

   ANS: C

10. Which one of the following lesions is characteristically attached to the roots of a tooth?
    A. Cementoblastoma
    B. Central ossifying fibroma
    C. Complex odontoma
    D. Fibrous dysplasia
    E. Juvenile ossifying fibroma

    ANS: A

dentlearn.ir

11. What is typically the most appropriate management for a simple bone cyst of the jaws?
    A. Curettage followed by peripheral ostectomy
    B. Interferon alfa-2a, alone or in combination with surgical enucleation
    C. Intralesional steroid injection
    D. Segmental resection
    E. Surgical exploration to establish the diagnosis followed by periodic radiographic examination to monitor for resolution

    ANS: E

12. The most likely complication of florid cemento-osseous dysplasia is:
    A. fracture of the mandible.
    B. secondary hyperparathyroidism.
    C. secondary hypocalcemia.
    D. secondary infection.
    E. transformation into osteosarcoma.

    ANS: D

13. Which one of the following radiographic patterns may be an early sign of osteosarcoma?
    A. Cotton-wool opacity
    B. Dome-shaped radiopacity in the maxillary sinus
    C. Ground-glass opacity
    D. Radiolucency with scalloped borders
    E. Widening of the periodontal ligament space

    ANS: E

14. Which one of the following is the most significant feature of Gardner syndrome?
    A. Development of colon cancer
    B. Development of insulin-resistant diabetes
    C. Development of melanoma
    D. Disorderly eruption of the teeth
    E. Hypercalcemia leading to kidney stones

    ANS: A

15. What is the treatment of choice for periapical cemento-osseous dysplasia?
    A. Apicoectomy and periapical curettage
    B. Broad-spectrum antibiotics
    C. Extraction of the involved teeth
    D. Root canal therapy
    E. No treatment is indicated

    ANS: E

16. Microscopically, the bony lesions of cherubism most closely resemble:
    A. central giant cell granuloma.
    B. simple bone cyst.
    C. odontogenic keratocyst.
    D. cemento-osseous dysplasia.
    E. Paget disease.

    ANS: A

dentlearn.ir

Sample Exam Questions

CHAPTER 15: ODONTOGENIC CYSTS AND TUMORS

1. Which one of the following odontogenic lesions is more common in the maxilla than the mandible?
   A. Adenomatoid odontogenic tumor
   B. Ameloblastic fibroma
   C. Calcifying epithelial odontogenic tumor
   D. Lateral periodontal cyst
   E. Odontogenic keratocyst

   ANS: A

2. Which one of the following is the most common presenting sign/symptom of the compound odontoma?
   A. Bluish swelling of the gingiva
   B. Failure of eruption of a permanent tooth
   C. Pain upon mastication
   D. Spontaneous abscess formation
   E. Spontaneous crevicular bleeding

   ANS: B

3. What is the inheritance pattern of the nevoid basal cell carcinoma syndrome?
   A. Autosomal dominant
   B. Autosomal recessive
   C. Multifactorial
   D. X-linked dominant
   E. X-linked recessive

   ANS: A

4. Which one of the following odontogenic tumors is most common?
   A. Adenomatoid odontogenic tumor
   B. Ameloblastoma
   C. Odontogenic fibroma
   D. Odontogenic myxoma
   E. Squamous odontogenic tumor

   ANS: B

5. The nevoid basal cell carcinoma syndrome is caused by a mutation of which gene?
   A. Enamelin gene
   B. Keratin 6a or keratin 6b
   C. Patched (PTCH) gene
   D. Ras
   E. RET proto-oncogene

   ANS: C

6. The most common location for the lateral periodontal cyst is:
   A. mandibular bicuspid area.
   B. mandibular molar area.
   C. maxillary bicuspid area.
   D. maxillary incisor area.
   E. maxillary molar area.

   ANS: A

7. By definition, a dentigerous cyst must occur:
   A. after the age of 25 when all odontogenic activity should have ceased.
   B. in a periapical location.
   C. in association with the crown of an unerupted tooth.
   D. in the place of a tooth that failed to develop.
   E. in the third molar area.

   ANS: C

8. The lateral periodontal cyst is most closely related to what other odontogenic cyst?
   A. Buccal bifurcation cyst
   B. Dentigerous cyst
   C. Gingival cyst of the adult
   D. Odontogenic keratocyst
   E. Paradental cyst

   ANS: C

9. The most so-called primordial cysts are microscopically diagnosed as:
   A. dentigerous cysts.
   B. glandular odontogenic cysts.
   C. odontogenic keratocysts.
   D. paradental cysts.
   E. unicystic ameloblastomas.

   ANS: C

10. The botryoid variant of the lateral periodontal cyst got its name because:
    A. it grossly resembles a cluster of grapes.
    B. it has a high recurrence rate.
    C. it was first described by Thomas Botry.
    D. the epithelial lining is ulcerated.
    E. the original description of the cystic fluid compared it to the slimy trail left by a snail.

    ANS: A

dentlearn.ir

11. The most common site for the glandular odontogenic cyst is:
    A. anterior mandible.
    B. anterior maxilla.
    C. parotid gland.
    D. posterior mandible.
    E. posterior maxilla.

    ANS: A

12. Approximately what percentage of ameloblastomas occur in the mandible?
    A. 33%
    B. 55%
    C. 67%
    D. 85%
    E. 98%

    ANS: D

13. Which microscopic variant of ameloblastoma often presents radiographically as a mixed radiolucent and radiopaque lesion?
    A. Desmoplastic ameloblastoma
    B. Follicular ameloblastoma
    C. Granular cell ameloblastoma
    D. Plexiform ameloblastoma
    E. Unicystic ameloblastoma

    ANS: A

14. A microscopically typical ameloblastoma that happens to metastasize to regional lymph nodes is known as:
    A. ameloblastic carcinoma.
    B. ameloblastic fibrosarcoma.
    C. clear cell odontogenic carcinoma.
    D. malignant ameloblastoma.
    E. squamous cell carcinoma.

    ANS: D

15. Which one of the following odontogenic cysts has the highest recurrence rate?
    A. Calcifying odontogenic cyst
    B. Dentigerous cyst
    C. Glandular odontogenic cyst
    D. Lateral periodontal cyst
    E. Periapical cyst

    ANS: C

16. The adenomatoid odontogenic tumor is frequently associated with an impacted tooth. Which impacted tooth is most likely to be involved?
    A. Tooth #1
    B. Tooth #6
    C. Tooth #17
    D. Tooth #27
    E. Tooth #30

    ANS: B

17. Which one of the following microscopic variants of ameloblastoma has the lowest recurrence rate?
    A. Acanthomatous
    B. Desmoplastic
    C. Follicular
    D. Plexiform
    E. Unicystic

    ANS: E

18. Which one of the following odontogenic cysts is often associated with an odontoma?
    A. Calcifying odontogenic cyst
    B. Gingival cyst of the adult
    C. Gingival cyst of the newborn
    D. Glandular odontogenic cyst
    E. Orthokeratinizing odontogenic cyst

    ANS: A

19. If left untreated, an ameloblastic fibro-odontoma would most likely evolve into which lesion?
    A. Adenomatoid odontogenic tumor
    B. Ameloblastic carcinoma
    C. Ameloblastoma
    D. Calcifying epithelial odontogenic tumor
    E. Complex odontoma

    ANS: E

20. Which odontogenic cyst may sometimes be associated with the nevoid basal cell carcinoma syndrome?
    A. Glandular odontogenic cyst
    B. Gorlin cyst
    C. Lateral periodontal cyst
    D. Odontogenic keratocyst
    E. Residual cyst

    ANS: D

21. Which one of the following is NOT a feature of the nevoid basal cell carcinoma syndrome?
    A. Bifid ribs
    B. Calcification of the falx cerebri
    C. Diabetes insipidus
    D. Frontal and parietal bossing
    E. Pitting defects on the palms and soles

    ANS: C

22. All of the following statements about ameloblastoma are true EXCEPT:
    A. Ameloblastoma may present as either a unilocular or multilocular radiolucency.
    B. Ameloblastomas are more common in the mandible than the maxilla.
    C. Ameloblastomas are more common in the posterior jaw than the anterior jaw.
    D. Ameloblastomas are most common in young adults.
    E. Ameloblastomas are usually best treated with curettage and have a low recurrence rate.

    ANS: E

dentlearn.ir

23. Which one of the following odontogenic tumors occasionally is associated with a central giant cell granuloma?
    A. Adenomatoid odontogenic tumor
    B. Ameloblastoma
    C. Calcifying epithelial odontogenic tumor
    D. Central odontogenic fibroma
    E. Squamous odontogenic tumor

    ANS: D

24. Which one of the following odontogenic lesions has the highest recurrence rate?
    A. Adenomatoid odontogenic tumor
    B. Ameloblastic fibro-odontoma
    C. Complex odontoma
    D. Dentigerous cyst
    E. Odontogenic myxoma

    ANS: E

25. Which one of the following lesions is also known as a Pindborg tumor?
    A. Adenomatoid odontogenic tumor
    B. Ameloblastic fibro-odontoma
    C. Calcifying odontogenic cyst
    D. Odontogenic keratocyst
    E. None of the above

    ANS: E

26. The eruption cyst is really a variant of the:
    A. dentigerous cyst.
    B. lateral periodontal cyst.
    C. odontogenic keratocyst.
    D. periapical cyst.
    E. none of the above.

    ANS: A

27. In addition to amyloid that is deposited in various body tissues in systemic amyloidosis, amyloid-like proteins sometimes are discovered within certain tumors. Which one of the following odontogenic tumors often contains amyloid?
    A. Ameloblastic fibroma
    B. Ameloblastoma
    C. Calcifying epithelial odontogenic tumor
    D. Complex odontoma
    E. Odontogenic myxoma

    ANS: C

28. Recurrence after surgery is LEAST likely with which one of the following lesions?
    A. Ameloblastic fibro-odontoma
    B. Ameloblastoma
    C. Odontogenic keratocyst
    D. Odontogenic myxoma
    E. Pindborg tumor

    ANS: A

29. The microscopic hallmark of the calcifying odontogenic cyst is:
    A. amyloid production.
    B. ghost cell keratinization.
    C. orthokeratin production.
    D. plexiform epithelium.
    E. reverse polarization.

    ANS: B

30. The radiographic appearance of the odontogenic myxoma is most likely to mimic:
    A. ameloblastoma.
    B. complex odontoma.
    C. fibrous dysplasia.
    D. osteosarcoma.
    E. periapical cemental dysplasia.

    ANS: A

dentlearn.ir

Sample Exam Questions

CHAPTER 16: DERMATOLOGIC DISEASES

1. Which one of the following is not a feature of CREST syndrome?
   A. Calcinosis cutis
   B. Raynaud phenomenon
   C. Esophageal motility problems
   D. Splenomegaly
   E. Telangiectasias

   ANS: D

2. Widening of the periodontal ligament spaces may be associated with:
   A. discoid lupus erythematosus.
   B. hereditary hypohidrotic ectodermal dysplasia.
   C. psoriasis.
   D. systemic lupus erythematosus.
   E. systemic sclerosis.

   ANS: E

3. Xerostomia is a common finding in patients with:
   A. Ascher syndrome.
   B. cleidocranial dysplasia.
   C. dentin dysplasia type II.
   D. Gardner syndrome.
   E. hypohidrotic ectodermal dysplasia.

   ANS: E

4. Which one of the following vesiculobullous diseases is the most serious and will usually be fatal if left untreated?
   A. Bullous lichen planus
   B. Erosive lichen planus
   C. Mucous membrane pemphigoid
   D. Pemphigus vulgaris
   E. Primary herpetic gingivostomatitis

   ANS: D

5. The recommended mode of therapy for most patients with benign migratory glossitis (erythema migrans) is:
   A. multivitamin therapy.
   B. low-dose systemic corticosteroid therapy.
   C. surgical removal of lesions as they occur.
   D. topical corticosteroid therapy.
   E. no treatment is indicated.

   ANS: E

6. The most common site for oral lichen planus is:
   A. dorsum of tongue.
   B. gingiva.
   C. hard and soft palate.
   D. lower lip vermilion.
   E. posterior buccal mucosa.

   ANS: E

7. Which one of the following vesiculobullous disorders is characterized by the so-called target lesions on the skin?
   A. Bullous pemphigoid
   B. Cicatricial pemphigoid
   C. Erosive lichen planus
   D. Erythema multiforme
   E. Pemphigus vulgaris

   ANS: D

8. Which of the following conditions may be associated with a positive Nikolsky sign?
   A. Candidiasis
   B. Erythema migrans
   C. Major aphthous stomatitis
   D. Pemphigus vulgaris
   E. Traumatic granuloma

   ANS: D

9. Which of the following conditions is associated with the development of oral premalignant lesions?
   A. Dyskeratosis congenita
   B. Ectodermal dysplasia
   C. Erythema multiforme
   D. Pachyonychia congenita
   E. White sponge nevus

   ANS: A

10. Hemorrhagic, crusting lip lesions are most characteristic of:
    A. dyskeratosis congenita.
    B. erosive lichen planus.
    C. erythema multiforme.
    D. hereditary benign intraepithelial dyskeratosis.
    E. pemphigus.

    ANS: C

dentlearn.ir

11. Which one of the following diseases typically has an acute, explosive onset?
    A. Erosive lichen planus
    B. Erythema multiforme
    C. Mucous membrane pemphigoid
    D. Pemphigus vulgaris
    E. Psoriasis

    ANS: B

12. Which one of the following conditions is least likely to show oral involvement?
    A. Erythema multiforme
    B. Lichen planus
    C. Mucous membrane pemphigoid
    D. Pemphigus
    E. Psoriasis

    ANS: E

13. All of the following are typical features of systemic lupus erythematosus EXCEPT:
    A. elevated antinuclear antibodies.
    B. skin rash.
    C. more common in males.
    D. joint pain.
    E. glomerular damage.

    ANS: C

14. The most common site for skin lesions of lichen planus is:
    A. chest.
    B. flexor surface of the forearms.
    C. malar eminence.
    D. scalp.
    E. soles of the feet.

    ANS: B

15. Which one of the following vesiculobullous disorders is characterized by suprabasilar epithelial separation with acantholysis?
    A. Epidermolysis bullosa
    B. Erythema multiforme
    C. Mucous membrane pemphigoid
    D. Pemphigus vulgaris
    E. Recurrent aphthous stomatitis

    ANS: D

16. Indirect immunofluorescence is performed using the patient's:
    A. biopsy tissue.
    B. blood.
    C. saliva.
    D. sputum.
    E. urine.

    ANS: B

17. Oral lesions of lupus erythematosus are most likely to mimic what other condition?
    A. Erythema migrans
    B. Leukoedema
    C. Lichen planus
    D. Median rhomboid glossitis
    E. Traumatic granuloma

    ANS: C

18. Pruritis is a common feature of the skin lesions of lichen planus. This feature refers to:
    A. bilateral distribution.
    B. color of the lesions.
    C. itching of the lesions.
    D. location on extensor surfaces.
    E. positive Koebner phenomenon.

    ANS: C

19. The most typical oral feature of Darier disease is:
    A. diffuse white lesions that partially rub off.
    B. interlacing white striae.
    C. rough, pebbly hard palate.
    D. salmon-colored macules.
    E. wart-like keratotic lesions throughout the mouth.

    ANS: C

20. Which one of the following conditions is associated with development of intestinal polyps and an increased risk for gastrointestinal adenocarcinoma?
    A. Addison disease
    B. Darier disease
    C. Hereditary mucoepithelial dysplasia
    D. Peutz-Jeghers syndrome
    E. White sponge nevus

    ANS: D

21. The microscopic appearance of erythema migrans (geographic tongue) most closely resembles:
    A. lichen planus.
    B. psoriasis.
    C. lupus erythematosus.
    D. white sponge nevus.
    E. pemphigus vulgaris.

    ANS: B

dentlearn.ir

Sample Exam Questions

CHAPTER 17: ORAL MANIFESTATIONS OF SYSTEMIC DISEASES

1. In primary hyperparathyroidism, what abnormal laboratory value would be expected?
   A. Decreased adrenocorticotropic hormone levels
   B. Increased angiotensin-converting enzyme
   C. Increased levels of thyroid stimulating hormone
   D. Increased serum calcium levels
   E. Increased serum phosphate levels

   ANS: D

2. Addison disease is characterized by:
   A. excess insulin production.
   B. insufficient production of adrenal corticosteroids.
   C. ulcerating oral nodules.
   D. uncontrollable ("malignant") hypertension.
   E. none of the above.

   ANS: B

3. Pernicious anemia is caused by defective absorption of:
   A. iron.
   B. niacin.
   C. riboflavin.
   D. vitamin C.
   E. none of the above.

   ANS: E

4. Amyloidosis is most likely to present intraorally as:
   A. hairy tongue.
   B. macroglossia.
   C. palatal ulceration with an associated nasal fistula.
   D. rapidly progressive periodontitis.
   E. recurrent aphthous ulcers.

   ANS: B

5. Pyostomatitis vegetans is most often associated with:
   A. deep fungal infections such as blastomycosis.
   B. diabetes mellitus.
   C. positive Koebner phenomenon.
   D. superior vena cava syndrome.
   E. ulcerative colitis.

   ANS: E

6. Kidney stones are a common feature of:
   A. diabetes mellitus.
   B. Frey's syndrome.
   C. hyperparathyroidism.
   D. hyperthyroidism.
   E. hypothyroidism.

   ANS: C

7. Which one of the following special stains is used in the diagnosis of amyloidosis?
   A. Congo red
   B. GMS
   C. PAS
   D. PTAH
   E. Steiner

   ANS: A

8. Which one of the following conditions has been associated with an increased risk for oral squamous cell carcinoma?
   A. Addison disease
   B. Amyloidosis
   C. Pernicious anemia
   D. Plummer-Vinson syndrome
   E. Pyostomatitis vegetans

   ANS: D

9. A 45-year-old white female presents with a $2 \times 2\ cm^2$ radiolucent lesion of the mandible, which is diagnosed as a central giant cell granuloma. Which one of the following conditions should be ruled out?
   A. Addison disease
   B. Crohn's disease
   C. Gigantism
   D. Hyperparathyroidism
   E. Multiple sclerosis

   ANS: D

10. Mandibular prognathism is a clinical feature of:
    A. acromegaly.
    B. beriberi.
    C. Cushing syndrome.
    D. scurvy.
    E. vitamin-D-resistant rickets.

    ANS: A

dentlearn.ir

11. Which one of these conditions may be associated with delayed tooth eruption?
    A. Diabetes mellitus
    B. Gigantism
    C. Hemifacial hyperplasia
    D. Hyperthyroidism
    E. Hypothyroidism

    ANS: E

12. Pernicious anemia is caused by:
    A. autoimmune destruction of the parietal cells in the stomach lining.
    B. chronic blood loss from the gastrointestinal tract.
    C. diets that are low in B vitamins.
    D. gluten sensitivity leading to malabsorption.
    E. hereditary lack of ferritin production.

    ANS: A

13. "Secondary" hyperparathyroidism is usually secondary to:
    A. chronic renal failure.
    B. hyperthyroidism.
    C. pituitary adenocarcinoma.
    D. primary hyperparathyroidism.
    E. use of calcium-channel blockers.

    ANS: A

14. Which one of the following conditions is most likely to be associated with macroglossia?
    A. Diabetes mellitus
    B. Hyperparathyroidism
    C. Hyperthyroidism
    D. Hypoparathyroidism
    E. Hypothyroidism

    ANS: E

15. Exophthalmos is frequently observed in patients with:
    A. cretinism.
    B. Graves' disease.
    C. pellagra.
    D. scurvy.
    E. all of the above.

    ANS: B

16. Which one of the following conditions is most strongly associated with an increased risk for systemic amyloidosis?
    A. Acromegaly
    B. Diabetes mellitus
    C. Hunter syndrome
    D. Hurler syndrome
    E. Multiple myeloma

    ANS: E

17. Which one of the following vitamin deficiencies is associated with roughness of sun-exposed areas of the skin?
    A. Niacin
    B. Riboflavin
    C. Thiamin
    D. Vitamin A
    E. Vitamin C

    ANS: A

18. Which one of the following conditions is characterized by granulomatous inflammation?
    A. Crohn's disease
    B. Lipoid proteinosis
    C. Rheumatoid arthritis
    D. Trigeminal neuralgia
    E. Uremic stomatitis

    ANS: A

19. Premature loss of the deciduous teeth is a characteristic dental finding in patients with:
    A. celiac sprue.
    B. hyperthyroidism.
    C. hypophosphatasia.
    D. pellagra.
    E. uremic stomatitis.

Sample Exam Questions

CHAPTER 18: FACIAL PAIN AND NEUROMUSCULAR DISEASES

1. An increased prevalence of trigeminal neuralgia is seen in patients with:
   A. Bell palsy.
   B. congenitally missing teeth.
   C. diabetes mellitus.
   D. multiple sclerosis.
   E. Sturge-Weber syndrome.

   ANS: D

2. Burning mouth syndrome would be most likely to occur in which patient?
   A. 15-year-old female
   B. 25-year-old male
   C. 35-year-old female
   D. 45-year-old male
   E. 55-year-old female

   ANS: E

3. Which nerve is affected by Bell palsy?
   A. Auriculotemporal
   B. Vidian
   C. V
   D. VII
   E. VIII

   ANS: D

4. The most common cause of Frey syndrome is:
   A. eating overly spicy foods.
   B. exposure to cold weather.
   C. exposure to hot weather.
   D. sarcoidosis.
   E. surgery of the parotid gland.

   ANS: E

5. Nerve paralysis similar to Bell palsy may be seen in patients with:
   A. migraine.
   B. multiple endocrine neoplasia type 2B.
   C. Ramsay Hunt syndrome.
   D. rheumatoid arthritis.
   E. systemic lupus erythematosus.

   ANS: C

6. The most significant complication associated with temporal arteritis is:
   A. Bell palsy.
   B. encephalitis.
   C. loss of hearing.
   D. loss of taste.
   E. permanent loss of vision.

   ANS: E

7. The starch-iodine test can be used in the diagnosis of:
   A. diabetes mellitus.
   B. Frey's syndrome.
   C. hyperparathyroidism.
   D. hyperthyroidism.
   E. hypothyroidism.

   ANS: B

8. In Frey syndrome, sweating of the temporal region is stimulated by:
   A. closing the eyes tightly.
   B. eating.
   C. exposure to cold.
   D. sleep apnea.
   E. yawning.

   ANS: B

9. Which one of the following medications can be most beneficial for patients with idiopathic burning mouth syndrome?
   A. Albuterol
   B. Barbiturates
   C. Clonazepam
   D. Diltiazem
   E. Etanercept

   ANS: C

dentlearn.ir

Prescriptions for Oral Diseases

The following represent examples of prescriptions for medications used in treating a variety of common and uncommon oral disorders. As we have emphasized throughout the text, treatment must be based on an accurate diagnosis. If the treatment does not seem to help, then it may be appropriate to reevaluate the accuracy of the diagnosis. Many of the proposed treatments (especially for immune-mediated conditions) represent empirical recommendations or are derived from extrapolation of cutaneous disease treatment trials. Relatively few well-designed, double-blind, placebo-controlled trials can be found in the dental or medical literature with respect to treatment of oral diseases. The authors recognize that medications available in the United States may not be available in all countries, with the converse being true as well. In addition, the trade names of the medications may vary among countries. In some instances, off-label uses for the super-potent topical corticosteroid gel preparations have been described. The authors further recognize that we are not necessarily familiar with every therapy that has been used, and the following suggested regimens represent our own preferences with respect to prescribing medications to treat oral disorders.

HERPES SIMPLEX VIRUS (HSV, HHV-1 AND -2)

Primary

This condition must be recognized during the first 2–3 days of the infection, otherwise the beneficial effect of the antiviral medication will be minimal.

In addition, Popsicles or other cold, icy treats may be helpful for pain management, especially for young patients.

Rx acyclovir (Zovirax) suspension 200 mg/5 mL
Disp: up to 125 mL (5 mg/kg)
Sig: Use 0.25–1 teaspoonful (depending on the patient's weight) as a mouth rinse for 2–5 minutes, then swallow. Repeat five times daily for 5 days.

This regimen is particularly good for small children with primary herpes who might have trouble swallowing a capsule.

Rx valacyclovir (Valtrex) tablets 1 g
Disp: 5
Sig: Take two tablets initially, then two at 12 hours, and one at 24 hours

Rx acyclovir (Zovirax) capsules 800 mg
Disp: 7
Sig: Take four capsules initially, then two at 12 hours and one at 24 hours

Recurrent Herpes Labialis

Treatment must start at the earliest prodromal symptom; once the vesicles appear, antiviral treatment will not be of any benefit. Patient-initiated systemic valacyclovir seems to be the most effective treatment. Topical antiviral therapy may show a *statistically* significant reduction in the duration of lesions, although it could be debated whether the reduction is clinically significant (particularly in view of the expense). It has been suggested that combined use of systemic and topical antiviral medication may be more effective than either agent alone, but controlled studies are needed to support this hypothesis.

Rx valacyclovir (Valtrex) tablets 1 g
Disp: 5
Sig: Take two tablets initially, two at 12 hours, then one at 24 hours

Rx acyclovir (Zovirax) capsules 800 mg
Disp: 7
Sig: Take four initially, then two at 12 hours and one at 24 hours

Rx penciclovir (Denavir) cream 1%
Disp: 1.5 g tube
Sig: Apply a thin film to the lesion every 4 hours while awake, for 2 days

Rx acyclovir (Zovirax) cream 5%
Disp: 2 g tube
Sig: Apply a thin film to the lesion every 4 hours while awake, for 2 days

VARICELLA (VZV, HHV3)

Primary lesions (chickenpox) should be a thing of the past due to the availability of the varicella vaccine, although some parents are resistant to having their children vaccinated. Most children will experience rather mild disease and thus will not necessarily require treatment. Usually treatment of chickenpox is reserved for immunocompromised or those who might be prone to develop more severe disease. This virus is less susceptible to antiviral drugs compared to HSV; consequently the therapeutic dose is four to five times greater.

HERPES ZOSTER (SHINGLES)

Rx valacyclovir (Valtrex) tablets 1 g
Disp: 60
Sig: Take five tablets initially, then five every 12 hours until gone

dentlearn.ir

Note: Most dental practitioners would be more comfortable having the patient's primary care provider or an infectious disease specialist manage herpes zoster. Some practitioners will also prescribe a course of systemic corticosteroids in order to attempt to reduce the possibility of postherpetic neuralgia. Herpes zoster affecting the tip of the nose suggests involvement of the nasociliary nerve, with potential ocular lesions. This is an ophthalmologic emergency and should be managed by an ophthalmologist.

COXSACKIE AND OTHER ENTEROVIRUS INFECTIONS (HERPANGINA; HAND, FOOT AND MOUTH DISEASE; ACUTE LYMPHONODULAR PHARYNGITIS)

Supportive care is generally adequate, including ibuprofen or acetaminophen for pain or fever management.

TOPICAL ANALGESIA

For patients who require acute relief of oral pain due to diffuse distribution of their oral ulcers, several preparations have been recommended. *Please note that these preparations are not appropriate for children or mentally disabled adults who are not able to understand the importance of not swallowing the medication.* Numbness of the oropharyngeal mucosa may increase the likelihood of aspiration of liquids or food, resulting in significant pulmonary complications.

Rx xylocaine (Lidocaine) viscous
Disp: 100 mL
Sig: For solitary ulcers, apply medication to the lesion with a cotton swab, as needed. For diffuse ulcers, rinse and expectorate, as needed. Care must be taken to minimize oropharyngeal contact.

Rx diphenhydramine (Benadryl) and calcium carbonate antacid (e.g., Maalox) suspension
Disp: 100 mL
Sig: Use 5–10 mL as a mouth rinse, then expectorate, as needed. If swallowed, some sedative effect of the diphenhydramine may be gained, perhaps improving sleep patterns.

Mixing equal parts of Benadryl and Maalox can be done by the patient. Having the pharmacist do this will markedly increase the cost of the treatment.

A 50:50 mixture of diphenhydramine and colloidal bismuth subsalicylate (Kaopectate; Pepto-Bismol) has also been recommended for relieving the pain of oral ulcers. Children or teenagers who are recovering from influenza or chickenpox should not be given this suspension due to the association of Reye's syndrome with exposure to salicylates.

"Magic Mouthwash"—Various recipes for this compounded suspension exist, and most include tetracycline syrup, nystatin suspension, a low-potency corticosteroid, and diphenhydramine (Benadryl) or xylocaine. The basic idea is that even if one is unsure of the diagnosis, at least one of these drugs in the formulation might help. Typically minimal benefit is derived, probably because the various components are diluted to the point that their therapeutic effects are decreased. Even if the medication does not improve the patient's oral lesions, the diphenhydramine or xylocaine will provide some brief topical anesthetic relief. The philosophy of the authors is to establish as firm a diagnosis as possible, then treat accordingly. If no improvement is seen in a reasonable period of time (this will depend on the disease that is being treated), then reconsider the differential diagnosis, perhaps with additional testing (e.g., biopsy, cytology, culture).

APHTHOUS ULCERS

Minor or Major Aphthae

Rx augmented betamethasone dipropionate gel 0.05% (previously marketed as Diprolene Gel)
Disp: 15 g
Sig: Apply a thin film to the lesion, four to six times daily, as early in the course of the process as possible

Rx fluocinonide gel 0.05% (previously marketed as Lidex Gel)
Disp: 15 g
Sig: Apply a thin film to the lesion, four to six times daily, as early in the course of the process as possible

Rx clobetasol (Temovate) gel 0.05%
Disp: 15 g
Sig: Apply a thin film to the lesion, four to six times daily, as early in the course of the process as possible

Applying a thin protective film of an over-the-counter mucoadhesive product (such as Zilactin or Orafilm) to the lesion, after placement of the corticosteroid, may provide additional relief.

Note: Although triamcinolone acetonide compounded with carboxymethyl-cellulose paste has been approved by the Food and Drug Administration for oral use, patients often complain of the difficulty they have in applying the medication. The vehicle is thick and grainy, and unless the area to which it is to be applied is dried, the paste will slide around and basically adhere to every other mucosal site except the one that's symptomatic. Furthermore, triamcinolone is only an intermediate-strength corticosteroid, so its impact on many of the immune-mediated oral disorders may be modest.

Additional note: Corticosteroid medications should be used only for immune-mediated conditions. Treating a traumatic (that is, not immune-mediated) ulcer with a corticosteroid may actually prolong the healing process. If a traumatic ulcer heals while being treated with a topical corticosteroid, it does so in spite of the use of the medication, not because of the medication.

dentlearn.ir

Herpetiform Aphthae

Rx dexamethasone solution (0.5 mg/5 mL) (previously marketed as Decadron)
Disp: 240 mL
Sig: use 5 mL as a mouth rinse, then swallow, each morning for 2–4 days

Note: Dexamethasone elixir or syrup may also be used to treat these lesions; however, both of these contain a small amount of alcohol. As a result, patients may complain of a burning, stinging sensation (elixir more than syrup) when these products are used.

Rx prednisolone (Prelone) syrup (15 mg/5 mL)
Disp: 100 mL
Sig: Use 10 mL as a mouthrinse, then swallow, each morning for 2–4 days

Rx betamethasone (Celestone) solution (0.6 mg/5 mL)
Disp: 240 mL
Sig: Use 5 mL as a mouth rinse, then expectorate, three times daily

PEMPHIGUS VULGARIS

This is a systemic disease that should be managed by someone who has experience using systemic immunosuppressive therapy. Although topical medication is often mentioned with respect to treatment of oral lesions, it is likely that any effect is due to absorption of additional corticosteroid, thereby boosting the systemic dosage.

ERYTHEMA MULTIFORME MINOR WITH ORAL INVOLVEMENT

This is often a diagnosis of exclusion that may require biopsy with direct immunofluorescence studies (to rule out disorders such as pemphigus and pemphigoid) if the lesions of erythema multiforme are not classically characteristic from a clinical standpoint. Treatment of this immune-mediated condition is somewhat controversial, but patients seem to respond to systemic corticosteroids, often given as a liquid in order to obtain (theoretically) an additional topical effect.

Rx prednisolone (Prelone) syrup (15 mg/5 mL)
Disp: 100 mL
Sig: Use 10 mL as a mouthrinse, then swallow, each morning for up to 10 days

MUCOUS MEMBRANE (CICATRICIAL) PEMPHIGOID

Tetracycline and Niacinamide Regimen

Rx tetracycline HCl 250 mg (up to 500 mg)
Disp: 120
Sig: Take one tablet three times daily

Rx niacinamide 250 mg (up to750 mg) (available over-the-counter)
Disp: 120
Sig: Take one tablet three times daily

Corticosteroid Preparations

Rx augmented betamethasone dipropionate gel 0.05% (previously marketed as Diprolene Gel)
Disp: 15 g
Sig: Apply a thin film to the lesions, four to six times daily, as early in the course of the process as possible

Rx dexamethasone elixir, syrup or solution (0.5 mg/5 mL) (previously marketed as Decadron)
Disp: 240 mL
Sig: one tsp. as mouth rinse, holding it in the mouth for at least 1–2 minutes, then expectorate, two to four times daily, depending on disease severity

Rx fluocinonide gel 0.05% (previously marketed as Lidex Gel)
Disp: 15 g
Sig: Apply a thin film to the lesions, four to six times daily, as early in the course of the process as possible

Rx clobetasol (Temovate) gel 0.05%
Disp: 30 g
Sig: Apply a thin film to the lesions, four to six times daily, as early in the course of the process as possible

For gingival involvement with mucous membrane pemphigoid or erosive lichen planus, some practitioners have recommended the use of molded plastic trays as a delivery system for topical corticosteroids. While such trays may provide some therapeutic benefit, experience with fluoride trays that are used by xerostomic patients suggests that patient compliance may be a problem.

EROSIVE LICHEN PLANUS

Rx augmented betamethasone dipropionate gel 0.05% (previously marketed as Diprolene Gel)
Disp: 15 g
Sig: Apply a thin film to lesion, four to six times daily, as early in the course of the process as possible

Rx fluocinonide gel 0.05% (previously marketed as Lidex Gel)
Disp: 15 g
Sig: Apply a thin film to lesion, four to six times daily, as early in the course of the process as possible

Rx clobetasol (Temovate) gel 0.05%
Disp: 30 g
Sig: Apply a thin film to lesion, four to six times daily, as early in the course of the process as possible

Note: All of these super-potent topical corticosteroid gel preparations include a package insert that states that this

dentlearn.ir

medication should not be used in the mouth. Several published studies have shown that no significant side effects develop with intermittent use of these compounds. (The most common local oral complication is the development of candidiasis.) Nevertheless, patients should be cautioned that they should not be consuming multiple tubes of this medication weekly. The only instances in which patients have been reported to develop significant systemic problems with these medications were when they ignored the recommended application schedule.

Another treatment note: With respect to corticosteroids, immune-mediated disorders often respond better if they are treated with a high dose initially, and after the problem is under control, the corticosteroid is reduced to a minimal dose that will keep the condition under control.

Additional treatment note: While most cases of the various immune-mediated diseases will respond to one of the regimens listed above, a few patients will have lesions that are more resistant to these treatments (assuming that they are using the medication as directed). A wide range of additional medications has been reported as being helpful in these situations. Most of these drugs have potential drawbacks, such as significant systemic side effects or extremely high cost. Furthermore, most of these agents either do not have a long "track record" or have not been evaluated in double-blind, placebo-controlled trials. A partial list would include cyclosporine, azathioprine, mycophenolate mofetil, cyclophosphamide, rituximab, tacrolimus, and pimecrolimus. For the above-mentioned reasons we have elected not to include them in this discussion. If a clinician feels that a patient might benefit from one of these medications, we would urge the clinician to perform a thorough literature search in order to become as familiar as possible with the drug and be able to reasonably assess whether the risk:benefit ratio is appropriate for that patient.

CANDIDIASIS

As with any infection, the patient should understand that the entire course of medication should be taken in order to reduce the possibility of recurrence or selection of more resistant organisms.

Rx clotrimazole (Mycelex) oral troches 10 mg
Disp: 50
Sig: Dissolve one troche in the mouth five times each day

Note: The drug company recommends a 14-day course of medication, which may be appropriate for an immunocompromised patient. Most patients with oral candidiasis are not immunocompromised, and a 10-day course seems more than adequate. If the patient has burning symptoms caused by candidiasis, dramatic improvement should be noticed within 24–48 hours after starting the medication. If no significant change in symptoms is noticed, then other conditions (e.g., burning mouth syndrome; megaloblastic anemia) should be considered in the differential diagnosis.

Rx fluconazole (Diflucan) tablets 100 mg
Disp: 8
Sig: Take two tablets on Day 1, then one each day until gone

Rx nystatin (Mycostatin) oral suspension 100,000 units/mL
Disp: 240 mL
Sig: Use 10 mL as a mouthrinse, holding it in the mouth for as long as possible, then swallow, five times daily

Note: While nystatin is an excellent antifungal medication, this drug is not absorbed significantly by the gastrointestinal tract. Because the drug is compounded as a liquid in the United States, patients often cannot hold the medication in the mouth long enough for optimal therapeutic effect. Furthermore, some patients may have an inherited ability to taste the nystatin molecule, which to them is very bitter. For this reason, flavoring agents and sugar are added to the suspension. This may not be an ideal combination for patients who have xerostomia and natural dentition.

Angular cheilitis (must exclude or treat concurrent intraoral candidiasis, if present)

Rx iodoquinol and hydrocortisone acetate (Vytone; Alcortin A) cream
Disp: 1 oz. tube
Sig: Apply a thin film to the corners of the mouth, three times daily

Note: Although iodoquinol and hydrocortisone cream have been suggested to be marginally effective for treatment of angular cheilitis, it is not known whether this assessment was based on proper treatment of any concurrent intraoral candidiasis. If dentures are not disinfected or if central papillary atrophy of the tongue is not treated, then the angular cheilitis will return very quickly after treatment.

Rx nystatin and triamcinolone acetonide (Mycolog-II) cream
Disp: 15 g
Sig: Apply a thin film to the corners of the mouth, three times daily

DENTURE DISINFECTION

Patients with dentures (especially maxillary dentures) often will have *Candida albicans* growing in microscopic concavities of the tissue-bearing surface of the denture. While actual infection (that is, candidal hyphae penetrating the keratin layer of the mucosa) is rarely identified histopathologically, the presence of the yeast frequently will elicit a host immune response, resulting in the asymptomatic reddened palatal mucosa that is known as denture stomatitis. Continued contact with the yeast may induce the development of inflammatory papillary hyperplasia (denture papillomatosis). Disinfection of the denture is usually considered appropriate in this situation, as well as for denture-wearing patients who have oral candidiasis at other sites (such as corners of the

dentlearn.ir

mouth or mid-posterior dorsal tongue). It is important to note that treatment of oral candidiasis at these other intraoral sites will fail if sources of candidal colonization (such as dentures) are not disinfected at the same time that the oral mucosa or angle of the mouth is treated.

Acrylic Denture (No Metallic Framework)

Overnight soak in a solution of 10–20 mL of sodium hypochlorite (laundry bleach) in approximately 250 mL (one cup) of water. This is done each night for 7–10 days. Patients should rinse their dentures very well before reinserting them in the mouth. Concurrent treatment of the oral mucosa with one of the antifungal medications may also be necessary.

Removable Partial Denture With Chrome-Cobalt Metallic Framework

Soaking a chrome-cobalt metallic framework in a bleach solution will severely corrode the metal, turning it black and pitting the surface. For that reason, if a partial denture needs to be disinfected, soaking the denture overnight in nystatin suspension for 7–10 days is recommended.

XEROSTOMIA

OTC OralBalance Liquid or Spray (Biotene)
OTC Moi-Stir (Kingswood Laboratories)
OTC Oasis Moisturizing Mouth Spray (GlaxoSmithKline)
OTC MedOral Dry Mouth Spray (MedActive)

Rx pilocarpine HCl (Salagen) tablets 5 mg
Disp: 90 tablets
Sig: Take one tablet three times daily (may be increased to two tablets three times daily, if necessary and side effects are tolerated)

Rx cevimeline HCl (Evoxac) capsules 30 mg
Disp: 90 capsules
Sig: Take one capsule, three times daily

Note: The medications that are prescribed to stimulate salivary flow (pilocarpine and cevimeline) require the presence of intact salivary acini. Patients who have severe Sjogren syndrome or who have had significant radiation therapy to the parotid and submandibular salivary glands may not benefit from this treatment. The principal side effect is excessive sweating, which may cause approximately 20% of patients to discontinue this treatment. Contraindications for prescribing these medications include a history of chronic obstructive pulmonary disease (COPD) or narrow-angle glaucoma.

BURNING MOUTH SYNDROME (BMS)

A wide variety of treatments have been described for the relatively common oral sensory neuropathy known as burning mouth syndrome. Perhaps this is because BMS often has a waxing and waning course, in addition to the fact that a significant number of these patients may experience spontaneous resolution of their symptoms. If a treatment is started at the peak of one of the periods when symptoms are most severe, it may appear that this treatment was beneficial, when in reality, the patient was experiencing an episode of waning that would have occurred even without the treatment. Alternatively, if the patient is given a medication at the time when the BMS was going to resolve spontaneously, it might appear that the treatment was beneficial, when actually the condition was going to get better anyhow. *Just because a doctor does something to a patient and the patient's condition improves does not necessarily mean that what the doctor did was actually beneficial.* Sometimes the improvement is due to placebo effect, and sometimes it is due to the natural course of the disease. For this reason, double-blind, placebo-controlled studies are often necessary in order to confirm the effectiveness of a treatment. Such studies are generally lacking for many of the treatments that are provided in medicine and dentistry. One treatment regimen that has shown some promise in managing patients with BMS is clonazepam.

Rx clonazepam (Klonopin) disintegrating tablets 0.25 mg
Disp: 90
Sig: Dissolve one tablet on the tongue each night before retiring. If no significant improvement is noted after 2 weeks and side effects are minimal, the dose can be increased to two tablets nightly.

Note: Clonazepam is a benzodiazepine, similar to diazepam (Valium), alprazolam (Xanax), and lorazepam (Ativan), among others. It is a controlled substance and requires a DEA number in order to prescribe it. The main side effect is drowsiness, although this is generally not a problem because the medication is given at bedtime. Care should be taken when this medication is given to older individuals, especially if they are taking other psychoactive medications, and combining two different benzodiazepines is typically not a good idea.

dentlearn.ir
