Preface

The first edition of this textbook was published 29 years ago in 1995. At that time, we never could have dreamed that we would still be involved in writing updates of this text nearly three decades later. With this in mind, reaching our fifth edition represents somewhat of a milestone for us, and we are extremely grateful to have the opportunity to continue producing this work.

The basic format of the book remains the same. However, over the years, the content for many topics has changed dramatically due to the incredible explosion of new research and technology. One of the challenges with any new edition is deciding what new information should be included and what other information should be trimmed. This task becomes more difficult when one takes into account the diversity of our intended audience. For example, this new edition includes considerable new information about specific gene mutations and translocations that are associated with various hereditary diseases and neoplasms. Although the details of these specific molecular changes may seem of lesser importance to students taking their first course in oral pathology, they hold more significance for some of our other readers.

In addition to the updated information on existing topics, new entities in this fifth edition include molar root–incisor malformation, foreign body gingivitis, peri-implant diseases, coronavirus disease 2019 (COVID-19), lichenoid and granulomatous stomatitis, ectomesenchymal chondromyxoid tumor, central xanthoma of the jaws, and primordial odontogenic tumor. A total of 152 new images have been added, and we are greatly indebted to our many colleagues who generously shared their excellent clinical photographs and radiographs with us. We have attempted to be as thorough as possible in listing credit for these images. However, if someone's name has been inadvertently omitted, then please accept our apologies.

Our sincere thanks again go to Dr. Edward E. Herschaft, who updated his excellent chapter on forensic dentistry. We also welcome Dr. N. Lyn Wilson Westmark, who revised the chapter on facial pain and neuromuscular diseases. In addition, we must acknowledge the outstanding support and guidance provided by the staff at Elsevier in making this book a success. Special thanks go to Lauren Boyle, Joslyn Dumas, and Meredith Madeira for all of their assistance in the editorial process.

As always, our greatest appreciation goes to our families, who have once again provided us with their unconditional love and support during the countless hours spent working on this latest edition. (Although this new edition may have been somewhat of a milestone for us, we are worried that it may have seemed like a millstone to them!) We could never have accomplished it without you.

Developmental Defects of the Oral and Maxillofacial Region

◆ OROFACIAL CLEFTS

The formation of the face and oral cavity is complex in nature and involves the development of multiple tissue processes that must merge and fuse in a highly orchestrated fashion. Disturbances in the growth of these tissue processes or their fusion may result in the formation of **orofacial clefts**.

Development of the central face begins around the end of the fourth week of human development with the appearance of the nasal (olfactory) placodes on either side of the inferior aspect of the frontonasal process. Proliferation of ectomesenchyme on both sides of each placode results in the formation of the medial and lateral nasal processes. Between each pair of processes is a depression, or nasal pit, that represents the primitive nostril.

During the sixth and seventh weeks of development, the upper lip forms when the medial nasal processes merge with each other and with the maxillary processes of the first branchial arches. Thus the midportion of the upper lip is derived from the medial nasal processes, and the lateral portions are derived from the maxillary processes. The lateral nasal processes are not involved in the formation of the upper lip, but they give rise to the alae of the nose.

The **primary palate** also is formed by the merger of the medial nasal processes to form the intermaxillary segment. This segment gives rise to the premaxilla, a triangular-shaped piece of bone that will include the four incisor teeth and hard palate anterior to the incisive foramen. The **secondary palate,** which makes up 90% of the hard and soft palates, is formed from the maxillary processes of the first branchial arches.

During the sixth week, bilateral projections emerge from the medial aspects of the maxillary processes to form the palatal shelves. Initially, these shelves are oriented in a vertical position on each side of the developing tongue. As the mandible grows, the tongue drops down, allowing the palatal shelves to rotate to a horizontal position and grow toward one another. By the eighth to ninth week, sufficient growth has occurred to allow the anterior aspects of these shelves to begin fusion with one another. The palatal shelves also fuse with the primary palate and the nasal septum. The fusion of the palatal shelves begins in the anterior palate and progresses posteriorly; it is completed by the twelfth week.

Defective fusion of the medial nasal process with the maxillary process leads to **cleft lip (CL)**. Likewise, failure of the palatal shelves to fuse results in **cleft palate (CP)**. Frequently, CL and CP occur together. Approximately 45% of cases are CL + CP with 30% being CP only (CPO) and 25% being isolated CL. Both isolated CL and CL associated with CP are thought to be etiologically related conditions and can be considered as a group: CL, with or without CP (i.e., CL ± CP). Isolated CPO appears to represent a separate entity from CL ± CP.

The cause of CL ± CP and CPO is still being debated. First of all, distinguishing isolated clefts from cases associated with specific syndromes is important. Although many facial clefts are isolated anomalies, more than 400 developmental syndromes have been identified that may be associated with CL ± CP or CPO. Studies have suggested that up to 30% of patients with CL ± CP and 50% of those with CPO have associated anomalies. Some of these cases are single-gene syndromes that may follow autosomal dominant, autosomal recessive, or X-linked inheritance patterns. Other syndromes are the result of chromosome anomalies or are idiopathic. Anomalies frequently associated with CPO include congenital heart defects, hydrocephalus, and urinary tract defects.

The cause of nonsyndromic clefts does not follow any simple Mendelian pattern of inheritance but appears to be heterogeneous. Thus the propensity for cleft development may be related to a number of major genes, minor genes, and environmental factors that can combine to surpass a developmental threshold. Numerous candidate clefting genes and loci have been identified on different chromosome regions. Maternal alcohol consumption has been associated with an increased risk for both syndromic and nonsyndromic clefts. Maternal cigarette smoking at least doubles the frequency of cleft development compared with nonsmoking mothers. An increased frequency also has been related to anticonvulsant therapy, especially phenytoin, which causes a nearly tenfold greater risk of cleft formation. Although evidence has been mixed, a number of studies have suggested that folic acid supplementation may play a role in prevention of orofacial clefts.

CL ± CP and CPO represent the vast majority of orofacial clefts. However, other rare clefts also may occur.

dentlearn.ir

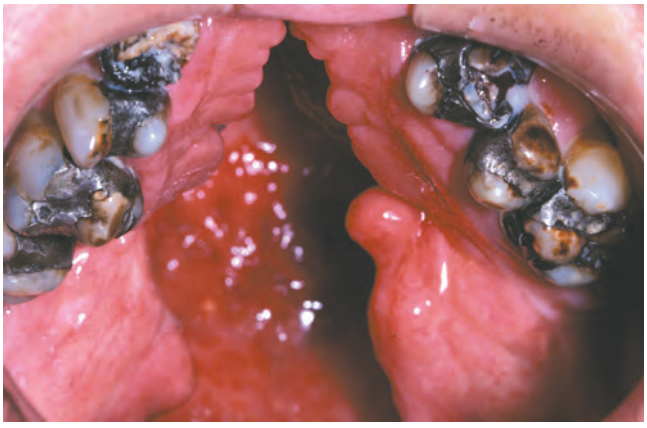
The **lateral facial cleft** is caused by lack of fusion of the maxillary and mandibular processes and represents 0.3% of all facial clefts. This cleft may be unilateral or bilateral, extending from the commissure toward the ear, resulting in macrostomia. The lateral facial cleft may occur as an isolated defect, but more often it is associated with other disorders, such as the following:

- Mandibulofacial dysostosis (see page 43)
- Oculo-auriculo-vertebral spectrum (hemifacial microsomia)
- Nager acrofacial dysostosis
- Amniotic rupture sequence

The **oblique facial cleft** extends from the upper lip to the eye. It is nearly always associated with CP, and severe forms often are incompatible with life. The oblique facial cleft may involve the nostril, as in CL, or it may bypass the nose laterally as it extends to the eye. This cleft is rare, representing only 1 in 1300 facial clefts. Some of these clefts may represent failure of fusion of the lateral nasal process with the maxillary process; amniotic bands may cause others.

Median cleft of the upper lip is an extremely rare anomaly that results from failure of fusion of the medial nasal processes. It may be associated with a number of syndromes, including the oral-facial-digital syndromes and Ellis-van Creveld syndrome. Most apparent median clefts of the upper lip actually represent agenesis of the primary palate associated with holoprosencephaly.

Clinical and Radiographic Features



Clefting is one of the most common major congenital defects in humans. Considerable racial variation in prevalence is seen. In whites, CL ± CP occurs in 1 of every 700 to 1000 births. The frequency of CL ± CP in Asian populations is about 1.5 times higher than in whites. In contrast, the prevalence of CL ± CP in blacks is much lower, occurring in 0.4 of 1000 births. Native Americans appear to have the highest frequency, around 3.6 of 1000 births. CPO is less common than CL ± CP, with a frequency of 0.4 of 1000 births in whites and blacks.

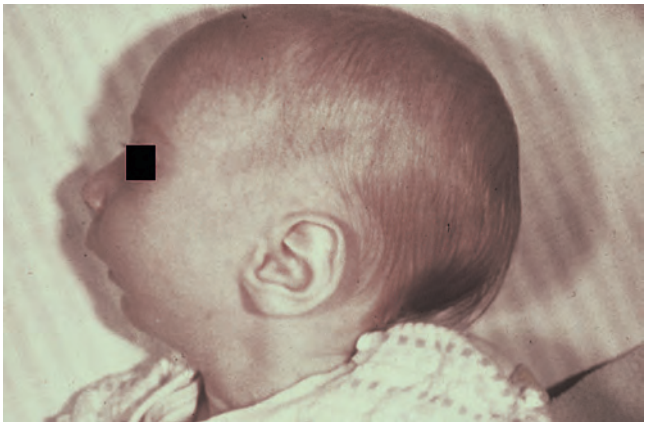
CL ± CP is more common in males than in females. The more severe the defect, the greater the male predilection; the male-to-female ratio for isolated CL is 1.5:1; the ratio for CL +CP is 2:1. In contrast, CPO is more common in females. Likewise, the more severe the cleft, the greater the female predilection. Clefts of both the hard and soft palates are twice as common in females, but the ratio is nearly equal for clefts of the soft palate only.

Approximately 80% of cases of CL will be unilateral with 20% bilateral (Fig. 1.1). Approximately 70% of unilateral CLs occur on the left side. In addition, about 70% of unilateral CLs will be associated with CP, whereas the frequency of concomitant CP increases to 85% for patients with bilateral CL. CLs can be classified into three categories: microform, incomplete, and complete. A microform CL shows a notch or groove in the lip and vermilion junction, but all of the lip tissues are still present. An incomplete CL is more severe, exhibiting dehiscence of the orbicularis oris muscle with a variable degree of overlying skin involvement. A thin band of soft tissue (Simonart band) remains intact across the superior aspect of the cleft at the nasal sill. A complete CL extends through the length of the lip and across the nasal sill, resulting in abnormal insertion of the orbicularis oris into the nasal ala and columella. Complete clefts involving the alveolus usually occur between the lateral incisor and cuspid. It is not unusual for teeth, especially the lateral incisor, to be missing in the cleft area. Conversely, supernumerary teeth may be discovered. The bony defect can be observed on radiographs.

• **Fig. 1.1 Cleft Lip (CL).** Infant with bilateral cleft of the upper lip. (Courtesy of Dr. William Bruce.)

• **Fig. 1.2 Cleft Palate (CP).** Palatal defect resulting in communication with the nasal cavity.

A CP shows considerable range in severity (Fig. 1.2). Clefts of the primary palate occur anterior to the incisive foramen and extend to the alveolar ridge. Clefts of the secondary palate occur posterior to the incisive foramen and may involve the hard and soft palates or the soft palate alone. Complete CPs involve both the primary and secondary palates. The minimal manifestation of CP is a **cleft** or **bifid uvula** (Fig. 1.3). The prevalence of cleft uvula is much higher than that of CP, with a frequency of 1 in every 80 white individuals. The frequency in Asian and Native American populations is as high as 1 in 10. Cleft uvula is less common in blacks, occurring in 1 out of every 250 persons.



dentlearn.ir

• **Fig. 1.3 Bifid Uvula.**

• **Fig. 1.4 Submucous Palatal Cleft.** A cleft of the midline palatal bone exists, but the overlying mucosa is intact. A bifid uvula also is present.

• **Fig. 1.5 Pierre Robin Sequence.** Micrognathic mandible in an infant with cleft palate (CP). (Courtesy of Dr. Robert Gorlin.)

In some instances a **submucous palatal cleft** develops. The surface mucosa is intact, but a defect exists in the underlying musculature of the soft palate (Fig. 1.4). Frequently a notch in the bone is present along the posterior margin of the hard palate. This incomplete cleft occasionally appears as a bluish midline discoloration but is best identified by palpation with a blunt instrument. An associated cleft uvula also usually is seen.

The **Pierre Robin sequence** (Fig. 1.5) is a well-recognized presentation characterized by CP, mandibular micrognathia, and glossoptosis (airway obstruction caused by lower, posterior displacement of the tongue). This condition may occur as an isolated phenomenon, or it may be associated with a wide variety of syndromes or other anomalies. Stickler syndrome and velocardiofacial syndrome (22q11.2 deletion syndrome) are the two most frequently associated genetic disorders. The prevalence of Pierre Robin sequence is estimated at 1 in 8000 to 14,000 births. Researchers have theorized that constraint of mandibular growth in utero results in failure of the tongue to descend, thus preventing fusion of the palatal shelves. The retruded mandible results in the following:

- Posterior displacement of the tongue
- Lack of support of the tongue musculature
- Airway obstruction

Respiratory difficulty, especially when the child is in a supine position, usually is noted from birth and can cause asphyxiation. The palatal cleft often is U-shaped and wider than isolated CP.

The patient with a cleft is burdened with a variety of problems, some obvious and some less so. The most obvious problem is the clinical appearance, which may lead to psychosocial difficulties. Feeding and speech difficulties are inherent, especially with CP. Malocclusion is caused by collapse of the maxillary arch, possibly along with missing teeth, supernumerary teeth, or both.

Treatment and Prognosis

The management of the patient with an orofacial cleft is challenging. Ideally, treatment should involve a multidisciplinary approach, including (but not limited to) a pediatrician, oral and maxillofacial surgeon, otolaryngologist, plastic surgeon, pediatric dentist, orthodontist, prosthodontist, speech pathologist, and geneticist.

During the neonatal period, lip taping and nasoalveolar molding may be utilized in an attempt to reduce the severity of the cleft deformity. Surgical repair often involves multiple primary and secondary procedures throughout childhood. The specific types of surgical procedures and their timing will vary, depending on the severity of the defect and the philosophy of the treatment team. A detailed discussion of these procedures is beyond the scope of this text. However, primary lip closure usually is accomplished during the first few months of life, followed by repair of the palate between 7 and 15 months of age. Secondary soft tissue, bone grafting, and orthognathic/orthodontic procedures often are used to improve function and cosmetic appearance. Distraction osteogenesis of the maxilla can prove useful in patients in whom palatal scarring limits the amount of advancement possible at the time of osteotomy.

Breathing difficulties in infants with Pierre Robin sequence are managed best with conservative measures, such as side and prone positioning. However, in children with significant airway obstruction, placement of a nasopharyngeal

dentlearn.ir

airway may be warranted. In more severe cases, mandibular distraction osteogenesis may be a preferable treatment alternative to tracheostomy. Death from isolated Pierre Robin sequence is uncommon (1.2%), but the mortality rate in infants who also have related syndromes can increase to as high as 26% due to central nervous system anomalies, cardiac anomalies, or respiratory difficulties.

Genetic counseling is important for the patient and family. In nonsyndromic cases of orofacial clefting, the risk for cleft development in a sibling or offspring of an affected person is 3%–5% if no other first-degree relatives also are affected. The risk increases to 10%–20% if other first-degree relatives are affected. The risk may be even higher for those with clefts that are associated with syndromes, depending on the possible inheritance pattern.

◆ COMMISSURAL LIP PITS

Commissural lip pits are small mucosal invaginations that occur at the corners of the mouth on the vermilion border. Their location suggests that they may represent a failure of normal fusion of the embryonal maxillary and mandibular processes.

Commissural lip pits appear to be common in adults, where they have been reported in 12%–20% of the population. Their prevalence in children is considerably lower, ranging from 0.2% to 0.7% of those examined.

Although commissural lip pits are generally considered to be congenital lesions, these figures suggest that these invaginations often develop later in life. Commissural pits are seen more often in males than in females. A family history suggestive of autosomal dominant transmission has been noted in some cases.

Clinical Features

Commissural lip pits usually are discovered on routine examination, and the patient often is unaware of their presence. These pits may be unilateral or bilateral. They manifest as blind fistulas that may extend to a depth of 1 to 4 mm (Fig. 1.6). In some cases, a small amount of fluid may be expressed when the pit is squeezed, presumably representing saliva from minor salivary glands that drain into the depth of the invagination.

Unlike **paramedian lip pits** (described in the following section), commissural lip pits are not associated with facial or palatal clefts. However, there does appear to be a significantly higher prevalence of preauricular pits (aural sinuses) in these patients.

• **Fig. 1.6 Commissural Lip Pit.** Depression at the labial commissure.

Histopathologic Features

Although biopsy rarely is performed for patients with commissural lip pits, microscopic examination reveals a narrow invagination lined by stratified squamous epithelium. Ducts from minor salivary glands may drain into this invagination.

Treatment and Prognosis

Because commissural lip pits are virtually always asymptomatic and innocuous, no treatment is usually necessary. In extremely rare instances, salivary secretions may be excessive or secondary infection may occur, necessitating surgical excision of the pit.

◆ PARAMEDIAN LIP PITS (CONGENITAL FISTULAS OF THE LOWER LIP; CONGENITAL LIP PITS)

Paramedian lip pits are rare congenital invaginations of the lower lip. They are believed to arise from persistent lateral sulci on the embryonic mandibular arch. These sulci normally disappear by 6 weeks of embryonic age.

Clinical Features

Paramedian lip pits typically appear as bilateral and symmetric fistulas on either side of the midline of the vermilion of the lower lip (Fig. 1.7). Their appearance can range from

• **Fig. 1.7 Paramedian Lip Pits.** Bilateral pits on the lower lip in a patient with van der Woude syndrome. (Courtesy of Dr. Nadarajah Vigneswaran.)

dentlearn.ir

• **Fig. 1.8 Van der Woude Syndrome.** Same patient as depicted in Fig. 1.7 with a cleft of the soft palate. (Courtesy of Dr. Nadarajah Vigneswaran.)

subtle depressions to prominent humps. These blind sinuses can extend down to a depth of 1.5 cm and may express salivary secretions. Occasionally, only a single pit is present that may be centrally located or lateral to the midline.

The greatest significance of paramedian lip pits is that they usually are inherited as an autosomal dominant trait in combination with cleft lip (CL) and/or cleft palate (CP) **(van der Woude syndrome)** (Fig. 1.8). Van der Woude syndrome is the most common form of syndromic clefting and accounts for 2% of all cases of CL and CP. Associated hypodontia also may be observed. Genetic studies have shown that this condition is caused by mutations in the gene that encodes interferon regulatory factor 6 (*IRF6*), which has been mapped to chromosome locus 1q32-q41. Some people who carry the trait may not demonstrate clefts or may have a submucous CP; however, they may pass the full syndrome to their offspring.

Paramedian lip pits also may be a feature of the **popliteal pterygium syndrome** and **Kabuki syndrome**. Popliteal webbing **(pterygia),** CL and/or CP, genital abnormalities, and congenital bands connecting the upper and lower jaws **(syngnathia)** characterize popliteal pterygium syndrome, which also is caused by mutation of the *IRF6* gene and is closely related to van der Woude syndrome. Kabuki syndrome is a separate condition that received its name because affected patients exhibit eversion of the lower lateral eyelids, which is reminiscent of the makeup used by actors in Kabuki, the traditional form of Japanese theater. Other common findings include intellectual disability, large ears, CL and/or CP, hypodontia, joint laxity, and various skeletal abnormalities.

Histopathologic Features

Microscopic examination of a paramedian lip pit shows a tract that is lined by stratified squamous epithelium. Minor salivary glands may communicate with the sinus. A chronic inflammatory cell infiltrate often is noted in the surrounding connective tissue.

• **Fig. 1.9 Double Lip.** When the patient smiles, a redundant fold of tissue partially covers the right anterior maxillary teeth. (Courtesy of Dr. Logan Barnes.)

Treatment and Prognosis

If necessary, the labial pits may be excited for cosmetic reasons. The most significant problems are related to associated congenital anomalies, such as CL and/or CP, and the potential for transmission of the trait to subsequent generations.

◆ DOUBLE LIP

Double lip is a rare oral anomaly characterized by a redundant fold of tissue on the mucosal side of the lip. Most often it is congenital in nature, but it may be acquired later in life. Congenital cases are believed to arise during the second to third month of gestation as a result of the persistence of the sulcus between the pars glabrosa and pars villosa of the lip. Acquired double lip may be a component of **Ascher syndrome,** or it may result from trauma or oral habits, such as sucking on the lip.

Clinical Features

In a patient with double lip, the upper lip is affected much more often than the lower lip; occasionally, both lips are involved. With the lips at rest, the condition is usually unnoticeable, but when the patient smiles or when the lips are tensed, the excess fold of tissue is visible (Fig. 1.9).

Ascher syndrome is characterized by a triad of features:

- Double lip
- Blepharochalasis
- Nontoxic thyroid enlargement

In a person with blepharochalasis, recurring edema of the upper eyelid leads to sagging of the lid at the outer canthus of the eye (Fig. 1.10). This drooping may be severe enough to interfere with vision. Both the double lip and blepharochalasis usually occur abruptly and simultaneously, but in some cases they develop more gradually.

The nontoxic thyroid enlargement occurs in as many as 50% of patients with Ascher syndrome and may be mild in degree. The cause of Ascher syndrome is not certain; autosomal dominant inheritance has been suggested in some cases.

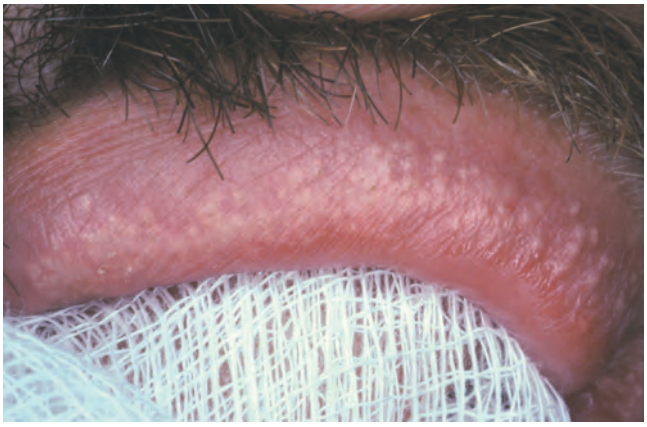
dentlearn.ir

• **Fig. 1.10 Ascher Syndrome.** Edema of the upper eyelids (blepharochalasis).

Histopathologic Features

On microscopic examination, double lip shows essentially normal structures. Often there is an abundance of minor salivary glands. The blepharochalasis of Ascher syndrome usually shows hyperplasia of the lacrimal glands or prolapse of orbital fat.

Treatment and Prognosis

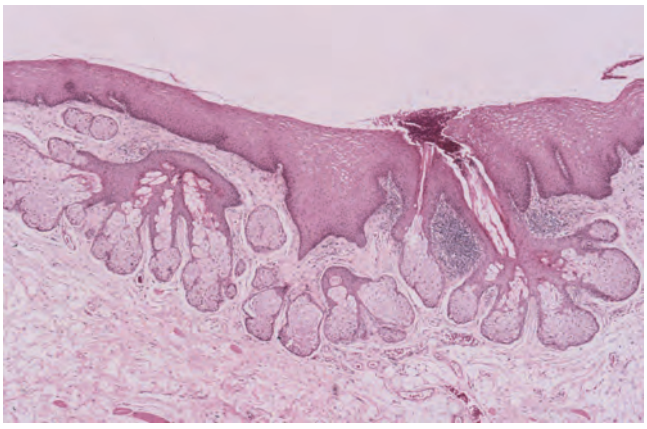


In mild cases of double lip, no treatment may be required. In more severe cases, simple surgical excision of the excess tissue can be performed for aesthetic purposes.

◆ FORDYCE GRANULES

Fordyce granules are sebaceous glands that occur on the oral mucosa. Similar lesions also have been reported on the genital mucosa. Because sebaceous glands typically are considered to be dermal adnexal structures, those found in the oral cavity often have been considered to be "ectopic." However, because Fordyce granules have been reported in more than 80% of the population, their presence must be considered a normal anatomic variation.

Clinical Features



Fordyce granules appear as multiple yellow or yellow-white papules that are most common on the buccal mucosa and the lateral portion of the vermilion of the upper lip (Figs. 1.11 and 1.12). Occasionally, these glands also may appear in the retromolar area and anterior tonsillar pillar. They are more common in adults than in children, probably as a result of hormonal factors; puberty appears to stimulate their development. The lesions are typically asymptomatic, although patients may be able to feel a slight roughness to the mucosa. Considerable clinical variation may exist; some patients may have only a few lesions, whereas others may have literally hundreds of these "granules."

• **Fig. 1.11 Fordyce Granules.** Yellow papules on the vermilion of the upper lip.

• **Fig. 1.12 Fordyce Granules.** Lesions on the buccal mucosa.

• **Fig. 1.13 Fordyce Granules.** Multiple sebaceous glands below the surface epithelium.

Histopathologic Features

Except for the absence of associated hair follicles, Fordyce granules closely resemble normal sebaceous glands found in the skin. Acinar lobules can be seen immediately beneath the epithelial surface, often communicating with the surface through a central duct (Fig. 1.13). The sebaceous cells in these lobules are polygonal in shape, containing centrally located nuclei and abundant foamy cytoplasm.

dentlearn.ir

Treatment and Prognosis

Because Fordyce granules represent a normal anatomic variation and are asymptomatic, no treatment is indicated. Usually, the clinical appearance is characteristic and biopsy is not necessary for diagnosis.

On occasion, Fordyce granules may become hyperplastic or may form keratin-filled pseudocysts. Tumors arising from these glands are exceedingly rare.

◆ LEUKOEDEMA

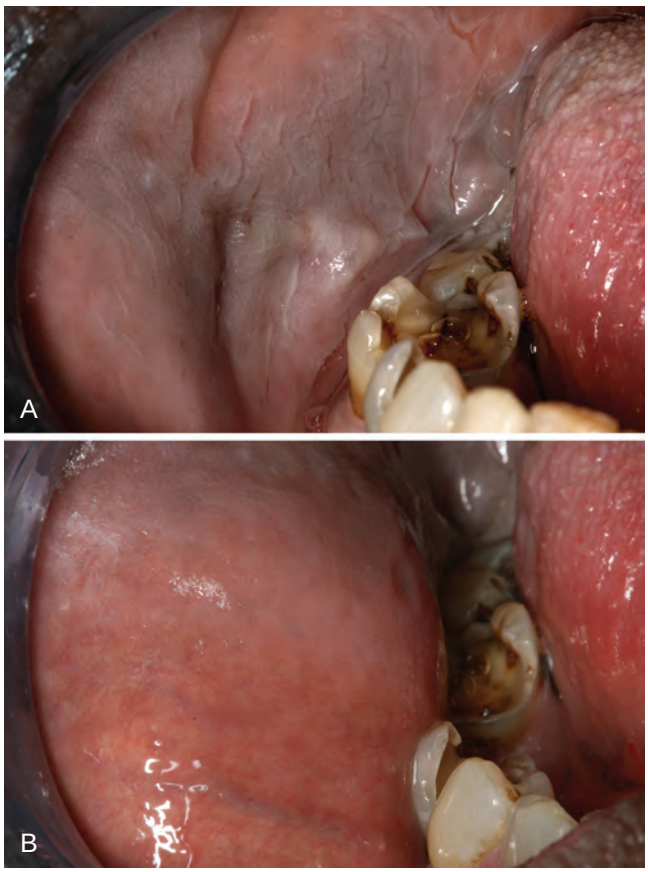
Leukoedema is a common oral mucosal condition of unknown cause. It occurs more commonly in blacks than in whites, supporting the likelihood of an ethnic predisposition to its development. Leukoedema has been reported in 70%–90% of black adults and in 50% of black children. The prevalence in whites is considerably less, although published reports have ranged from less than 10% to more than 90%. This variation may reflect differing population groups, examination conditions, and stringency of criteria used to make the diagnosis. At any rate, leukoedema shows a much milder presentation in whites and often is hardly noticeable. The difference in racial predilection may be explained by the presence of background mucosal pigmentation in blacks that makes the edematous changes more noticeable.

Because leukoedema is so common, it can reasonably be argued that it represents a *variation of normal* rather than a disease. The finding of similar edematous mucosa in the vagina and larynx further supports this argument. Although leukoedema appears to be developmental in nature, some studies have indicated that it is more common and more severe in smokers and becomes less pronounced with cessation of smoking.

Clinical Features

Leukoedema is characterized by a diffuse, gray-white, milky, opalescent appearance of the mucosa (Fig. 1.14). The surface frequently appears folded, resulting in wrinkles or whitish streaks. The lesions do not rub off. Leukoedema typically occurs bilaterally on the buccal mucosa and may extend forward onto the labial mucosa. On rare occasions, it also can involve the floor of the mouth and palatopharyngeal tissues. Leukoedema can be easily diagnosed clinically because the white appearance greatly diminishes or disappears when the cheek is everted and stretched (Fig. 1.15).

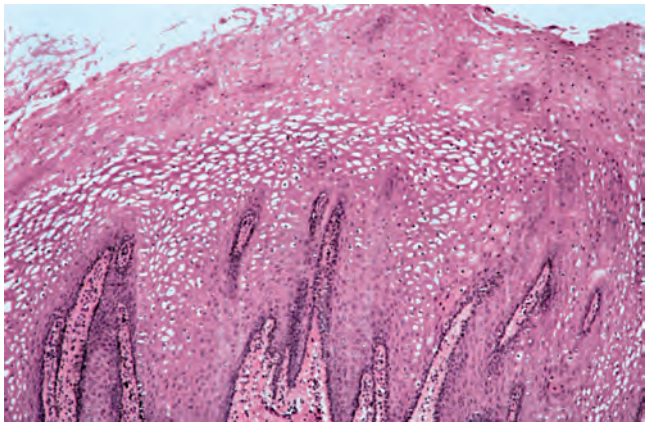
Histopathologic Features



Biopsy specimens of leukoedema demonstrate an increase in thickness of the epithelium with striking intracellular edema of the spinous layer (Fig. 1.16). These vacuolated cells appear large and have pyknotic nuclei. The epithelial surface is frequently parakeratinized, and the rete ridges are broad and elongated.

Treatment and Prognosis

Leukoedema is a benign condition, and no treatment is required. The characteristic milky-white, opalescent lesions of the buccal mucosa that disappear when stretched help distinguish it from other common white lesions, such as leukoplakia, candidiasis, and lichen planus. The affected mucosa always should be stretched during clinical examination to



• **Fig. 1.14 Leukoedema.** White, wrinkled appearance of the buccal mucosa.

• **Fig. 1.15 Leukoedema. A,** Diffuse white appearance of the buccal mucosa. **B,** Whiteness disappears when the cheek is stretched.

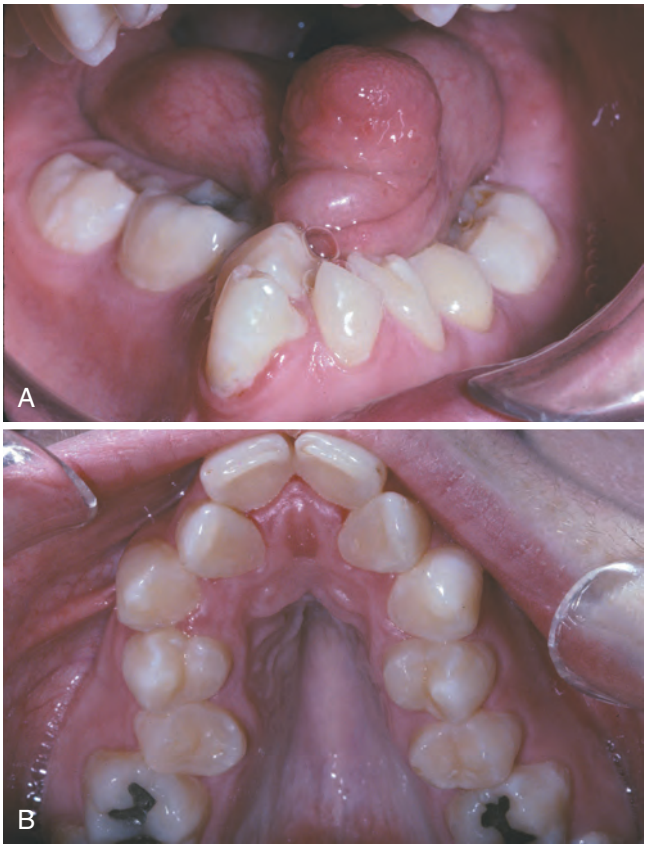
dentlearn.ir

• **Fig. 1.16 Leukoedema.** Parakeratosis and intracellular edema of the spinous layer.

rule out any underlying lesions that may be hidden by the edematous change.

◆ MICROGLOSSIA (HYPOGLOSSIA)

Clinical Features



Microglossia is an uncommon developmental condition of unknown cause that is characterized by an abnormally small tongue. In rare instances, virtually the entire tongue may be missing **(aglossia)**. Isolated microglossia is known to occur, and mild degrees of microglossia may be difficult to detect and may go unnoticed. However, most reported cases have been associated with one of a group of overlapping conditions known as **oromandibular-limb hypogenesis syndromes**. These syndromes feature associated limb anomalies, such as **hypodactylia** (i.e., absence of digits) and **hypomelia** (i.e., hypoplasia of part or all of a limb). Other patients have had coexisting anomalies, such as cleft palate, intraoral bands, and *situs inversus*. Microglossia frequently is associated with hypoplasia of the mandible, and the lower incisors may be missing (Fig. 1.17).

Treatment and Prognosis

Treatment of the patient with microglossia depends on the nature and severity of the condition. Surgery and orthodontics may improve oral function. Surprisingly, speech development often is quite good but depends on tongue size.

◆ MACROGLOSSIA

Macroglossia is an uncommon condition characterized by enlargement of the tongue. The enlargement may be caused by a wide variety of conditions, including congenital malformations and acquired diseases. The most frequent causes are vascular malformations and muscular hypertrophy. Box 1.1 lists the most common and important causes of macroglossia. Many of these diseases are discussed in greater detail in subsequent chapters of this book.

• **Fig. 1.17 Microglossia**. **A,** Abnormally small tongue associated with constricted mandibular arch. **B,** Same patient with associated constriction of the maxillary arch.

• BOX 1.1 Causes of Macroglossia

Congenital and Hereditary

- Vascular malformations
- Lymphangioma
- Hemangioma
- Hemihyperplasia
- Cretinism
- Beckwith-Wiedemann syndrome
- Down syndrome
- Duchenne muscular dystrophy
- Mucopolysaccharidoses
- Neurofibromatosis type I
- Multiple endocrine neoplasia, type 2B

Acquired

- Edentulous patients
- Amyloidosis
- Myxedema
- Acromegaly
- Angioedema
- Myasthenia gravis
- Amyotrophic lateral sclerosis
- Carcinoma and other tumors

dentlearn.ir

• **Fig. 1.18 Macroglossia**. Large tongue in a patient with Down syndrome. (Courtesy of Dr. Sanford Fenton.)

• **Fig. 1.19 Macroglossia**. The tongue enlargement has resulted in a crenated border that corresponds to the embrasures between the teeth.

Clinical Features

Macroglossia most commonly occurs in children and can range from mild to severe (Fig. 1.18). In infants, macroglossia may be manifested first by noisy breathing, drooling, and difficulty in eating. The tongue enlargement may result in a lisping speech. The pressure of the tongue against the mandible and teeth can produce a crenated lateral border to the tongue (Fig. 1.19), open bite, and mandibular prognathism. If the tongue constantly protrudes from the mouth, it may ulcerate and become secondarily infected or may even undergo necrosis. Significant macroglossia can contribute to obstructive sleep apnea or, rarely, result in overt airway obstruction.

Macroglossia is a characteristic feature of **Beckwith-Wiedemann syndrome,** a rare hereditary condition that includes many other possible defects, such as the following:

- Omphalocele (i.e., protrusion of part of the intestine through a defect in the abdominal wall at the umbilicus)
- Visceromegaly
- Gigantism
- Neonatal hypoglycemia

Individuals with Beckwith-Wiedemann syndrome have an increased risk for several childhood visceral tumors, including Wilms tumor, adrenal carcinoma, hepatoblastoma, rhabdomyosarcoma, and neuroblastoma. Facial features may include nevus flammeus of the forehead and eyelids, linear indentations of the earlobes, and maxillary hypoplasia (resulting in relative mandibular prognathism). Most examples of Beckwith-Wiedemann syndrome are sporadic, but 10%–15% of cases show autosomal dominant inheritance with preferential maternal transmission. The genetic basis is complex, involving a variety of alterations within two domains of imprinted growth-regulatory genes on chromosome 11p15.

In patients with **hypothyroidism** (see page 835), Beckwith-Wiedemann syndrome, or neuromuscular disorders, the tongue usually shows a diffuse, smooth, generalized enlargement. In those with other forms of macroglossia, the tongue usually has a multinodular appearance. Examples of this nodular type include **amyloidosis** (see page 824) and neoplastic conditions, such as **neurofibromatosis** (see page 537) and **multiple endocrine neoplasia, type 2B** (see page 540).

In patients with **lymphangiomas** (see page 553), the tongue surface is characteristically pebbly and exhibits multiple vesicle-like blebs that represent superficial dilated lymphatic channels. The enlarged tongue in those with **Down syndrome** typically demonstrates a papillary, fissured surface.

In patients with **hemifacial hyperplasia** (see page 37), the enlargement will be unilateral. Some patients with neurofibromatosis also can have unilateral lingual enlargement.

In edentulous patients, the tongue often appears elevated and tends to spread out laterally because of loss of the surrounding teeth; as a result, wearing a denture may become difficult.

Histopathologic Features

The microscopic appearance of macroglossia depends on the specific cause. In some cases, such as the tongue enlargement seen with Down syndrome or in edentulous patients, no histologic abnormality can be detected. When macroglossia is due to tumor, a neoplastic proliferation of a particular tissue can be found (e.g., lymphatic vessels, blood vessels, neural tissue). Muscular enlargement occurs in those with hemihyperplasia and Beckwith-Wiedemann syndrome. In neuromuscular disorders, such as myasthenia gravis or amyotrophic lateral sclerosis, tongue enlargement may result from muscular atrophy with prominent fatty replacement. In the patient with amyloidosis, an abnormal protein material is deposited in the tongue.

Treatment and Prognosis

The treatment and prognosis of macroglossia depend on the cause and severity of the condition. In mild cases, surgical treatment may not be necessary, although speech therapy may be helpful if speech is affected. In symptomatic patients, reduction glossectomy may be needed.

dentlearn.ir

ANKYLOGLOSSIA (TONGUE-TIE)

Ankyloglossia is a developmental anomaly of the tongue characterized by a short, thick lingual frenum resulting in limitation of tongue movement. It has been reported to occur in 0.1%–16% of neonates, being more common in boys than in girls. In adults, mild forms are not unusual, but severe ankyloglossia is a relatively uncommon condition that has been estimated to occur in about two to three of every 10,000 people. Most examples of ankyloglossia appear to be sporadic, although evidence suggests that there could be a genetic influence in some cases.

Clinical Features

Ankyloglossia can range in severity from mild cases with little clinical significance to rare examples of complete ankyloglossia in which the tongue is actually fused to the floor of the mouth (Fig. 1.20). The term *anterior ankyloglossia* is used when the frenum attachment extends toward the tip of the tongue. Sometimes slight clefting of the tongue tip may be seen. *Posterior ankyloglossia* is more subtle to detect, being related to short collagen bundles in the posterior midline floor of the mouth, which result in limitation of tongue movement.

With the increase in popularity of breast-feeding in recent decades, clinicians have related tongue-tie with feeding problems, such as nipple pain or difficulty in the baby attaching to the breast. Some investigators have speculated that ankyloglossia may lead to the development of an anterior open bite because the inability to raise the tongue to the roof of the mouth prevents development of the normal adult swallowing pattern. However, others have questioned this theory. It also is possible that a high mucogingival attachment of the lingual frenum may contribute to gingival recession, although a clear relationship has not been established.

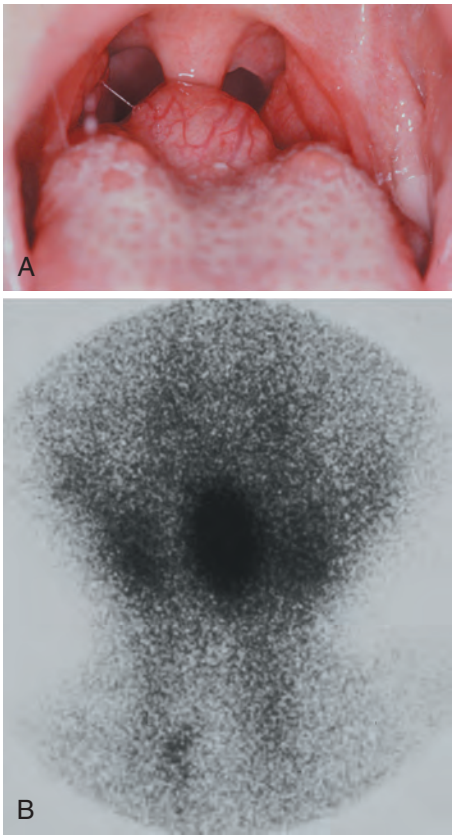
It has been suggested that tongue-tie may result in speech defects. Usually, however, the shortened frenum results in only minor difficulties because most people can compensate for the limitation in tongue movement. Yet there are rare examples of patients who have experienced an immediate noticeable improvement in speech after surgical correction of ankyloglossia.

• **Fig. 1.20 Ankyloglossia**. Abnormal attachment of the lingual frenum, limiting tongue mobility.

Treatment and Prognosis

Because most cases of ankyloglossia result in few or no clinical problems, treatment is often unnecessary. For infants with specific breast-feeding problems, a frenotomy ("clipping" or simple release of the frenulum) can be performed, which has been shown to improve nipple pain and breast-feeding scores. In children or adults with associated functional or periodontal difficulties, a frenuloplasty (release with plastic repair) may allow greater freedom of tongue movement. In young children, it often is recommended that surgery be postponed until age 4 or 5. Because the tongue is always short at birth, assessing the degree of tongue limitation caused by ankyloglossia is difficult in the infant's early life. As the infant grows, the tongue becomes longer and thinner at the tip, often decreasing the severity of the tongue-tie. The condition probably is self-correcting in many cases because it is less common in adults.

LINGUAL THYROID



During the third to fourth week of fetal life, the thyroid gland begins as an epithelial proliferation in the floor of the pharyngeal gut. By the seventh embryonic week, this thyroid bud normally descends into the neck to its final resting position anterior to the trachea and larynx. The site where this descending bud invaginates later becomes the foramen cecum, located at the junction of the anterior two-thirds and posterior third of the tongue in the midline. If the primitive gland does not descend normally, ectopic thyroid tissue may be found between the foramen cecum and the epiglottis. Of all ectopic thyroids, 90% are found in this region.

Clinical Features

Based on autopsy studies, small asymptomatic remnants of thyroid tissue can be discovered on the posterior dorsal tongue in about 10% of both men and women. However, clinically evident or symptomatic **lingual thyroids** are rare, with a prevalence of 1 per 100,000–300,000 persons. Such lesions are four to seven times more frequent in females, presumably because of hormonal influences. Symptoms most often develop during puberty, adolescence, pregnancy, or menopause. In 70% of cases, this ectopic gland is the patient's only thyroid tissue.

Lingual thyroids may range from small, asymptomatic, nodular lesions to large masses that can block the airway (Fig. 1.21). The most common clinical symptoms are dysphagia, dysphonia, and dyspnea. The mass often is vascular, but the physical appearance is variable, and there are no reliable features to distinguish it from other masses that might develop in this area. Hypothyroidism can develop in up to 72% of patients. Many authors say that lingual thyroid

dentlearn.ir

• **Fig. 1.21 Lingual Thyroid**. **A,** Nodular mass of the posterior dorsal midline of the tongue in a 4-year-old girl. **B,** Thyroid scan of the same patient. The scan shows localization (central dark zone) of iodine isotope in the tongue mass and minimal uptake in the neck.

enlargement is a secondary phenomenon, compensating for thyroid hypofunction. Interestingly, from 25% to 75% of patients with infantile hypothyroidism have some ectopic thyroid tissue.

Diagnosis is best established by thyroid scan using iodine isotopes or technetium-99 m (^{99m}Tc). Computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography can be helpful in delineating the size and extent of the lesion. Biopsy is often avoided because of the risk of hemorrhage and because the mass may represent the patient's only functioning thyroid tissue. In some cases, incisional biopsy may be needed to confirm the diagnosis or to rule out malignant changes.

Treatment and Prognosis

No treatment except periodic follow-up is required for patients with asymptomatic lingual thyroids. In symptomatic patients, suppressive therapy with supplemental thyroid hormone often can reduce the size of the lesion. Some authors advise that this treatment also should be tried in asymptomatic patients to prevent possible subsequent enlargement. If hormone therapy does not eliminate symptoms, surgical removal or ablation with radioactive iodine-131 can be performed. If the mass is excised, autotransplantation to another body site can be attempted to maintain functional thyroid tissue and to prevent hypothyroidism.

Rare examples of carcinomas arising in lingual thyroids have been reported; malignancy develops in about 1% of identified cases. Although lingual thyroids are decidedly more common in females, this predilection for females is less pronounced for lingual thyroid carcinomas. Because a disproportionate number of these malignancies have been documented in males, some authors have advocated prophylactic excision of lingual thyroids in men older than 30 years of age.

• **Fig. 1.22 Fissured Tongue**. Extensive fissuring involving the entire dorsal tongue surface. (Courtesy of Chris Neville.)

◆ FISSURED TONGUE (SCROTAL TONGUE; LINGUA PLICATA)

Fissured tongue is a relatively common condition that is characterized by the presence of numerous grooves, or fissures, on the dorsal tongue surface. The cause is uncertain, but heredity appears to play a significant role. Evidence indicates that the condition may be either a polygenic trait or an autosomal dominant trait with incomplete penetrance. A variety of other factors also may contribute to its development, including aging, smoking, and a history of psoriasis.

Clinical Features

Patients with fissured tongue exhibit multiple grooves, or furrows, on the surface of the tongue, ranging from 2 to 6 mm in depth (Fig. 1.22). Considerable variation can be seen. In the most severe cases, numerous fissures cover the entire dorsal surface and divide the tongue papillae into multiple separate "islands." Some patients have fissures that are located mostly on the dorsolateral areas of the tongue. Other patients exhibit a large central fissure with smaller fissures branching outward at right angles. The condition usually is asymptomatic, although some patients may complain of mild burning or soreness.

The prevalence of fissured tongue ranges from 2% to 5% of the overall population in some studies; however, other

dentlearn.ir

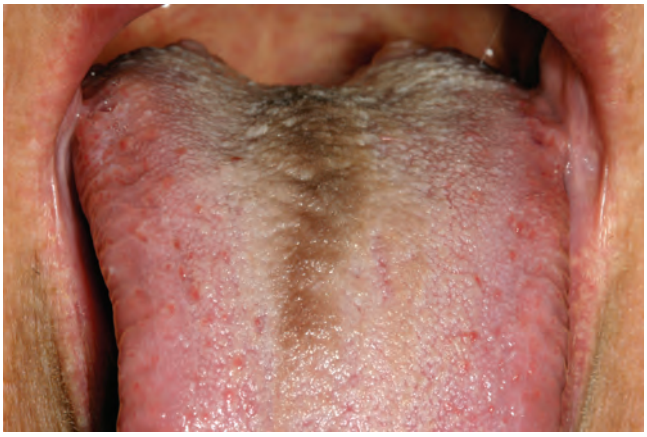
reports suggest prevalence rates as high as 20%–73%, probably related to the stringency of the diagnostic criteria. The condition may be seen in children or adults, but the prevalence and severity appear to increase with age, affecting as many as 30% of older adults. In some investigations, a male predilection has been noted.

A strong association has been found between fissured tongue and **geographic tongue** (see page 784) with many patients having both conditions. A hereditary basis also has been suggested for geographic tongue, and the same gene or genes may possibly be linked to both conditions. In fact, it even has been suggested that geographic tongue may *cause* fissured tongue. Fissured tongue also may be a component of **Melkersson-Rosenthal syndrome** (see page 330).

Histopathologic Features

Microscopic examination of fissured tongue reveals hyperplasia of the rete ridges and loss of the keratin "hairs" on the surface of the filiform papillae. The papillae vary in size and often are separated by deep grooves. Polymorphonuclear leukocytes can be seen migrating into the epithelium, often forming microabscesses in the upper epithelial layers. A mixed inflammatory cell infiltrate is present in the lamina propria. This overall pattern of inflammation is similar to that observed in erythema migrans and psoriasis.

Treatment and Prognosis



Fissured tongue is a benign condition, and no specific treatment is indicated. The patient should be encouraged to brush the tongue, because food or debris entrapped in the grooves may act as a source of irritation.

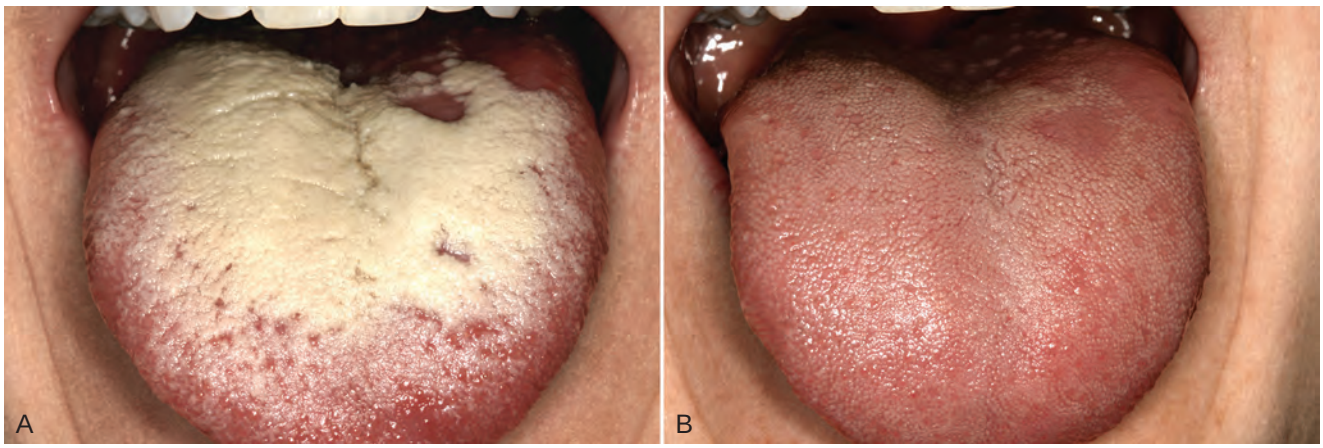
◆ HAIRY TONGUE (BLACK HAIRY TONGUE; COATED TONGUE)

Hairy tongue is characterized by marked accumulation of keratin on the filiform papillae of the dorsal tongue, resulting in a hairlike appearance. The condition apparently represents an increase in keratin production or a decrease in normal keratin desquamation. Depending on the population being studied, the prevalence of hairy tongue in adults ranges from 0.5% to 11.3%. Although the cause is uncertain, many affected people are heavy smokers. Other possible associated factors include general debilitation, poor oral hygiene, drugs that induce xerostomia, and a history of radiation therapy to the head and neck. Several reports have related transient development of hairy tongue with usage of the antibiotic linezolid.

Clinical Features

Hairy tongue most commonly affects the midline just anterior to the circumvallate papillae, sparing the lateral and anterior borders (Fig. 1.23). The elongated papillae are usually

• **Fig. 1.23 Hairy Tongue**. Elongated, brown filiform papillae on the midline dorsal surface of the tongue.



• **Fig. 1.24 Hairy Tongue**. Marked elongation and brown staining of the filiform papillae, resulting in a hairlike appearance.

brown, yellow, or black as a result of growth of pigment-producing bacteria or staining from tobacco and food. Sometimes most of the dorsal tongue may be involved, resulting in a thick, matted appearance (Fig. 1.24). Multiple individual elongated filiform papillae may be elevated by using gauze or a dental instrument. The condition is typically asymptomatic, although occasionally patients complain of a gagging sensation or a bad taste in the mouth. Because the diagnosis usually can be made from the clinical appearance, biopsy is unnecessary in most instances.

In some individuals, numerous bacteria and desquamated epithelial cells accumulate on the dorsal tongue surface, but without the hairlike filiform projections (Fig. 1.25). Such cases, which often are designated as a **coated tongue,** also may be a source of oral malodor. Coated tongue often is misdiagnosed as candidiasis and treated unnecessarily with antifungal medications.

dentlearn.ir

• **Fig. 1.25 Coated Tongue**. **A,** This patient had a severe outbreak of aphthous ulcers, which made routine oral hygiene difficult. The dorsal tongue has become white and markedly thickened from the accumulation of keratin and bacteria on the surface. **B,** After resolution of her oral ulcers plus improved hygiene, the tongue has returned to its normal appearance.

• **Fig. 1.26 Bismuth Staining**. Transitory staining of the posterior dorsal tongue after using bismuth subsalicylate for an upset stomach.

Transitory black staining of the dorsal tongue without elongation of the filiform papillae sometimes can occur in patients who use bismuth subsalicylate to control upset stomach. The bismuth in such preparations can react with trace amounts of sulfur in the saliva to form bismuth sulfide, which accumulates on the tongue surface (Fig. 1.26). However, this discoloration rapidly resolves after discontinuation of the medication.

Histopathologic Features

On histopathologic examination, hairy tongue is characterized by marked elongation and hyperparakeratosis of the filiform papillae (Fig. 1.27). Usually, numerous bacteria can be seen growing on the epithelial surface.

Treatment and Prognosis

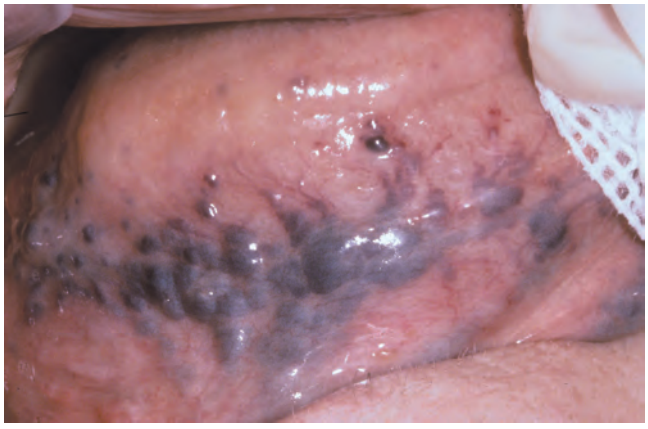
Hairy or coated tongue is a benign condition with no serious sequelae. The major concern is often the aesthetic appearance of the tongue along with possible associated bad breath. Any predisposing factors, such as tobacco, should be eliminated, and excellent oral hygiene should be encouraged. Periodic scraping or brushing with a toothbrush or tongue scraper can promote desquamation of the hyperkeratotic papillae and surface debris. Keratolytic agents, such as podophyllin, also have been tried with success, but for safety reasons their use probably should not be encouraged.

• **Fig. 1.27 Hairy Tongue**. Elongation and marked hyperkeratosis of the filiform papillae with bacterial accumulation on the surface.

Because of the similarity in names, care should be taken to avoid confusing hairy tongue with **hairy leukoplakia** (see page 253), which typically occurs on the lateral border of the tongue. Hairy leukoplakia is caused by the Epstein-Barr virus and usually is associated with human immunodeficiency virus (HIV) infection or other immunosuppressive conditions.

◆ VARICOSITIES (VARICES)

Varicosities, or **varices,** are abnormally dilated and tortuous veins. Age appears to be an important etiologic factor because varices are rare in children but common in older adults. This



dentlearn.ir

suggests that their development may be an age-related degeneration manifested by weakening of blood vessel walls and loss of tone in the supporting connective tissues. One study found that people with varicose veins of the legs are more likely to have varicosities of the tongue. Other related factors include a history of smoking, cardiovascular disease, hypertension, and cirrhosis.

Clinical Features

The most common type of oral varicosity is the **sublingual varix,** which occurs in two-thirds of people older than 60 years of age. Sublingual varicosities classically present as multiple blue-purple, elevated or papular blebs on the ventral and lateral border of the tongue (Fig. 1.28). The lesions usually are asymptomatic, except in rare instances when secondary thrombosis occurs.

Less frequently, solitary varices occur in other areas of the mouth, especially the lips and buccal mucosa. These isolated varicosities often are first noticed after they have become thrombosed (Fig. 1.29). Clinically, a thrombosed varix presents as a firm, nontender, blue-purple nodule that may feel like a BB beneath the mucosal surface.

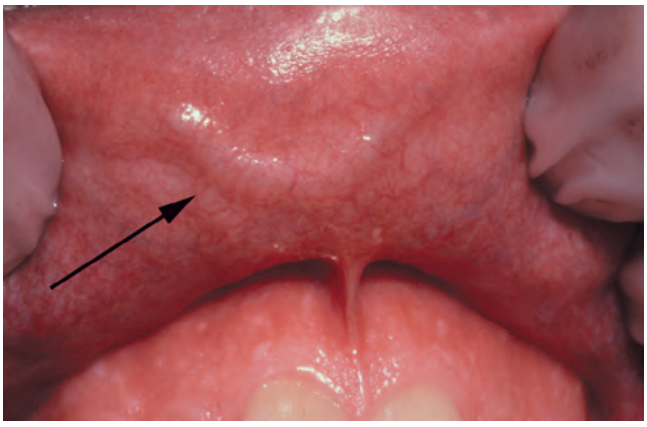
• **Fig. 1.28 Varicosities**. Multiple purple dilated veins on the ventral and lateral surface of the tongue.

• **Fig. 1.29 Varicosity**. Firm, thrombosed varix on the lower lip.

Histopathologic Features

Microscopic examination of a varix reveals a dilated vein, the wall of which shows little smooth muscle and poorly developed elastic tissue. If secondary thrombosis has occurred, then the lumen may contain concentrically layered zones of platelets and erythrocytes (lines of Zahn). The clot can undergo organization via granulation tissue with subsequent recanalization. Older thrombi may exhibit dystrophic calcification, resulting in formation of a **phlebolith** (*phlebo* = vein; *lith* = stone).

Treatment and Prognosis



Sublingual varicosities typically are asymptomatic, and no treatment is indicated. Solitary varicosities of the lips and buccal mucosa may need to be surgically removed to confirm the diagnosis or for aesthetic purposes.

◆ CALIBER-PERSISTENT ARTERY

A **caliber-persistent artery** is a common vascular anomaly in which a main arterial branch extends up into the superficial submucosal tissues without a reduction in its diameter. Similar to oral varices, caliber-persistent arteries are seen more frequently in older adults. This suggests that their development may be an age-related degenerative phenomenon in which there is a loss of tone in the surrounding supporting connective tissue.

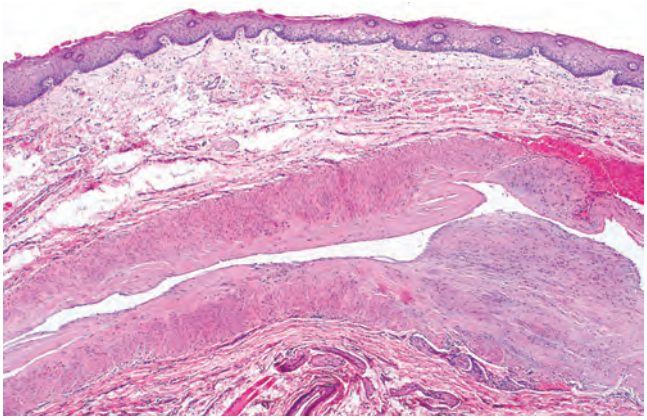
Clinical Features

The caliber-persistent artery occurs almost exclusively on the labial mucosa, especially on the upper lip. Some patients may have bilateral lesions or lesions on both lips. The average patient age is 58 years, and the gender ratio is nearly equal. The lesion presents as a linear, arcuate, or papular elevation that ranges from pale to normal to bluish in color (Fig. 1.30). Stretching the lip usually causes the artery to become inconspicuous. The unique feature is pulsation—not only vertically but also in a lateral direction. However, usually it is

• **Fig. 1.30 Caliber-Persistent Artery**. Linear, arcuate lesion on the upper labial mucosa *(arrow).* (Courtesy of Dr. John Lovas.)

dentlearn.ir

not possible to feel a pulse in a caliber-persistent artery with gloved fingers.



The lesion is usually asymptomatic, being discovered as an incidental finding during an oral examination; rarely a patient may notice a pulsatile lip nodule. A few cases have been associated with ulceration of the overlying mucosa. In addition, a couple of examples have been found adjacent to labial squamous cell carcinomas, although this is probably coincidental.

Histopathologic Features

Microscopic examination shows a thick-walled artery situated close to the mucosal surface (Fig. 1.31).

Treatment and Prognosis

If the true nature of the caliber-persistent artery can be recognized clinically, no treatment is necessary. Oftentimes a biopsy is performed when the lesion is mistaken for a mucocele or another vascular lesion, such as a varix or hemangioma. Brisk bleeding typically is encountered if the lesion is removed.

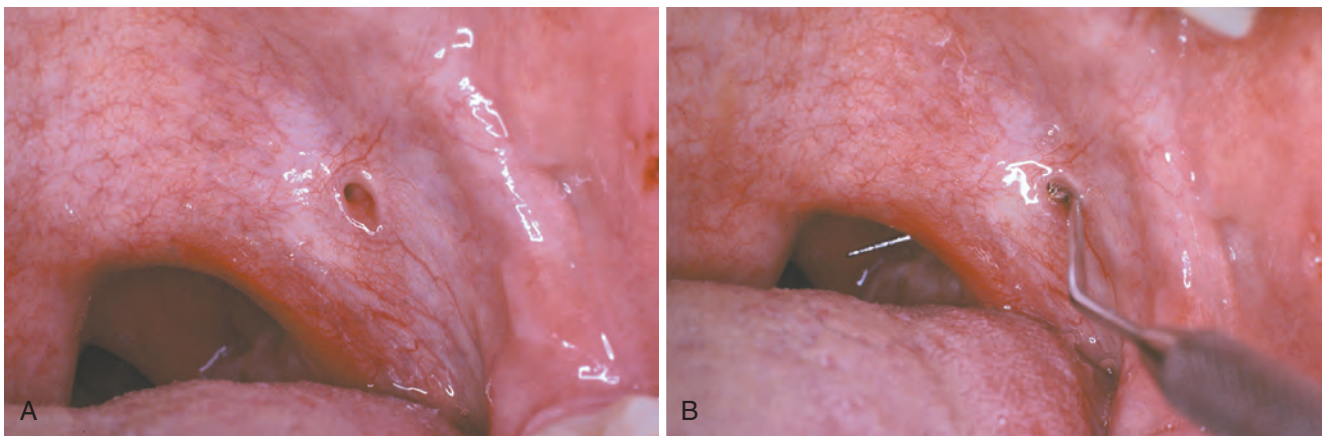
• **Fig. 1.31 Caliber-Persistent Artery**. Thick-walled artery located just beneath the mucosal surface.

◆ LATERAL SOFT PALATE FISTULAS

Lateral soft palate fistulas are rare anomalies of uncertain pathogenesis. Many cases appear to be congenital, possibly related to a defect in the development of the second pharyngeal pouch. Some fistulas may be the result of infection or surgery of the tonsillar region.

Clinical Features

Lateral soft palate fistulas usually are bilateral, but they may occur only on one side. They are more common on the anterior tonsillar pillar (Fig. 1.32), but they also may involve the posterior pillar. The perforations typically are asymptomatic, ranging from a few millimeters to more than 1 cm. A few cases have been associated with other anomalies, such as absence or hypoplasia of the palatine tonsils, hearing loss, and preauricular fistulas.



Treatment and Prognosis

The lesions are innocuous, and no treatment is necessary.

◆ CORONOID HYPERPLASIA

Hyperplasia of the coronoid process of the mandible is a rare developmental anomaly that may result in limitation of mandibular movement. The cause of **coronoid hyperplasia** is unknown, but the condition is three to five times more common in males than in females. Because most cases have been seen in pubertal males, an endocrine influence has been suggested. Heredity also may play a role, because cases have been noted in siblings.

Coronoid hyperplasia may be unilateral or bilateral, although bilateral cases are over four times more common than unilateral examples. Unilateral enlargement of the coronoid process also can result from a true tumor, such as an osteoma or osteochondroma, and such cases should be distinguished from pure coronoid hyperplasia. However, some

• **Fig. 1.32 Lateral Palatal Fistula**. **A,** Asymptomatic "hole" in the anterior tonsillar pillar. **B,** Periodontal probe has been used to demonstrate the communication of the lesion with the tonsillar fossa.

dentlearn.ir

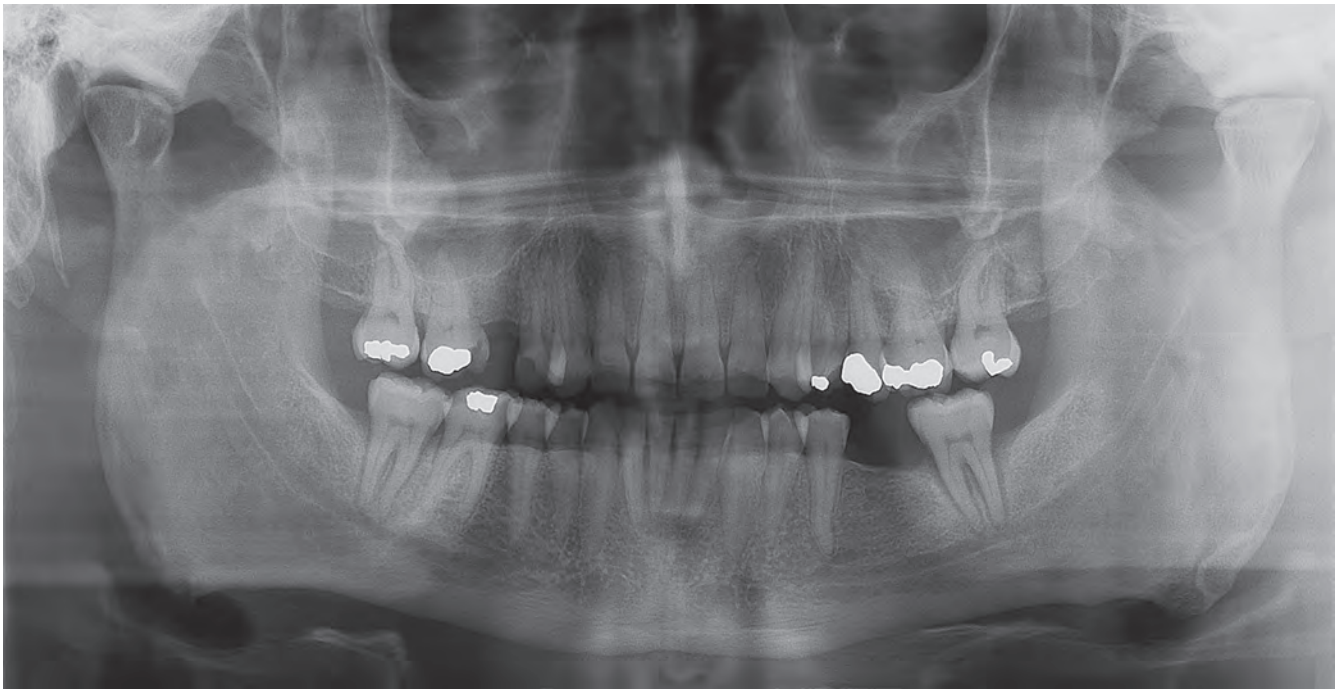
cases reported as tumors of the coronoid process actually may have been hyperplastic processes rather than true neoplasms.

Clinical and Radiographic Features

In a person with unilateral coronoid hyperplasia, the enlarged coronoid process impinges on the medial surface of the zygomatic arch, restricting mandibular opening. In addition, the mandible may deviate toward the affected side. Usually, there is no pain or associated abnormality in occlusion. Radiographs may reveal an irregular, nodular growth of the tip of the coronoid process.

In bilateral coronoid hyperplasia, the limitation of mandibular opening may progressively worsen over several years during childhood, reaching maximum severity during the late teens (Fig. 1.33). The radiographic appearance is characterized by regular elongation of both processes (Fig. 1.34). Because the coronoid process often is superimposed on the zygoma on conventional radiographs, CT scans often demonstrate the hyperplasia more effectively.

• **Fig. 1.33 Coronoid Hyperplasia**. Limited ability to open the mouth in a young man with bilateral hyperplasia of the coronoid processes.



Treatment and Prognosis

Treatment of coronoid hyperplasia consists of surgical removal of the elongated coronoid process or processes to allow freedom of mandibular motion. Coronoidectomy or coronoidotomy usually is accomplished via an intraoral approach. Although initial improvement in oral opening can be effected, the long-term results in some patients can be disappointing because of surgically induced fibrosis and the tendency for coronoid regrowth. Postoperative physiotherapy is important for reestablishing normal function.

◆ CONDYLAR HYPERPLASIA

Condylar hyperplasia is an uncommon malformation created by excessive growth of one or both of the mandibular condyles. The cause of this hyperplasia is unknown, but genetic factors, neoplasms, endocrine disturbances, and trauma have been suggested as possible etiologies. Table 1.1 summarizes two major classification systems.

Condylar hyperplasia can be difficult to distinguish from **hemifacial hyperplasia** (see page 37); however, in the latter condition the associated soft tissues and teeth also may be enlarged.

• **Fig. 1.34 Coronoid Hyperplasia**. Panoramic radiograph of patient depicted in Fig. 1.33, which shows bilateral elongation of the coronoid processes.

dentlearn.ir

TABLE 1.1 Classification of Condylar Hyperplasia

Authors	Category	Clinical Features
Obwegeser and Makek		
	Hemimandibular Hyperplasia	Primarily vertical overgrowth
	Hemimandibular Elongation	Primarily horizontal overgrowth with lateral mandibular displacement
	Hybrid	Combined features of both above types
Wolford et al.		
	Type 1 Type 1A Type 1B	Accelerated and prolonged aberration of "normal" condylar growth mechanism Bilateral Unilateral
	Type 2 Type 2A Type 2B	Unilateral condylar growth caused by an osteochondroma Predominantly vertical elongation and enlargement of the condyle Horizontal exophytic tumor growth from the condyle
	Type 3	Other benign tumors causing condylar enlargement
	Type 4	Malignant tumors causing enlargement of the condyle

• **Fig. 1.35 Condylar Hyperplasia**. Enlargement of the patient's right condyle has resulted in facial asymmetry.

Clinical and Radiographic Features

Condylar hyperplasia may manifest itself in a variety of ways, including facial asymmetry, prognathism, crossbite, and open bite (Fig. 1.35). Sometimes compensatory maxillary growth and tilting of the occlusal plane occurs. The condition most commonly is discovered in adolescents and young adults. Several studies have shown a significant female predilection, with an overall female-to-male ratio of approximately 3:1.

The radiographic features are quite variable. Some patients have an enlargement of the condylar head, and others show elongation of the condylar neck (Fig. 1.36). Many cases also demonstrate hyperplasia of the entire ramus, suggesting that the condition sometimes affects more than just the condyle. Other examples show a tumorlike mass (e.g., osteochondroma) affecting the condylar head. Single-photon emission computed tomography (SPECT) and scintigraphy using ^{99m}Tc-methylenediphosphonate (MDP) have been advocated as useful methods for assessing the degree of bone activity in condylar hyperplasia.

Histopathologic Features

Some cases will show an appearance that is similar to a normally growing condyle. Other examples will exhibit a nodular bony mass with a thickened cartilaginous cap consistent with an osteochondroma.

Treatment and Prognosis

Condylar hyperplasia is a self-limiting condition, and treatment is determined by the degree of functional difficulty and aesthetic change. Some patients can be treated with condylectomy, whereas others require unilateral or bilateral mandibular osteotomies. In patients with compensatory maxillary growth, a maxillary osteotomy also may be needed. Concomitant orthodontic therapy frequently is necessary.

◆ CONDYLAR HYPOPLASIA

Condylar hypoplasia, or underdevelopment of the mandibular condyle, can be either congenital or acquired. **Congenital condylar hypoplasia** often is associated with head and neck syndromes, including **mandibulofacial dysostosis** (see page 43), **oculoauriculovertebral syndrome (Goldenhar syndrome),** and **hemifacial microsomia**. In the most severe cases, complete agenesis of the condyle or ramus **(condylar aplasia)** is seen.

Acquired condylar hypoplasia results from disturbances of the growth center of the developing condyle. The most frequent cause is trauma to the condylar region during infancy or childhood. Other causes include infections, radiation therapy, and rheumatoid or degenerative arthritis.

dentlearn.ir

• **Fig. 1.36 Condylar Hyperplasia**. Panoramic radiograph of patient seen in Fig. 1.35, which shows prominent enlargement of the right mandibular condyle.

• **Fig. 1.37 Condylar Hypoplasia**. Panoramic radiograph showing bilateral hypoplasia of the mandibular condyles. (Courtesy of Dr. Rachel Sanyk.)

Clinical and Radiographic Features

Condylar hypoplasia can be unilateral or bilateral, producing a small mandible with a Class II malocclusion. Unilateral hypoplasia results in distortion and depression of the face on the affected side. The mandibular midline shifts to the involved side when the mouth is opened, accentuating the deformity. Ankylosis of the temporomandibular joint (TMJ) can develop in cases caused by trauma.

The deformity is observed easily on panoramic films and can range in severity (Fig. 1.37). In severe cases the condyle

dentlearn.ir

or ramus may be totally absent. Milder types demonstrate a short condylar process, shallow sigmoid notch, and poorly formed condylar head. A prominent antegonial notch may be present. CT scans may be helpful in evaluating the condyles.

Treatment and Prognosis

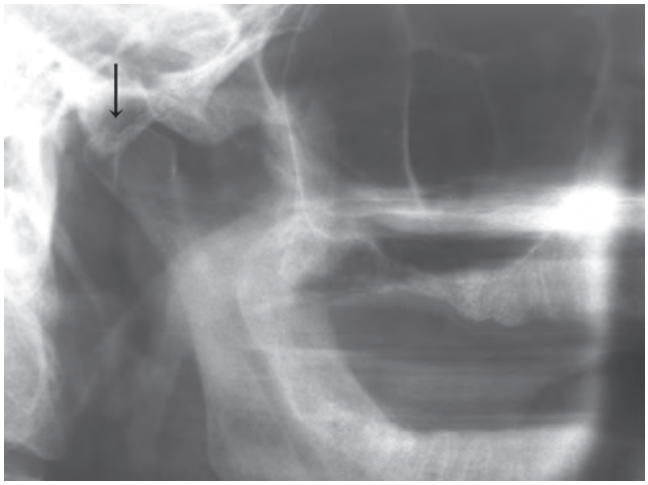
Treatment of the patient with condylar hypoplasia depends on the cause and severity of the defect, but surgery often is required. If the condyle is missing, then a costochondral rib graft can be placed to help establish an active growth center. In addition, osteotomies sometimes provide a cosmetically acceptable result. In certain instances, distraction osteogenesis can be used to stimulate new bone formation.

◆ BIFID CONDYLE

A **bifid condyle** is an uncommon developmental anomaly characterized by a double-headed mandibular condyle. The prevalence ranges from 0.31% to 1.82% in published reports. Most bifid condyles have a medial and lateral head divided by an anteroposterior groove. Some condyles may be divided into an anterior and posterior head.

The cause of bifid condyle is uncertain. Anteroposterior bifid condyles may be of traumatic origin, such as a childhood fracture. Mediolaterally divided condyles may result from trauma, abnormal muscle attachment, teratogenic agents, or persistence of a fibrous septum within the condylar cartilage.

Clinical and Radiographic Features



A bifid condyle usually is unilateral, but occasionally both sides may be affected. The malformation is often asymptomatic and may be discovered on routine radiographs, although some patients may have a "pop" or "click" of the TMJ when opening their mouths. Other patients may experience pain, hypomobility, or ankylosis. Panoramic radiographs and CT scans demonstrate a bilobed appearance of the condylar head (Fig. 1.38). Extremely rare examples of trifid and tetrafid condyles also have been reported.

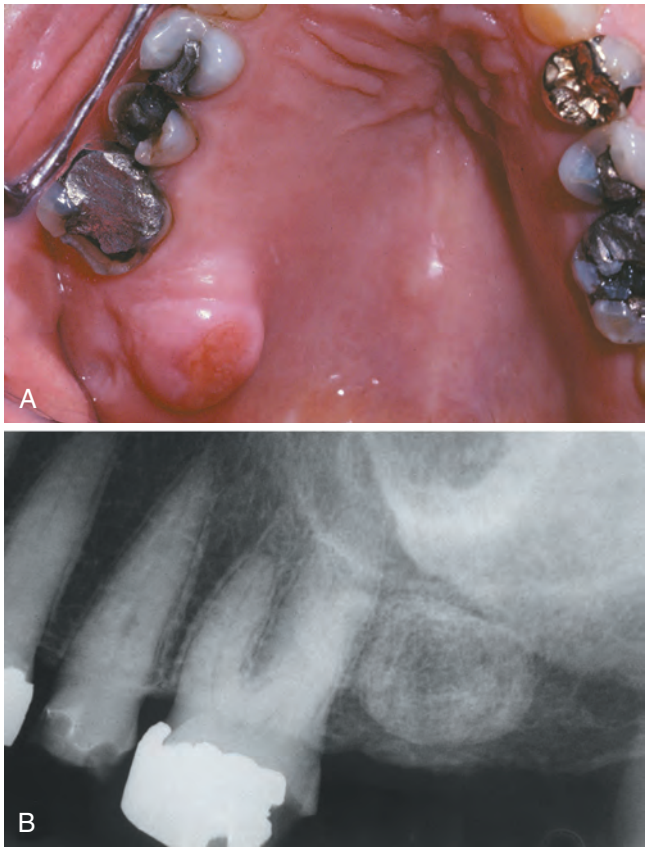
Treatment and Prognosis

Because a bifid condyle is usually asymptomatic, no treatment is necessary in most instances. If the patient has joint complaints, the appropriate temporomandibular therapy may be required.

◆ EXOSTOSES

Exostoses are localized bony protuberances that arise from the cortical plate. These benign growths frequently affect the jaws and may be related to stresses placed on the bone from the function of teeth. The best-known oral exostoses, the **torus palatinus** and the **torus mandibularis,** are described later in this chapter. Other types of exostoses also may affect the jaws and are considered here.

• **Fig. 1.38 Bifid Condyle**. Radiograph of the mandibular condyle showing a double head *(arrow).*



• **Fig. 1.39 Exostoses**. Multiple buccal exostoses of the maxillary and mandibular alveolar ridges.

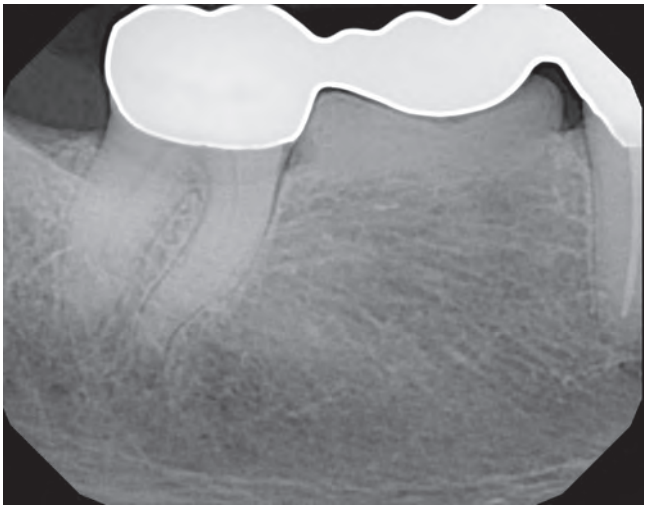
Clinical and Radiographic Features

Exostoses are discovered most often in adults. **Buccal exostoses** occur as a bilateral row of bony hard nodules along the facial aspect of the maxillary and/or mandibular alveolar ridge (Fig. 1.39). They usually are asymptomatic, unless the thin overlying mucosa becomes ulcerated from trauma. One study reported that buccal exostoses were found in nearly 1 of every 1000 adults (0.09%); however, a more recent survey found a much higher prevalence of nearly 19%. This variation may be due to the different populations being studied or to the clinical criteria used to make the diagnosis.

Palatal exostoses (palatal tubercles) are similar bony protuberances that develop from the lingual aspect of the maxillary tuberosities. These lesions usually are bilateral but may affect only one side (Fig. 1.40). They are more common in males and have been reported in 8%–69% of various

dentlearn.ir

• **Fig. 1.40 Exostosis**. **A,** Secondarily ulcerated palatal exostosis. **B,** Radiograph shows an ovoid radiopacity distal to the molar.



• **Fig. 1.41 Palatal Exostoses and Torus Palatinus**. Massive bilateral palatal exostoses in a patient with a large palatal torus.

populations. Many patients with buccal or palatal exostoses also will have palatal or mandibular tori (Fig. 1.41).

Less commonly, **solitary exostoses** may occur, possibly in response to local irritation. Such lesions may develop from the alveolar bone beneath free gingival grafts and skin grafts. Presumably placement of the graft acts as a stimulant to the periosteum to form new bone.

Another uncommon, interesting variant is the **reactive subpontine exostosis (subpontic osseous proliferation,**

• **Fig. 1.42 Reactive Subpontine Exostosis**. Nodular growth of dense bone beneath the pontic of a posterior mandibular bridge. (Courtesy of Dr. Ed Murphy.)

subpontic osseous hyperplasia), which may develop from the alveolar crestal bone beneath the pontic of a posterior bridge (Fig. 1.42).

If enough excess bone is present, exostoses may exhibit a relative radiopacity on dental radiographs (see Fig. 1.40, *B*). In rare instances an exostosis may become so large that distinguishing it from a tumor, such as an osteoma, is difficult (see page 655).

Histopathologic Features

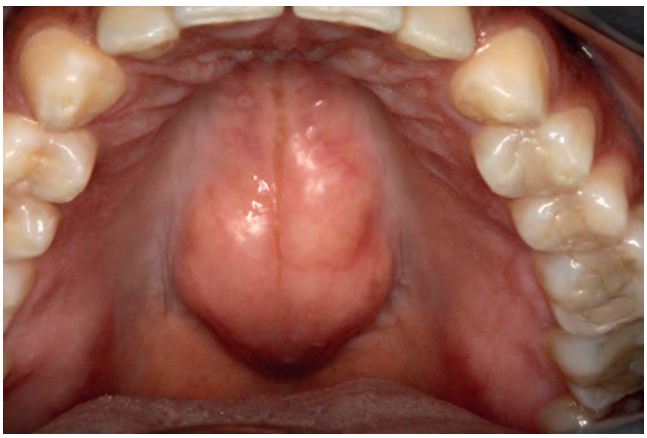
Microscopic examination reveals a mass of dense, lamellar, cortical bone with a small amount of fibrofatty marrow. In some cases an inner zone of trabecular bone also is present.

Treatment and Prognosis

Most exostoses are distinctive enough clinically to make biopsy unnecessary. If the diagnosis is uncertain, biopsy should be performed to rule out other bony pathosis. Sometimes the exostosis must be removed if it repeatedly has been exposed to trauma or has become ulcerated and painful. In addition, surgical removal may be required to accommodate a dental prosthesis or to allow for proper flap adaptation during periodontal surgery. Reactive subpontine exostoses may need to be removed if they interfere with oral hygiene or are associated with adjacent periodontal disease. Exostoses that develop secondary to adjacent tooth function may recur after removal if the teeth creating the stresses remain in place.

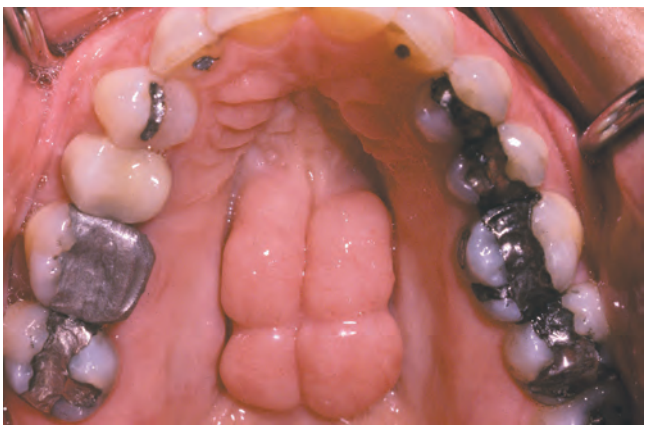
◆ TORUS PALATINUS

The **torus palatinus** is a common exostosis that occurs in the midline of the vault of the hard palate. The pathogenesis of these tori has long been debated with arguments centering on genetic versus environmental factors, such as masticatory stress. Some authorities have suggested that the torus



dentlearn.ir

palatinus is inherited as an autosomal dominant trait. However, others believe that the development of this lesion is multifactorial, including both genetic and environmental influences. In this model, patients are affected by a variety of hereditary and local environmental factors. If enough of these factors are present, then a "threshold" is surpassed and the trait (torus palatinus) is expressed.



Clinical and Radiographic Features

The torus palatinus presents as a bony hard mass that arises along the midline suture of the hard palate (Figs. 1.43 and 1.44). Tori sometimes are classified according to their morphologic appearance:

- The **flat torus** has a broad base and a slightly convex, smooth surface. It extends symmetrically onto both sides of the midline raphe.
- The **spindle torus** has a midline ridge along the palatal raphe. A median groove is sometimes present.
- The **nodular torus** arises as multiple protuberances, each with an individual base. These protuberances may coalesce, forming grooves between them.
- The **lobular torus** is also a multilobulated mass, but it rises from a single base. Lobular tori can be either sessile or pedunculated.

• **Fig. 1.43 Torus Palatinus**. Midline bony nodule of the palatal vault.

• **Fig. 1.44 Torus Palatinus**. Large, lobulated palatal mass.

Most palatal tori are small, measuring less than 2 cm in diameter; however, they can slowly increase in size throughout life—sometimes to the extent that they fill the entire palatal vault. Most tori cause no symptoms, but in some cases the thin overlying mucosa may become ulcerated secondary to trauma.

The torus palatinus usually does not appear on routine dental radiographs. Rarely, it may be seen as a radiopacity on periapical films if the film is placed behind the torus when the radiograph is taken.

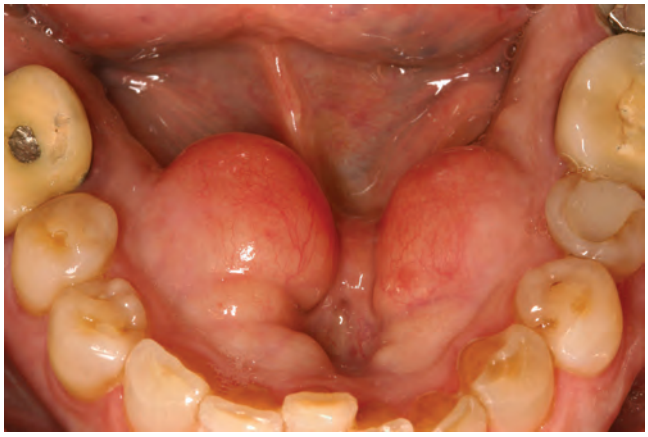
The prevalence of palatal tori has varied widely in a number of population studies, ranging from 4% to 60%. Some of this variation may be due to the criteria used to make the diagnosis and also may be based on whether the study was conducted on live patients or skulls. There appear to be significant racial differences, however, with a higher prevalence in Asian and Inuit populations. In the United States, most studies have shown a prevalence of 20%–35%, although these figures likely include a significant number of relatively small lesions. Almost all studies from around the world have shown a pronounced female-to-male ratio of 2:1. The prevalence peaks during early adult life, tapering off in later years. This finding supports the theory that tori are dynamic lesions that are related, in part, to environmental factors; in later life, some may undergo resorption remodeling in response to decreased functional stresses.

Histopathologic Features

Microscopic examination of the torus shows a mass of dense, lamellar, cortical bone. An inner zone of trabecular bone sometimes is seen.

Treatment and Prognosis

Most palatal tori can be diagnosed clinically based on their characteristic appearance; therefore biopsy rarely is necessary. In edentulous patients, the torus may need to be removed surgically to accommodate a denture base. Surgical removal also may be indicated for palatal tori that repeatedly become ulcerated or that interfere with oral function. It also should be noted that palatal tori are prone to medication-related osteonecrosis (see page 286).



◆ TORUS MANDIBULARIS

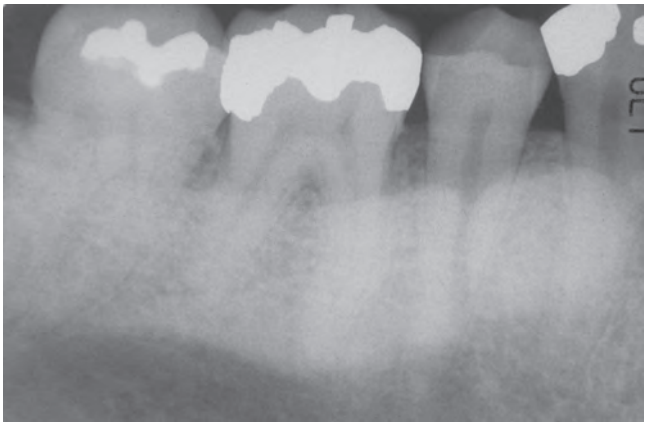
The **torus mandibularis** is a common exostosis that develops along the lingual aspect of the mandible. As with torus palatinus, the cause of mandibular tori probably is multifactorial, including both genetic and environmental influences.

Clinical and Radiographic Features

The mandibular torus presents as a bony protuberance along the lingual aspect of the mandible above the mylohyoid line in the region of the premolars (Fig. 1.45). Bilateral involvement occurs in more than 90% of cases. Most mandibular

dentlearn.ir

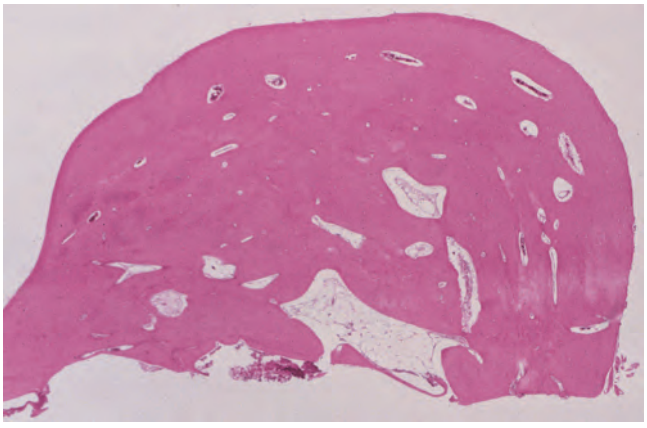
• **Fig. 1.45 Torus Mandibularis**. Bilateral lobulated bony protuberances of the mandibular lingual alveolar ridge.



• **Fig. 1.46 Torus Mandibularis**. Massive "kissing" tori meet in the midline.

tori occur as single nodules, although multiple lobules paralleling the teeth are not unusual. Patients often are unaware of their presence unless the overlying mucosa becomes ulcerated secondary to trauma. In rare instances, bilateral tori may become so large that they almost meet in the midline (Fig. 1.46). A large mandibular torus may appear on periapical radiographs as a radiopacity superimposed on the roots of the teeth (Fig. 1.47), especially on anterior films. Mandibular tori are easily visualized on occlusal radiographs (Fig. 1.48).

Most studies indicate that the torus mandibularis is not as common as the torus palatinus; the prevalence ranges from 3% to 58%. Like the torus palatinus, the mandibular torus appears to be more common in Asians and the Inuit. The prevalence in the United States ranges from 7% to 10% with little difference between blacks and whites. A slight male predilection has been noted.



The prevalence of mandibular torus peaks in early adult life, tapering slightly in later years. In addition, the prevalence has been correlated with both bruxism and the number of teeth remaining present. These findings support the theory that the torus mandibularis is multifactorial in development and responds to functional stresses.

• **Fig. 1.47 Torus Mandibularis**. Torus is causing a radiopacity that is superimposed over the roots of the mandibular teeth.

• **Fig. 1.48 Torus Mandibularis**. Occlusal radiograph showing bilateral mandibular tori.

• **Fig. 1.49 Torus Mandibularis**. Nodular mass of dense, cortical bone. Some fatty marrow is visible at the base of the specimen.

Histopathologic Features

The histopathologic appearance of the torus mandibularis is similar to that of other exostoses, consisting primarily of a nodular mass of dense, cortical lamellar bone (Fig. 1.49). An inner zone of trabecular bone with associated fatty marrow sometimes is visible.

dentlearn.ir

Treatment and Prognosis

Most mandibular tori are easily diagnosed clinically, and no treatment is necessary. However, surgical removal may be required to accommodate a lower full or partial denture. Occasionally, tori may recur if teeth are still present in the area.

◆ EAGLE SYNDROME (STYLOHYOID SYNDROME; STYLOCAROTID SYNDROME; STYLALGIA)

The styloid process is a slender bony projection that originates from the inferior aspect of the temporal bone, anterior and medial to the stylomastoid foramen. It is connected to the lesser cornu of the hyoid bone by the stylohyoid ligament. The external and internal carotid arteries lie on either side. Elongation of the styloid process or mineralization of the stylohyoid ligament complex is not unusual, having been reported in 18%–84% of the population with an increasing incidence with advancing age. Such mineralization is usually bilateral, but it may affect only one side. Most cases are asymptomatic; however, it is estimated that 4%–10% of patients with elongation of the styloid process experience symptoms of **Eagle syndrome,** caused by impingement or compression of adjacent nerves or blood vessels.

Clinical and Radiographic Features

Eagle syndrome most commonly affects adults, occurring more often in women than men. The patient experiences vague facial pain, especially while swallowing, turning the head, or opening the mouth. Other symptoms may include dysphagia, dysphonia, otalgia, headache, dizziness, syncope, and transient ischemic attacks.

Elongation of the styloid process or mineralization of the stylohyoid ligament complex can be seen on panoramic or lateral-jaw radiographs (Fig. 1.50). The mineralized stylohyoid complex may be palpated in the tonsillar fossa area, and pain often is elicited.

Classic Eagle syndrome occurs after a tonsillectomy. Development of scar tissue in the area of a mineralized stylohyoid complex then results in cervicopharyngeal pain in the region of cranial nerves V, VII, IX, and X, especially during swallowing. Some authors reserve the term *Eagle syndrome* only for those cases in which the ossification of the stylohyoid chain occurs as a result of the tonsillectomy or other neck trauma.

A second form of this condition unrelated to tonsillectomy is known as **stylocarotid syndrome**. The elongated, mineralized complex is thought to impinge on the internal or external carotid arteries and associated sympathetic nerve fibers. The patient may complain of pain in the neck when turning the head, and this pain may radiate to other sites in the head or neck. Less commonly, compression of the internal carotid artery can lead to transient ischemic attacks, stroke, and even internal carotid artery dissection.

• **Fig. 1.50 Eagle Syndrome**. Mineralization of the stylohyoid ligament is visible posterior to the mandibular ramus.

Traumatic Eagle syndrome also has been reported, in which symptoms develop after fracture of a mineralized stylohyoid ligament.

Treatment and Prognosis

Treatment of Eagle syndrome depends on the severity of the symptoms. For mild cases, no treatment may be necessary (except reassurance of the patient). Local injection of corticosteroids sometimes provides relief. In more severe cases, partial surgical excision of the elongated styloid process or mineralized stylohyoid ligament is required. This can be accomplished via either an intraoral or transcervical approach. The prognosis is generally good. Rare examples of stylocarotid syndrome that result in internal carotid artery dissection may require balloon angioplasty and stent placement.

◆ STAFNE DEFECT (STAFNE BONE CYST; LINGUAL MANDIBULAR SALIVARY GLAND DEPRESSION; LATENT BONE CYST; STATIC BONE CYST; STATIC BONE DEFECT; LINGUAL CORTICAL MANDIBULAR DEFECT)

In 1942, Stafne described a series of asymptomatic radiolucent lesions located near the angle of the mandible. Subsequent reports of similar lesions have shown that this condition represents a focal concavity of the cortical bone on the lingual surface of the mandible. In most cases, biopsy has revealed histologically normal salivary gland tissue, suggesting that these lesions represent developmental defects

dentlearn.ir

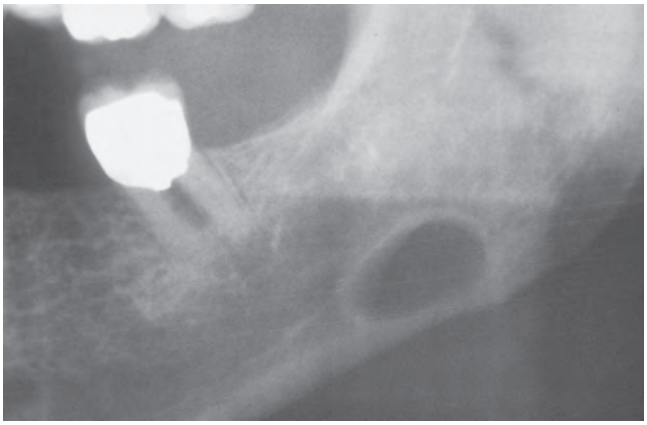
containing a portion of the submandibular gland. However, a few of these defects have been reported to be devoid of contents or to contain muscle, fibrous connective tissue, blood vessels, fat, or lymphoid tissue.

Similar lingual cortical defects also have been noted more anteriorly in the mandible, in the area of the incisor, canine, or premolar teeth. These rare defects have been related to the sublingual gland or to aberrant salivary gland tissue. In addition, a few reports have implicated the parotid gland as the cause of an apparent cortical defect in the upper mandibular ramus. Therefore, all of the major salivary glands appear to be capable of causing such cortical concavities.

In rare examples, the radiolucent defect has been reported to be totally surrounded by intact bone. Such cases might be explained by entrapment of embryonic salivary gland tissue within the jawbone.

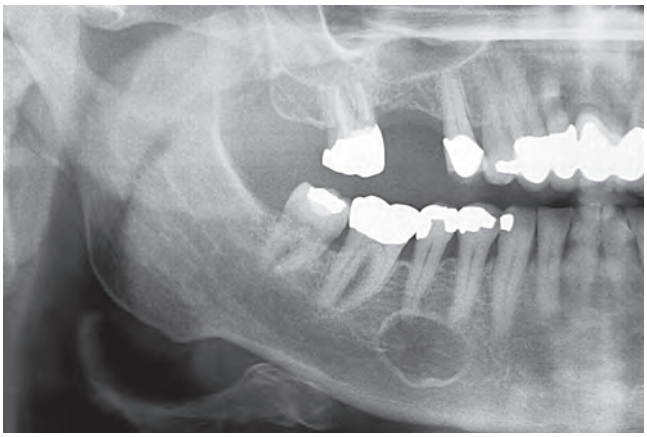
Clinical and Radiographic Features

The classic **Stafne defect** presents as an asymptomatic radiolucency below the mandibular canal in the posterior mandible, between the molar teeth and the angle of the mandible (Fig. 1.51). The lesion is typically well circumscribed and has a sclerotic border. Sometimes the defect may interrupt the continuity of the inferior border of the mandible, with a palpable notch observed clinically in this area. Most Stafne defects are unilateral, although bilateral cases may be seen. Anterior defects associated with the sublingual gland present as well-defined radiolucencies that may appear superimposed over the apices of the anterior or premolar teeth (Fig. 1.52). A parotid defect appears as a circumscribed radiolucency in the mandibular ramus (Fig. 1.53).



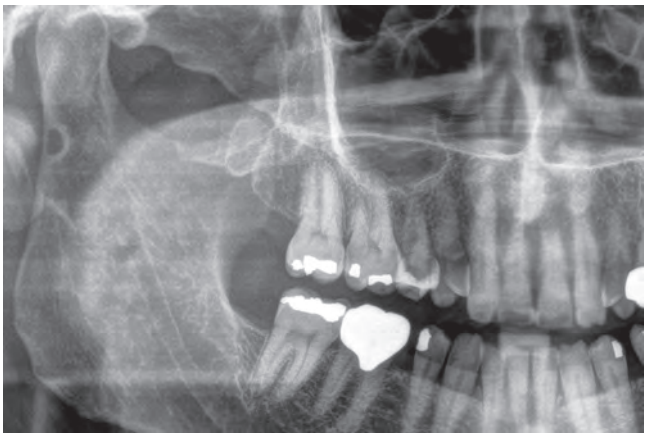
Stafne defects are not rare, having been reported in 0.08%–0.48% of panoramic radiographs. A striking male predilection is observed, with 80%–90% of all cases seen in men.

Although the defect is believed to be developmental in nature, it does not appear to be present from birth. Most cases have been reported in middle-aged and older adults, with children rarely affected; this implies that the lesion usually "develops" at a later age. Stafne defects typically remain stable in size; hence the name **static bone cyst**. In a few cases, however, the lesion has increased in size over time (Fig. 1.54). This also indicates that these lesions are not congenital.



The diagnosis usually can be made on a clinical basis by the typical radiographic location and lack of symptoms. If the clinical diagnosis is in doubt, then it can be confirmed by conventional CT scans, cone beam CT, MRI, or sialography. CT scans and MRIs show a well-defined concavity on the lingual surface of the mandible. Sialograms may be able to demonstrate the presence of salivary gland tissue in the area of the defect.

Histopathologic Features



Because of the typical radiographic appearance, biopsy usually is not necessary to establish the diagnosis of Stafne defects of the posterior mandible. If biopsy is performed, normal submandibular gland tissue often is found. However, some defects are devoid of tissue or contain muscle, blood vessels, fat, connective tissue, or lymphoid tissue. In cases reported to be devoid of contents, it is possible that the gland was simply displaced at the time of biopsy.

A,** Ill-defined radiolucency near the angle of the mandible. **B,** Appearance of the same defect several years later showing enlargement of the lesion. **C,** Computed tomography (CT) image of the same lesion showing a left lingual cortical defect *(arrow).* (Courtesy of Dr. Carroll Gallagher.)

Treatment and Prognosis

No treatment is necessary for patients with Stafne defects, and the prognosis is excellent. If the diagnosis is in question on plain films, appropriate CT imaging studies can confirm the presence of a well-defined, cupped-out lingual cortical defect, allowing a presumptive diagnosis to be made on a radiographic basis. Because anterior lingual salivary defects are more difficult to recognize, the diagnosis often is not suspected, and biopsy may be done to rule out other pathologic lesions.

DEVELOPMENTAL CYSTS

By definition, a **cyst** is a pathologic cavity (often fluid-filled) that is lined by epithelium. A number of different developmental cysts of the head and neck have been described. Some of these have been considered historically as "fissural" cysts because they were thought to arise from epithelium entrapped along embryonal lines of fusion. However, the concept of a fissural origin for many of these cysts has been questioned in more recent years. In many instances the exact pathogenesis of these lesions is still uncertain. Regardless of their origin, once cysts develop in the oral and maxillofacial region, they tend to slowly increase in size, possibly in response to a slightly elevated hydrostatic luminal pressure.

◆ PALATAL CYSTS OF THE NEWBORN (EPSTEIN'S PEARLS; BOHN'S NODULES)

Small developmental cysts are a common finding on the palate of newborn infants. Researchers have theorized that these "inclusion" cysts may arise in one of two ways. First, as the palatal shelves meet and fuse in the midline during embryonic life to form the secondary palate, small islands of epithelium may become entrapped below the surface along the median palatal raphe and form cysts. Second, these cysts may arise from epithelial remnants derived from the development of the minor salivary glands of the palate.

As originally described, **Epstein's pearls** occur along the median palatal raphe and presumably arise from epithelium entrapped along the line of fusion. **Bohn's nodules** reportedly arise along the lingual and buccal aspects of the alveolar ridge, often near the soft palate junction, and are believed to be derived from the minor salivary glands. However, these two terms have been used almost interchangeably in the literature and also have often been used to describe gingival cysts of the newborn (see page 697), similar-appearing lesions of dental lamina origin. Therefore, the term **palatal cysts of the newborn** may be preferable to help distinguish them from gingival cysts of the newborn. In addition, because these cysts are most common near the midline at the junction of the hard and soft palates, it is usually difficult to ascertain clinically whether they are arising from epithelium entrapped by fusion of the palate or from the developing minor salivary glands.

dentlearn.ir

Clinical Features

Palatal cysts of the newborn are quite common and have been reported in as many as 55%–85% of neonates. The cysts are small, 1- to 3-mm, white or yellow-white papules that appear most often along the midline near the junction of the hard and soft palates (Fig. 1.55). Occasionally, they may occur in a more anterior location along the raphe or on the posterior palate lateral to the midline. Frequently a cluster of two to six cysts is observed, although the lesions also can occur singly.

Histopathologic Features

Microscopic examination reveals keratin-filled cysts that are lined by stratified squamous epithelium. Sometimes these cysts demonstrate a communication with the mucosal surface.

Treatment and Prognosis

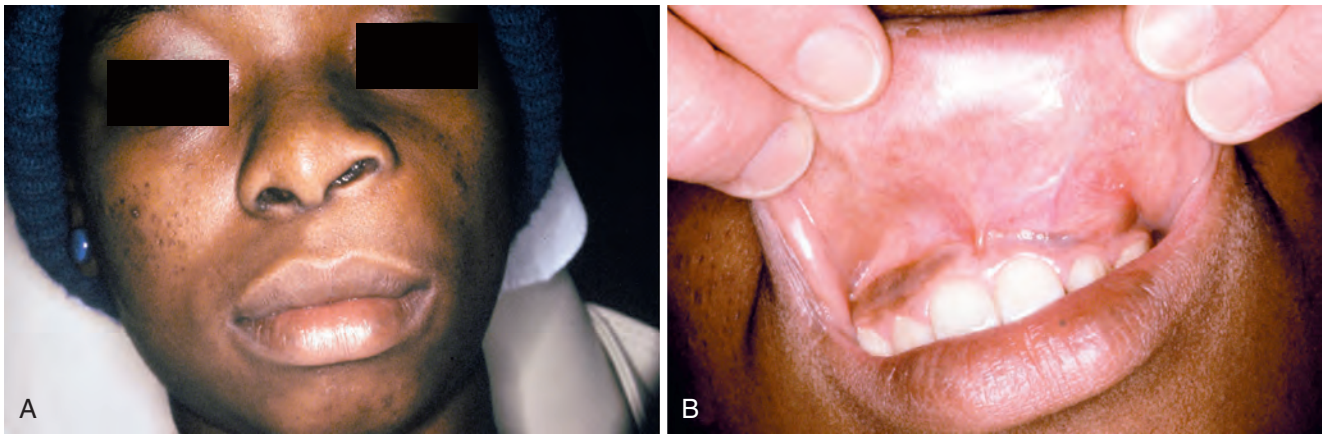
Palatal cysts of the newborn are innocuous lesions, and no treatment is required. They are self-healing and rarely observable several weeks after birth. Presumably the epithelium degenerates, or the cysts rupture onto the mucosal surface and eliminate their keratin contents.

• **Fig. 1.55 Epstein's Pearls**. Small keratin-filled cysts at the junction of the hard and soft palates. (Courtesy of Tristan Neville.)

◆ NASOLABIAL CYST (NASOALVEOLAR CYST; KLESTADT CYST)

The **nasolabial cyst** is a rare developmental cyst that occurs in the upper lip lateral to the midline. The pathogenesis is uncertain, although there are two major theories. One theory considers the nasolabial cyst to be a "fissural" cyst arising from epithelial remnants entrapped along the line of fusion of the maxillary, medial nasal, and lateral nasal processes. A second theory suggests that these cysts develop from misplaced epithelium of the nasolacrimal duct because of their similar location and histologic appearance.

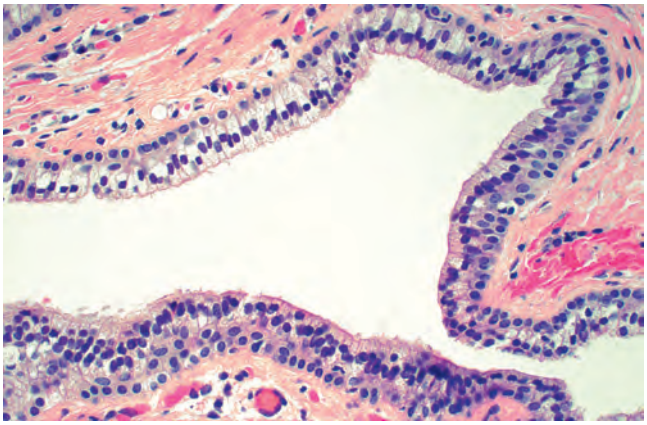
Clinical and Radiographic Features



The nasolabial cyst usually appears as a swelling of the upper lip lateral to the midline, resulting in elevation of the ala of the nose. The enlargement often elevates the mucosa of the nasal vestibule and obliterates the maxillary mucolabial fold (Fig. 1.56). On occasion, this expansion may result in nasal obstruction or may interfere with the wearing of a denture. Pain is uncommon unless the lesion is secondarily infected. The cyst may rupture spontaneously and may drain into the oral cavity or nose.

Nasolabial cysts are most commonly seen in adults, with peak prevalence in the fourth and fifth decades of life. A significant predilection exists for women, with a female-to-male ratio of 3.6: 1. Approximately 10% of the reported cases have been bilateral.

Because the nasolabial cyst arises in soft tissues, in most cases no bony radiographic changes are seen. Occasionally, pressure resorption of the underlying bone may occur.



Histopathologic Features

The nasolabial cyst is characteristically lined by pseudostratified columnar epithelium, often demonstrating goblet cells and cilia (Fig. 1.57). Areas of cuboidal epithelium and squamous metaplasia are not unusual. Apocrine changes also have

• **Fig. 1.56 Nasolabial Cyst**. **A,** Enlargement of the left upper lip with elevation of the ala of the nose. **B,** Intraoral swelling fills the maxillary labial fold. (Courtesy of Dr. Jim Weir.)

dentlearn.ir

• **Fig. 1.57 Nasolabial Cyst**. Pseudostratified columnar epithelial lining.

been reported. The cyst wall is composed of fibrous connective tissue with adjacent skeletal muscle. Inflammation may be seen if the lesion is secondarily infected.

Treatment and Prognosis

Complete surgical excision of the cyst via an intraoral approach has been the traditional treatment of choice. Because the lesion is often close to the floor of the nose, it is sometimes necessary to sacrifice a portion of the nasal mucosa to ensure total removal. However, an alternative transnasal approach has been developed that allows endoscopic marsupialization of the lesion, converting the cyst into an air-containing sinus with its opening on the nasal floor. Recurrence is rare.

◆ "GLOBULOMAXILLARY CYST"

As originally described, the "**globulomaxillary cyst**" was purported to be a fissural cyst that arose from epithelium entrapped during fusion of the globular portion of the medial nasal process with the maxillary process. This concept has been questioned, however, because the globular portion of the medial nasal process is primarily united with the maxillary process and a fusion does not occur. Therefore, epithelial entrapment should not occur during embryologic development of this area.

Virtually all cysts in the globulomaxillary region (between the lateral incisor and canine teeth) can be explained on an odontogenic basis. Many are lined by inflamed stratified squamous epithelium and are consistent with **periapical cysts** (see page 126). Some exhibit specific histopathologic features of an **odontogenic keratocyst** (see page 689) or developmental **lateral periodontal cyst** (see page 699). On rare occasions, cysts in the globulomaxillary area may be lined by pseudostratified, ciliated, columnar epithelium. Such cases may lend credence to the fissural theory of origin. However, this epithelium may be explained by the close proximity of the sinus lining. In addition, respiratory epithelium also has been reported in periapical cysts, dentigerous cysts, and glandular odontogenic cysts found in other locations.

Because a fissural cyst in this region probably does not exist, the term *globulomaxillary cyst* should no longer be used. When a radiolucency between the maxillary lateral incisor and canine is encountered, the clinician should first consider an odontogenic origin for the lesion.

◆ NASOPALATINE DUCT CYST (INCISIVE CANAL CYST)

The **nasopalatine duct cyst** is the most common nonodontogenic cyst of the oral cavity, occurring in about 1% of the population. The cyst is believed to arise from remnants of the **nasopalatine duct,** an embryologic structure connecting the oral and nasal cavities in the area of the incisive canal.

In the 7-week-old fetus, the developing palate consists of the **primary palate,** which is formed by the fusion of the medial nasal processes. Behind the primary palate, downgrowth of the nasal septum produces two communications between the oral and nasal cavities, the primitive nasal choanae. Formation of the **secondary palate** begins around the eighth intrauterine week, with downward growth of the medial parts of the maxillary processes (palatine processes) to a location on either side of the tongue.

As the mandible develops and the tongue drops down, these palatine processes grow horizontally, fusing with the nasal septum in the midline and with the primary palate along their anterior aspect. Two passageways persist in the midline between the primary and secondary palates (the **incisive canals**). Also formed by this fusion and found within the incisive canals are epithelial structures—the **nasopalatine ducts**. These ducts normally degenerate in humans but may leave epithelial remnants behind in the incisive canals.

The incisive canals begin on the floor of the nasal cavity on either side of the nasal septum, coursing downward and forward to exit the palatal bone via a common foramen in the area of the incisive papilla. In addition to the nasopalatine ducts, these canals contain the nasopalatine nerve plus anastomosing branches of the descending palatine and sphenopalatine arteries. Occasionally, two smaller foramina carrying the nasopalatine nerves—the **canals of Scarpa**—are found within the incisive foramen.

In some mammals the nasopalatine ducts remain patent and provide communication between the oral and nasal cavities. On rare occasions, patent or partially patent nasopalatine ducts may be encountered in humans. In mammals the nasopalatine ducts may communicate with the vomer-nasal **organ of Jacobson,** acting as an accessory olfactory organ. However, in humans, Jacobson's organ usually recedes in uterine life to become a vestigial structure.

Researchers have suggested that the nasopalatine duct cyst may arise from the epithelium of Jacobson's organ, but this appears highly unlikely. Trauma or infection of the duct and mucous retention of adjacent minor salivary glands also have been mentioned as possible etiologic factors, but the role of each has been questioned. Although the pathogenesis of this lesion is still uncertain, the lesion most likely represents a spontaneous cystic degeneration of remnants of the nasopalatine duct.

dentlearn.ir

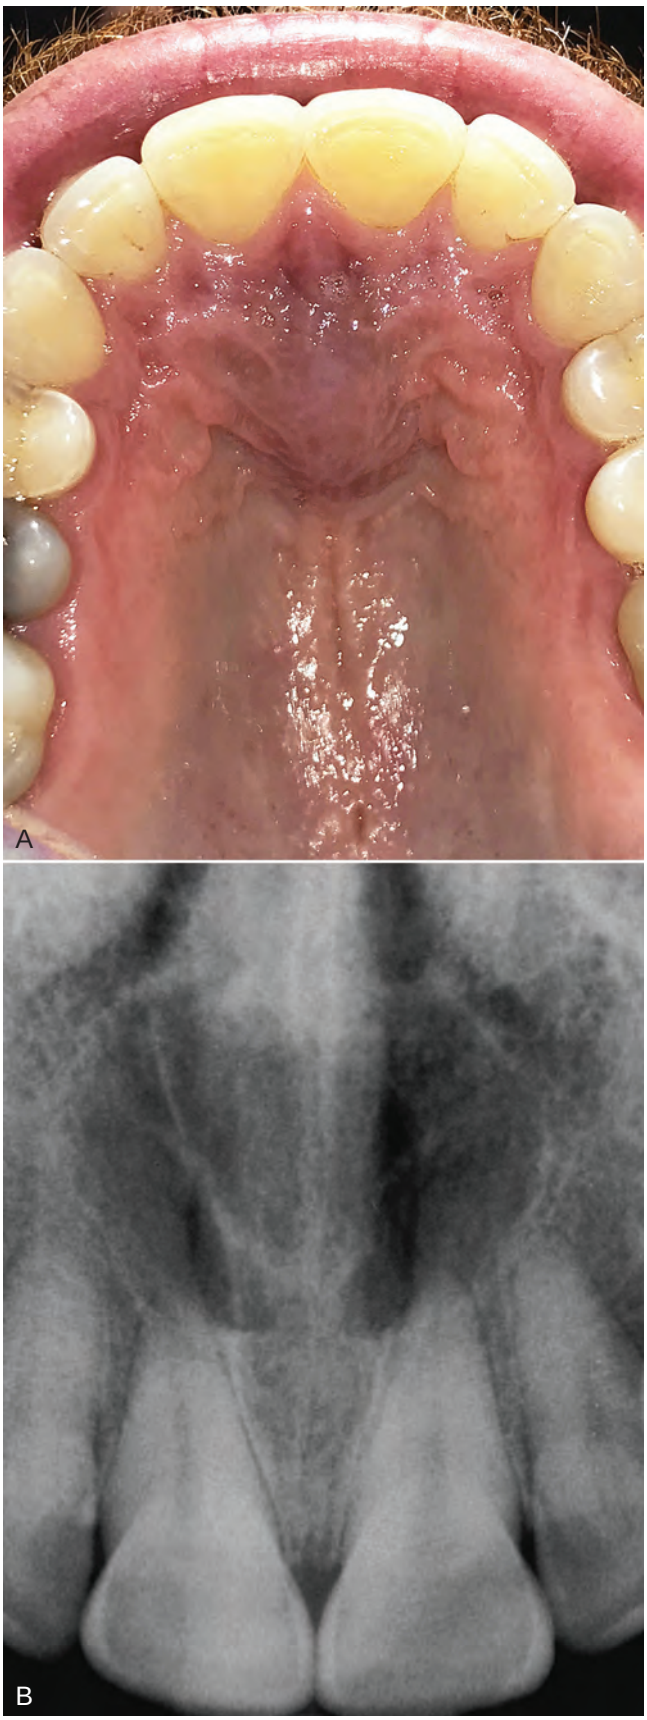
Clinical and Radiographic Features

The nasopalatine duct cyst may develop at almost any age but is most common in the fourth to sixth decades of life. In spite of its being a "developmental" cyst, the nasopalatine duct cyst is rarely seen during the first decade. Most studies have shown a male predilection.

The most common presenting symptoms include swelling of the anterior palate, drainage, and pain (Fig. 1.58, *A*). Patients sometimes relate a long history of these symptoms, probably because of their intermittent nature. However, many lesions are asymptomatic and are discovered on routine radiographs. Rarely a large cyst may produce a "through-and-through" fluctuant expansion involving the anterior palate and labial alveolar mucosa.

Radiographs usually demonstrate a well-circumscribed radiolucency in or near the midline of the anterior maxilla, between and apical to the central incisor teeth (Figs. 1.58, *B* and 1.59). Root resorption rarely is noted. The lesion most often is round or oval with a sclerotic border. Some cysts may have an inverted pear shape, presumably because of resistance of adjacent tooth roots. Other examples may show a classic heart shape as a result of superimposition of the nasal spine or because they are notched by the nasal septum.

The radiographic diameter of nasopalatine duct cysts can range from small lesions, less than 6 mm, to destructive lesions as large as 6 cm. However, most cysts are in the range of 1.0 to 2.5 cm, with an average diameter of 1.5 to 1.7 cm. It may be difficult to distinguish a small nasopalatine duct cyst from a large incisive foramen. It is generally accepted that a diameter of 6 mm is the upper limit of normal size for the incisive foramen. Therefore, a radiolucency that is 6 mm or smaller in this area usually is considered a normal foramen unless other clinical signs or symptoms are present.



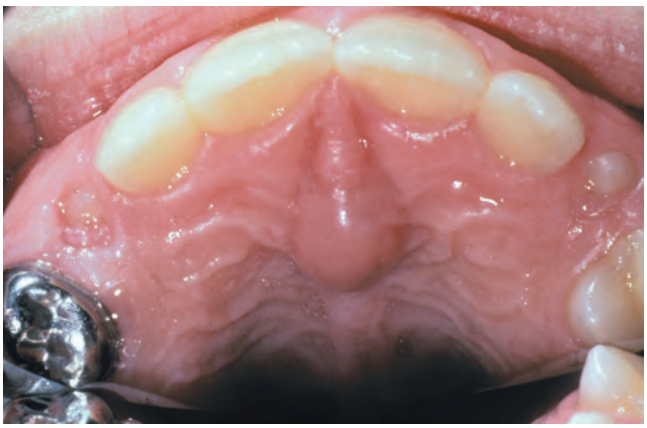
In rare instances, a nasopalatine duct cyst may develop in the soft tissues of the incisive papilla area without any bony involvement. Such lesions often are called **cysts of the incisive papilla**. These cysts frequently demonstrate bluish discoloration as a result of the fluid contents in the cyst lumen (Fig. 1.60).

Histopathologic Features

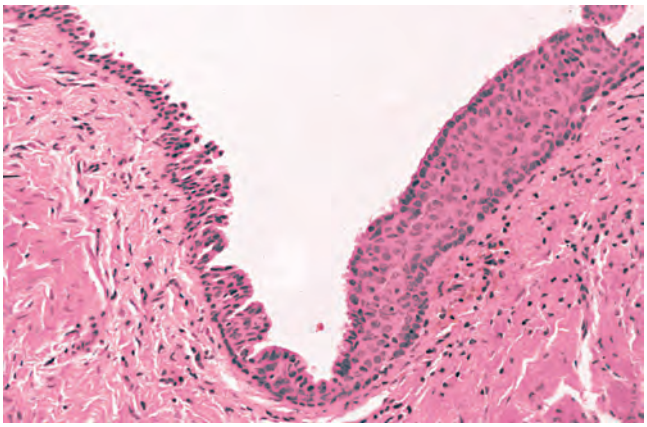
The epithelial lining of nasopalatine duct cysts is highly variable (Figs. 1.61 and 1.62). It may be composed of the following:

- Stratified squamous epithelium
- Pseudostratified columnar epithelium
- Simple columnar epithelium
- Simple cuboidal epithelium

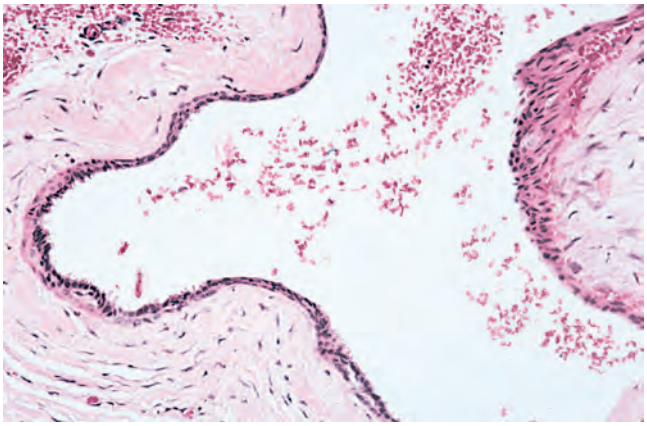
Frequently, more than one epithelial type is found in the same cyst. Stratified squamous epithelium is most common, present in at least three-fourths of all cysts. Pseudostratified columnar epithelium has been reported in from one-third to three-fourths of all cases. Simple cuboidal or columnar epithelium is discovered less frequently.



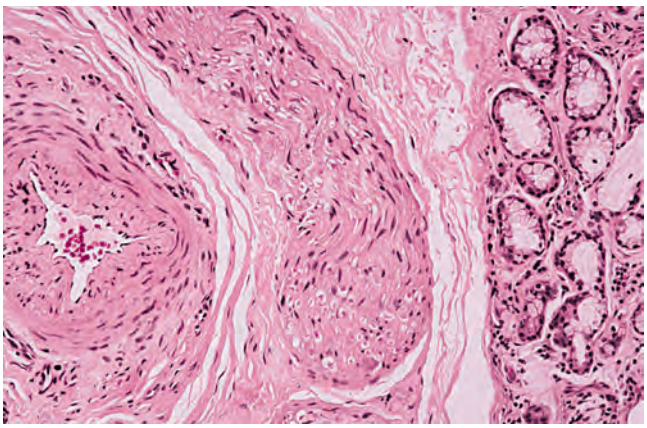
• **Fig. 1.58 Nasopalatine Duct Cyst. A,** Fluctuant swelling of the anterior hard palate. **B,** Periapical radiograph showing a well-circumscribed radiolucency apical to the roots of the maxillary central incisors. (Courtesy of Dr. Matt Koepke.)



dentlearn.ir



• **Fig. 1.59 Nasopalatine Duct Cyst**. Well-circumscribed radiolucency between and apical to the roots of the maxillary central incisors.



• **Fig. 1.60 Cyst of the Incisive Papilla**. Swelling of the incisive papilla.

• **Fig. 1.61 Nasopalatine Duct Cyst**. Cystic lining showing transition from pseudostratified columnar to stratified squamous epithelium.

• **Fig. 1.62 Nasopalatine Duct Cyst**. Flattened cuboidal epithelial lining.

• **Fig. 1.63 Nasopalatine Duct Cyst**. Cyst wall showing blood vessels, nerve bundles, and minor salivary glands.

Cilia and goblet cells may be found in association with columnar linings. The type of epithelium may be related to the vertical position of the cyst within the incisive canal. Cysts developing within the superior aspect of the canal near the nasal cavity are more likely to demonstrate respiratory epithelium; those in an inferior position near the oral cavity are more likely to exhibit squamous epithelium.

The contents of the cyst wall can be a helpful diagnostic aid. Because the nasopalatine duct cyst arises within the incisive canal, moderate-sized nerves and small muscular arteries and veins usually are found in the wall of the cyst (Fig. 1.63). Small mucous glands have been reported in as many as one-third of cases. Occasionally, one may see small islands of hyaline cartilage. Frequently, an inflammatory response is noted in the cyst wall and may range from mild to heavy. This inflammation usually is chronic in nature and is composed of lymphocytes, plasma cells, and histiocytes. Associated acute inflammatory cells (neutrophils) sometimes may be seen.

dentlearn.ir

Treatment and Prognosis

Nasopalatine duct cysts are treated by surgical enucleation. Biopsy is recommended because the lesion is not diagnostic radiographically; other benign and malignant lesions have been known to mimic the nasopalatine duct cyst. The lesion is best approached with a palatal flap that is reflected after an incision is made along the lingual gingival margin of the anterior maxillary teeth. Recurrence is rare. Malignant transformation has been reported in a couple of cases, but this is an extremely rare complication.

◆ MEDIAN PALATAL (PALATINE) CYST

The median palatal cyst is a rare fissural cyst that theoretically develops from epithelium entrapped along the embryonic line of fusion of the lateral palatal shelves of the maxilla. This cyst may be difficult to distinguish from a nasopalatine duct cyst. In fact, most "median palatal cysts" may represent posteriorly positioned nasopalatine duct cysts. Because the nasopalatine ducts course posteriorly and superiorly as they extend from the incisive canal to the nasal cavity, a nasopalatine duct cyst that arises from posterior remnants of this duct near the nasal cavity might be mistaken for a median palatal cyst. On the other hand, if a true median palatal cyst were to develop toward the anterior portion of the hard palate, then it could easily be mistaken for a nasopalatine duct cyst.

Clinical and Radiographic Features

The median palatal cyst presents as a firm or fluctuant swelling of the midline of the hard palate posterior to the palatine papilla (Fig. 1.64). The lesion appears most frequently in young adults. Often it is asymptomatic, but some patients complain of pain or expansion. The average size of this cyst is 2×2 cm, but sometimes it can become quite large. Occlusal radiographs demonstrate a well-circumscribed radiolucency in the midline of the hard palate (Fig. 1.65).

• **Fig. 1.64 Median Palatal Cyst**. Compressible mass in the midline of the hard palate posterior to the incisive papilla. (Courtesy of Dr. Craig Fowler.)

Occasional reported cases have been associated with divergence of the central incisors, although it may be difficult to rule out a nasopalatine duct cyst in these instances.

To differentiate the median palatal cyst from other cystic lesions of the maxilla, Gingell and associates suggested the following diagnostic criteria:

- Grossly appears symmetrical along the midline of the hard palate
- Located posterior to the palatine papilla
- Appears ovoid or circular radiographically
- Not intimately associated with a nonvital tooth
- Does not communicate with the incisive canal
- Shows no microscopic evidence of large neurovascular bundles, hyaline cartilage, or minor salivary glands in the cyst wall

It must be stressed that a true median palatal cyst should exhibit clinical enlargement of the palate. A midline radiolucency without clinical evidence of expansion is probably a nasopalatine duct cyst.

Histopathologic Features

Microscopic examination shows a cyst that usually is lined by stratified squamous epithelium. Areas of ciliated pseudostratified columnar epithelium have been reported in some cases. Chronic inflammation may be present in the cyst wall.

• **Fig. 1.65 Median Palatal Cyst**. Occlusal radiograph of same patient depicted in Fig. 1.64. A well-circumscribed midline radiolucent defect can be seen, which is separate from the incisive canal. (Courtesy of Dr. Craig Fowler.)

dentlearn.ir

Treatment and Prognosis

The median palatal cyst is treated by surgical removal. Recurrence should not be expected.

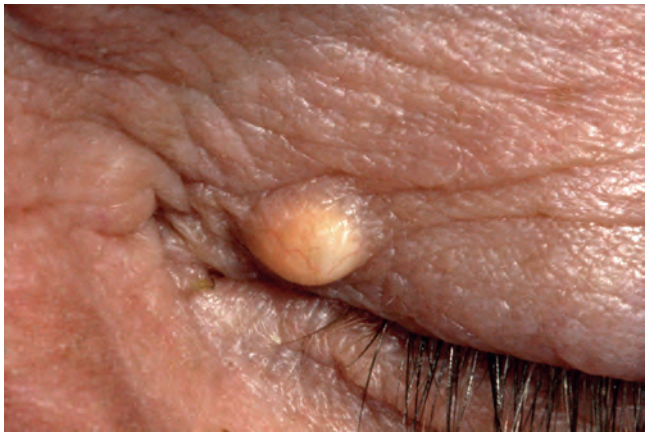
◆ "MEDIAN MANDIBULAR CYST"

The **"median mandibular cyst"** is a controversial lesion of questionable existence. Theoretically, it represents a fissural cyst in the anterior midline of the mandible that develops from epithelium entrapped during fusion of the halves of the mandible during embryonic life. However, the mandible actually develops as a single bilobed proliferation of mesenchyme with a central isthmus in the midline. As the mandible grows, this isthmus is eliminated. Therefore, because no fusion of epithelium-lined processes occurs, entrapment of epithelium should not be possible.

Because respiratory prosoplasia is not uncommon in odontogenic cysts, it appears likely that most (if not all) of these midline cysts are of odontogenic origin. Many purported cases would be classified today as examples of the *glandular odontogenic cyst* (see page 703), which has a propensity for occurrence in the midline mandibular region. Others could be classified as *periapical cysts, odontogenic keratocysts,* or *lateral periodontal cysts.* Because a fissural cyst in this region probably does not exist, the term *median mandibular cyst* should no longer be used.

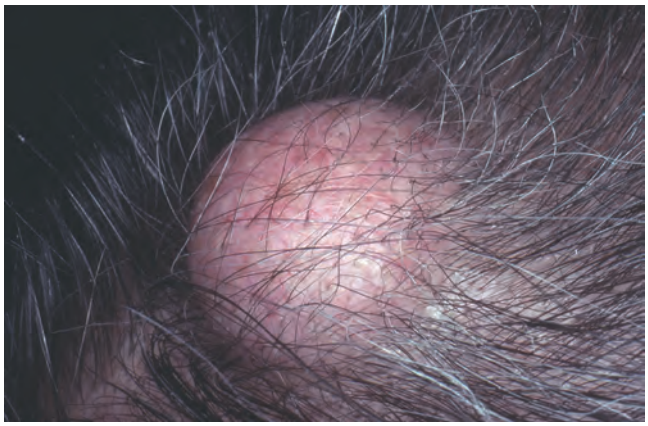
◆ FOLLICULAR CYSTS OF THE SKIN

Follicular cysts of the skin are common keratin-filled lesions that arise from one or more portions of the hair follicle. The most common type, which is derived from the follicular infundibulum, is known as an **epidermoid** or **infundibular cyst**. These cysts often arise after localized inflammation of the hair follicle and probably represent a nonneoplastic proliferation of the infundibular epithelium resulting from the healing process. The term **sebaceous cyst** sometimes is used mistakenly as a synonym for both the epidermoid cyst and another cyst of the scalp known as a **pilar, trichilemmal,** or **isthmus-catagen cyst**. However, because both the epidermoid cyst and pilar cyst are derived from the hair follicle rather than the sebaceous gland, the term *sebaceous cyst* should be avoided.



Keratin-filled cysts of the skin may occasionally arise after traumatic implantation of epithelium, although such lesions may be difficult to distinguish from an infundibular cyst. Rarely, such **epidermal inclusion (implantation) cysts** also can develop in the mouth. These small inclusion cysts should be distinguished from oral epidermoid cysts that occur in the midline floor of mouth region and represent the minimal manifestation of the teratoma-dermoid cyst-epidermoid cyst spectrum (see page 32).

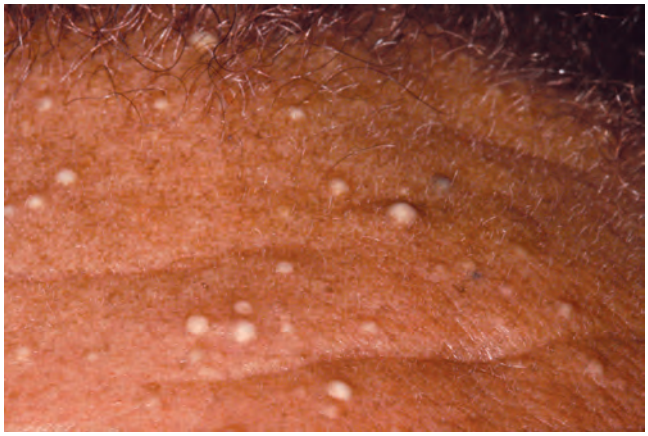
Clinical Features



Epidermoid (infundibular) cysts account for approximately 80% of follicular cysts of the skin and are most common in the acne-prone areas of the head, neck, and back. They are unusual before puberty unless they are associated with **Gardner syndrome** (see page 656). Young adults are more likely to have cysts on the face, whereas older adults are more likely to have cysts on the back. Males are affected more frequently than females.

Epidermoid cysts present as nodular, fluctuant subcutaneous lesions that may or may not be associated with inflammation (Fig. 1.66). Sometimes the cyst may exhibit a small orifice or punctum that communicates with the skin surface. If a noninflamed lesion presents in an area of thin skin, such as the earlobe, then it may be white or yellow.

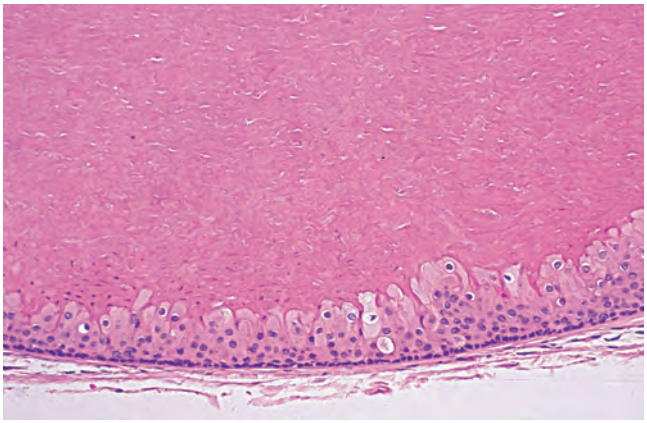
Pilar (trichilemmal) cysts comprise approximately 10%–15% of skin cysts, occurring most frequently on the scalp (Fig. 1.67). They are twice as common in women as in men. Some examples are inherited as an autosomal dominant trait, and affected patients can develop multiple cysts. The lesion is usually movable and shells out easily.



• **Fig. 1.66 Epidermoid Cyst**. Yellow nodule at the medial aspect of the eyelid.

• **Fig. 1.67 Pilar Cyst**. Nodular mass on the scalp.

dentlearn.ir



• **Fig. 1.68 Milia**. Multiple tiny keratin-filled cysts on the forehead.

Milia (singular: **milium**) are tiny keratin-filled cysts that resemble miniature epidermoid cysts (Fig. 1.68). A variety of such lesions have been described, including primary congenital milia, genodermatosis-associated milia, and milia that develop secondary to bullous disorders, trauma, or certain medications. Primary milia are thought to arise from the sebaceous collar of vellus hairs, whereas secondary milia may develop from eccrine ducts, hair follicles, or the overlying epidermis.

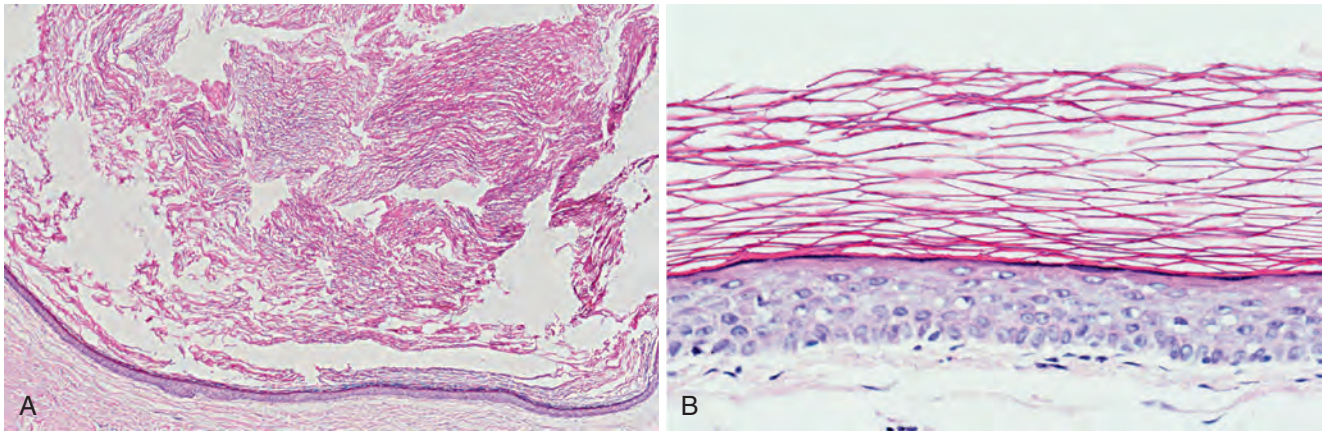
Histopathologic Features

Microscopic examination of an epidermoid cyst reveals a cavity that is lined by stratified squamous epithelium resembling epidermis (Fig. 1.69). A well-developed granular cell layer is seen, and the lumen is filled with degenerating orthokeratin. Not infrequently, the epithelial lining will be disrupted. When this occurs, a prominent granulomatous inflammatory reaction, including multinucleated giant cells, can be present in the cyst wall because the exposed keratin is recognized as a foreign material.

The pilar cyst also is lined by stratified squamous epithelium, although a granular cell layer usually is absent or greatly diminished (Fig. 1.70). The keratinocytes remain large in the upper epithelial layers with an abrupt transition to dense, compact keratin that fills the cyst lumen.

• **Fig. 1.70 Pilar Cyst**. Medium-power view showing an abrupt transition between the stratified squamous epithelial lining and compact keratin without the presence of a transitional granular cell layer.

Treatment and Prognosis



Epidermoid and pilar cysts usually are treated by conservative surgical excision, and recurrence is uncommon. Malignant transformation has been reported but is exceedingly rare.

An individual milium can be removed by evacuation, in which the lesion is nicked by a scalpel blade, followed by application of pressure with a comedone extractor or curette. Multiple milia can be managed via electrocautery or application of topical retinoids.

◆ DERMOID CYST (DYSONTOGENIC CYST)

The **dermoid cyst** is an uncommon developmental cystic malformation. The cyst is lined by epidermis-like epithelium and contains dermal adnexal structures in the cyst wall. It is generally classified as a benign cystic form of **teratoma**.

By definition, a teratoma is a developmental tumor composed of tissue from more than one germ layer and

• **Fig. 1.69 Epidermoid Cyst**. **A,** Low-power view showing a keratin-filled cystic cavity. **B,** High-power view showing stratified squamous epithelial lining with orthokeratin production.

dentlearn.ir

sometimes all three: (1) ectoderm, (2) mesoderm, and (3) endoderm. Such tumors are believed to arise from germ cells or entrapped totipotent blastomeres, which can produce derivatives of all three germ layers.

Teratomatous malformations have a spectrum of complexity. In their most complex form, these lesions produce multiple types of tissue that are arranged in a disorganized fashion. These "complex" teratomas are most common in the ovaries or testes and can be benign or malignant. Occasionally, ovarian teratomas (or "dermoids") produce well-formed teeth, or even partially complete jaws. Complex teratomas of the oral cavity are rare and usually are congenital in nature. When they occur, they usually extend through a cleft palate from the pituitary area via Rathke's pouch. Cervical teratomas also have been reported.

The term **teratoid cyst** has been used to describe a cystic form of teratoma that contains a variety of germ layer derivatives:

1. Skin appendages, including hair follicles, sebaceous glands, and sweat glands
2. Connective tissue elements, such as muscle, blood vessels, and bone
3. Endodermal structures, such as gastrointestinal lining

Rarely, oral cysts may be lined entirely by gastrointestinal epithelium. These **heterotopic oral gastrointestinal cysts (enterocystomas, enteric duplication cysts)** often are considered to be choristomas, or histologically normal tissue found in an abnormal location. However, these lesions probably can be included under the broad umbrella of teratomatous lesions, especially because they occasionally are found in combination with dermoid cysts.

Dermoid cysts are simpler in structure than complex teratomas or teratoid cysts. Although they do not contain tissue from all three germ layers, they probably represent a *forme fruste* of a teratoma. Similar cysts of the oral cavity can be seen that are lined by epidermis-like epithelium, but they contain no dermal appendages in the cyst wall. These lesions have been called **epidermoid cysts** and represent the simplest expression of the teratoma spectrum. These intraoral epidermoid cysts should not be confused with the more common **epidermoid cyst of the skin** (see page 31), a nonteratomatous lesion that arises from the hair follicle. Because the teratoid cyst/dermoid cyst/epidermoid cyst spectrum represents defective embryologic development, these cysts sometimes are known collectively as **dysontogenic cysts**.

Clinical and Radiographic Features

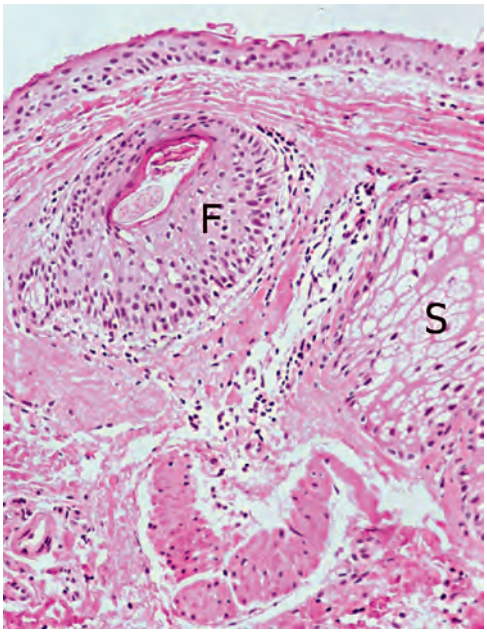
Dermoid cysts most commonly occur in the midline of the floor of the mouth (Fig. 1.71), although occasionally they are displaced laterally or develop in other locations. If the cyst develops above the geniohyoid muscle, then a sublingual swelling may displace the tongue toward the roof of the mouth and create difficulty in eating, speaking, or even breathing. Cysts that occur below the geniohyoid muscle often produce a submental swelling, with a "double-chin" appearance.

• **Fig. 1.71 Dermoid Cyst**. Fluctuant midline swelling in the floor of the mouth. (From Budnick SD: *Handbook of pediatric oral pathology*, Chicago, 1981, Year Book Medical.)

Oral dermoid cysts can vary in size from a few millimeters to 12 cm in diameter. They are most common in children and young adults; 15% of reported cases have been congenital. The lesion is usually slow growing and painless, presenting as a doughy or rubbery mass that frequently retains pitting after application of pressure. Secondary infection can occur, and the lesion may drain intraorally or onto the skin. MRIs, CT scans, or contrast medium radiographs may be helpful in delineating the extent of the lesion.

Histopathologic Features

Dermoid cysts are lined by orthokeratinized stratified squamous epithelium with a prominent granular cell layer. Abundant keratin often is found within the cyst lumen. On rare occasions, areas of respiratory epithelium can be seen. The cyst wall is composed of fibrous connective tissue that contains one or more skin appendages, such as sebaceous glands, hair follicles, or sweat glands (Fig. 1.72).



Treatment and Prognosis

Dermoid cysts are treated by surgical removal. Many examples can be removed by an intraoral incision, which avoids the creation of a scar on the skin. However, some lesions located below the geniohyoid muscle may require an extraoral approach. Recurrence is uncommon. Malignant transformation into squamous cell carcinoma has been reported only rarely.

◆ THYROGLOSSAL DUCT CYST (THYROGLOSSAL TRACT CYST)

The thyroid gland begins its development during the third to fourth week of embryonic life as a proliferation of endodermal cells from the ventral floor of the pharynx, between the tuberculum impar and copula of the developing tongue—a point that later becomes the foramen cecum. This thyroid anlage descends into the neck as a bilobed diverticulum

dentlearn.ir

• **Fig. 1.72 Dermoid Cyst**. Squamous epithelial lining *(top),* with hair follicle *(F),* sebaceous glands *(S)* in the cyst wall.

anterior to the developing hyoid bone and reaches its definitive level below the thyroid cartilage by the seventh embryonic week. Along this path of descent, an epithelial tract or duct is formed, maintaining an attachment to the base of the tongue. This thyroglossal duct becomes intimately associated with the developing hyoid bone. As the hyoid matures and rotates to its adult position, the thyroglossal duct passes in front and beneath the hyoid, looping upward and behind it before curving downward again into the lower neck. The caudal segment of this duct often persists, forming the pyramidal lobe of the thyroid gland.

The thyroglossal duct epithelium normally undergoes atrophy and is obliterated, although autopsy studies have shown that as many as 7% of the population will have *thyroglossal tract remnants.* These epithelial remnants usually are asymptomatic, although some can give rise to cysts along this tract known as **thyroglossal duct cysts**. The impetus for cystic degeneration is uncertain. Inflammation is the most frequently suggested stimulus, especially from adjacent lymphoid tissue that may react to draining infections of the head and neck. Retention of secretions within the duct is another possible factor. In addition, there are several reports of familial occurrence of such cysts.

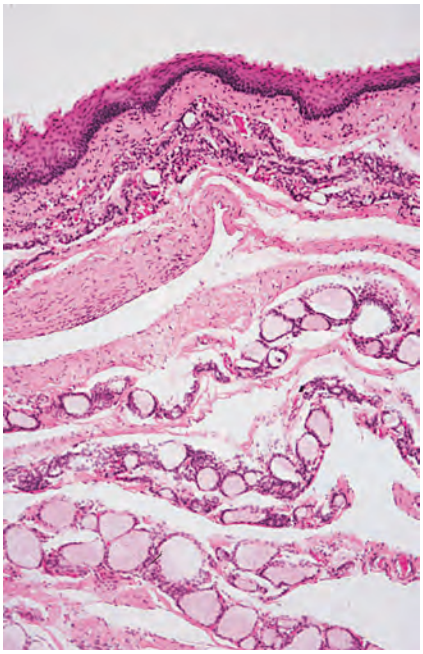
Clinical Features

Thyroglossal duct cysts classically develop in the midline and may occur anywhere from the foramen cecum area of the tongue to the suprasternal notch. Approximately 75% of cases develop inferior to the hyoid bone. Suprahyoid cysts may be submental in location. Cysts that develop in the area of the thyroid cartilage often are deflected lateral to the midline because of the sharp anterior margin of the thyroid cartilage. Intralingual cysts are rare.

• **Fig. 1.73 Thyroglossal Duct Cyst**. Swelling of the anterior midline of the neck. (Courtesy of Dr. Steven B. Whitaker.)

Thyroglossal duct cysts may develop at any age, but they are most commonly diagnosed in children and young to middle-aged adults; about 40% of cases occur before the age of 20. There is no sex predilection. The cyst usually presents as a painless, fluctuant, movable swelling unless it is complicated by secondary infection (Fig. 1.73). Lesions that develop at the base of the tongue may cause laryngeal obstruction. Most thyroglossal duct cysts are smaller than 3 cm in diameter, but occasional cysts may reach 10 cm in size. If the cyst maintains an attachment to the hyoid bone or tongue, it will move vertically during swallowing or protrusion of the tongue. Sinus tracts to the skin or mucosa develop in as many as one-third of cases, usually from rupture of an infected cyst or as a sequela of surgery.

Histopathologic Features



Thyroglossal duct cysts usually are lined by respiratory or stratified squamous epithelium (Fig. 1.74). Sometimes a mixture of epithelial types is present, or an intact epithelial lining cannot be found due to secondary inflammation. Thyroid tissue may occur in the cyst wall, but this is not a constant finding.

Treatment and Prognosis

Thyroglossal duct cysts are best treated by a Sistrunk procedure. In this operation the cyst is removed in addition to the midline segment of the hyoid bone and a generous portion of muscular tissue along the entire thyroglossal tract. The recurrence rate associated with this procedure is less than 10%. A much higher recurrence rate can be expected with less aggressive surgery.

Carcinoma arising in a thyroglossal duct cyst is a rare complication that occurs in approximately 1%–3% of cases. Most of these have been papillary thyroid adenocarcinomas. Fortunately, metastases from thyroglossal carcinoma are rare, and the prognosis for people with these tumors is good.

dentlearn.ir

• **Fig. 1.74 Thyroglossal Duct Cyst**. Cyst *(top)* lined by stratified squamous epithelium. Thyroid follicles can be seen in the cyst wall *(bottom)*.

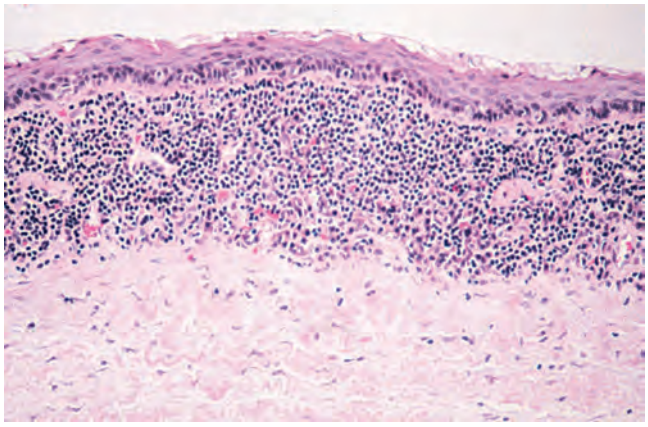
◆ BRANCHIAL CLEFT CYST (CERVICAL LYMPHOEPITHELIAL CYST)

The **branchial cleft cyst** is a developmental cyst that is derived from remnants of the branchial arches. During the fourth to seventh week of gestation, the head and neck region of the embryo develops paired branchial arches, which are covered by ectoderm on the external surface and endoderm on the internal surface. The outer arch surfaces are separated by clefts and the inner surfaces are divided by pouches. In fish and amphibians, the branchial arches are destined to become the gill apparatus; in humans, the clefts and pouches gradually are eliminated during embryonic life by ingrowth of mesenchyme. However, incomplete obliteration of these pharyngeal clefts and pouches may give rise to branchial cleft anomalies, such as cysts, fistulae, or sinus tracts. About 95% of these anomalies are believed to arise from the second branchial arch, with the remaining 5% originating from the first, third, and fourth branchial arches.

Clinical Features

Branchial cleft cysts from the second arch occur in the upper lateral neck anterior or deep to the sternocleidomastoid muscle (Figs. 1.75 and 1.76). They most frequently develop in children and young adults between the ages of 10 and 40. Clinically, the cyst appears as a soft, fluctuant mass that can range from 1 to 10 cm in diameter. Associated tenderness or pain sometimes may occur with secondary infection. Occasionally, the lesion becomes evident after an upper respiratory tract infection or trauma. Some branchial cleft anomalies appear as sinuses or fistulae that may produce a mucoid discharge onto the skin. In rare instances, bilateral cysts may develop.

• **Fig. 1.75 Branchial Cleft Cyst**. Fluctuant swelling of the lateral neck.



• **Fig. 1.76 Branchial Cleft Cyst**. Imaging study of the same cyst depicted in Fig. 1.75, showing a well-circumscribed lesion of the lateral neck *(arrows)*.

Anomalies from the first branchial arch comprise approximately 1% of branchial cleft malformations and usually are found in close proximity to the parotid gland. Third-cleft and fourth-cleft anomalies are rare and may develop in the lower neck or mediastinum.

Histopathologic Features

More than 90% of branchial cleft cysts are lined by stratified squamous epithelium that may or may not be keratinized (Fig. 1.77), although some cysts will exhibit respiratory epithelium. Those anomalies that present as sinus tracts or fistulae also will often have respiratory epithelium. The wall of the cyst typically contains lymphoid tissue, often

dentlearn.ir

• **Fig. 1.77 Branchial Cleft Cyst**. Medium-power view showing a cyst lined by stratified squamous epithelium. Note the lymphoid tissue in the cyst wall.

demonstrating germinal center formation. However, occasional cysts have been reported without lymphoid tissue.

Treatment and Prognosis

The branchial cleft cyst is treated by surgical removal. The lesion almost never recurs.

Rare examples of malignant transformation in these cysts have been reported. Although such an occurrence is theoretically possible, most suspected cases actually represent cystic metastases from previously undetected carcinomas of the head and neck region, especially human papillomavirus (HPV)-related tumors from the base of tongue, lingual tonsil, or palatine tonsil. When evaluating patients with cystic neck masses, fine-needle aspiration biopsy often is recommended to rule out the possibility of malignancy before surgery.

◆ ORAL LYMPHOEPITHELIAL CYST

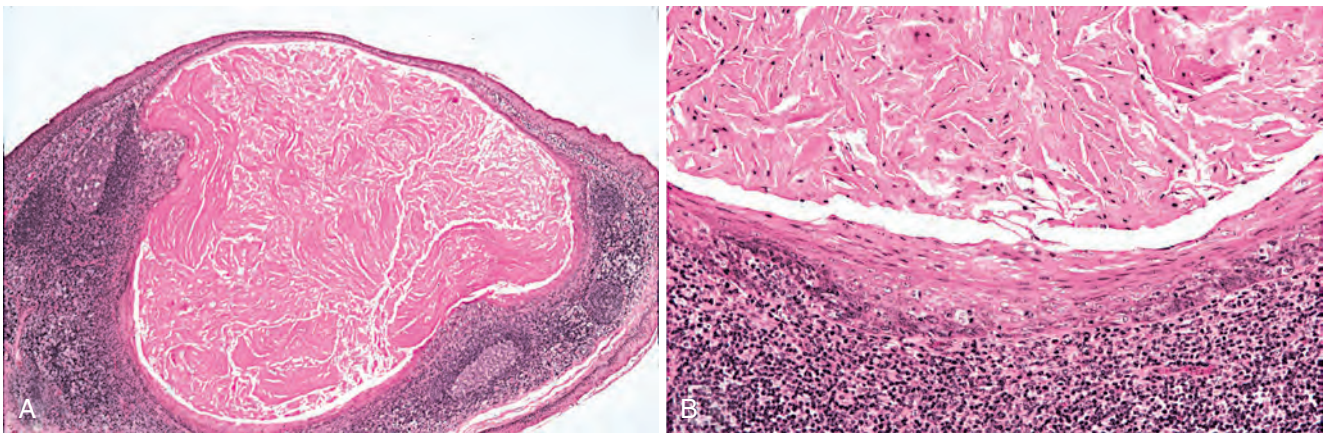
The **oral lymphoepithelial cyst** is an uncommon lesion of the mouth that develops within oral lymphoid tissue. It is microscopically similar to the branchial cleft cyst (cervical lymphoepithelial cyst) but much smaller in size.

Lymphoid tissue is normally found in the oral cavity and pharynx, principally consisting of **Waldeyer ring,** which includes the palatine tonsils, lingual tonsils, and pharyngeal adenoids. In addition, accessory oral tonsils or lymphoid aggregates may occur in the floor of the mouth, ventral surface of the tongue, and soft palate.

Oral lymphoid tissue has a close relationship with the overlying mucosal epithelium. This epithelium demonstrates invaginations into the tonsillar tissue, resulting in blind pouches or tonsillar crypts that may fill up with keratin debris. The tonsillar crypt may become obstructed or pinched off from the surface, producing a keratin-filled cyst within the lymphoid tissue just below the mucosal surface. It also is possible that oral lymphoepithelial cysts may develop from salivary or surface mucosal epithelium that becomes

• **Fig. 1.78 Oral Lymphoepithelial Cyst**. Small yellow-white nodule of the tonsillar fossa.

• **Fig. 1.79 Oral Lymphoepithelial Cyst**. Small yellow-white papule of the posterior lateral border of the tongue.



enclaved in lymphoid tissue during embryogenesis. It even has been suggested that these cysts may arise from the excretory ducts of the sublingual gland or minor salivary glands, and that the associated lymphoid tissue represents a secondary immune response.

Clinical Features

The oral lymphoepithelial cyst presents as a small submucosal mass that is usually less than 1 cm in diameter; rarely will the lesion be greater than 1.5 cm (Figs. 1.78 and 1.79). The cyst may feel firm or soft to palpation, and the overlying mucosa is smooth and nonulcerated. The lesion is typically white or yellow and often contains creamy or cheesy keratinous material in the lumen. The cyst is usually asymptomatic, although occasionally patients may complain of swelling or drainage. Pain is rare but may occur secondary to trauma.

Oral lymphoepithelial cysts may develop in people of almost any age, but they are most common in young adults. The most frequently reported locations are the floor of the mouth, ventral tongue, posterior lateral border of the tongue,

dentlearn.ir

• **Fig. 1.80 Oral Lymphoepithelial Cyst**. **A,** Low-power view showing a keratin-filled cyst below the mucosal surface. Lymphoid tissue is present in the cyst wall. **B,** High-power view showing lymphoid tissue adjacent to the cystic lining.

palatine tonsil, and soft palate. All of these locations represent sites of normal or accessory oral lymphoid tissue.

Histopathologic Features

Microscopic examination of the oral lymphoepithelial cyst demonstrates a cystic cavity that is lined by stratified squamous epithelium without rete ridges (Fig. 1.80). This epithelium is typically parakeratinized with desquamated epithelial cells seen filling the cyst lumen. In rare instances the epithelial lining also may contain mucous cells. Occasional cysts may communicate with the overlying mucosal surface.

The most striking feature is the presence of lymphoid tissue in the cyst wall. In most instances, this lymphoid tissue encircles the cyst, but sometimes it involves only a portion of the cyst wall. Germinal centers are usually, but not always, present.

Treatment and Prognosis

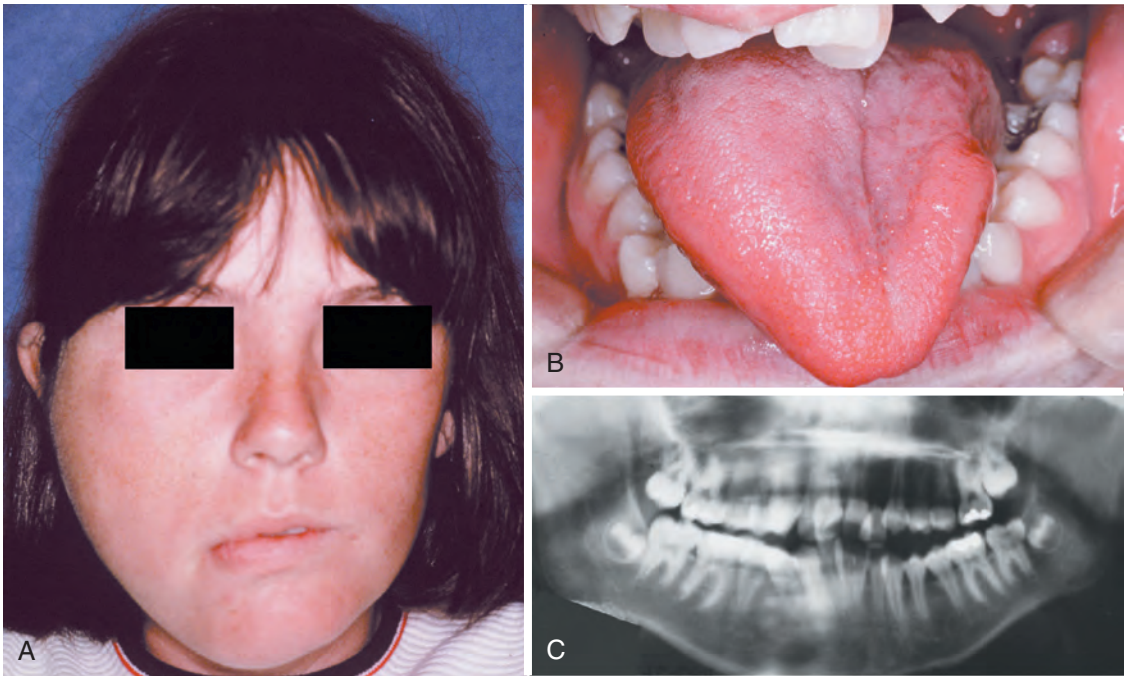
The oral lymphoepithelial cyst usually is treated with surgical excision and should not recur. Because the lesion is typically asymptomatic and innocuous, biopsy may not always be necessary if the lesion is distinctive enough to make the diagnosis on a clinical basis.

OTHER RARE DEVELOPMENTAL ANOMALIES

◆ HEMIHYPERPLASIA (HEMIHYPERTROPHY)

Hemihyperplasia is a rare developmental anomaly characterized by asymmetric overgrowth of one or more body parts. Although the condition sometimes is known as **hemihypertrophy,** it actually represents a hyperplasia of the tissues rather than a hypertrophy. Hemihyperplasia can be an isolated finding, but it also may be associated with a variety of malformation syndromes (Box 1.2).

• BOX 1.2 Malformation Syndromes Associated With Hemihyperplasia



- Beckwith-Wiedemann syndrome
- Neurofibromatosis
- Klippel-Trénaunay-Weber syndrome
- Proteus syndrome
- Russell-Silver syndrome
- Sotos syndrome
- McCune-Albright syndrome
- Epidermal nevus syndrome
- Triploid/diploid mixoploidy
- Langer-Giedion syndrome
- Multiple exostoses syndrome
- Maffucci syndrome
- Ollier syndrome
- Segmental odontomaxillary dysplasia

Almost all cases of isolated hemihyperplasia are sporadic. A number of possible etiologic factors have been suggested, but the cause remains obscure. Various theories include vascular or lymphatic abnormalities, central nervous system disturbances, endocrine dysfunctions, and aberrant twinning mechanisms. Some cases are related to genetic defects in the 11p15 chromosomal region, the same locus that is associated with Beckwith-Wiedemann syndrome.

Clinical and Radiographic Features

In a person with hemihyperplasia, one entire side of the body **(complex hemihyperplasia)** may be affected or the enlargement may be limited to a single limb **(simple hemihyperplasia)**. If the enlargement is confined to one side of the face, the term **hemifacial hyperplasia** may apply. The condition occasionally can be crossed, involving different areas on both sides of the body. Hemihyperplasia shows a nearly 2:1 female-to-male predilection, and it occurs more often on the right side of the body.

dentlearn.ir

• **Fig. 1.81 Hemihyperplasia. A,** Enlargement of the right side of the face. **B,** Same patient with associated enlargement of the right half of the tongue. **C,** Panoramic radiograph of the same patient showing enlargement of the mandible and teeth on the right side. (Courtesy of Dr. George Blozis.)

Asymmetry often is noted at birth, although in some cases the condition may not become evident until later in childhood (Fig. 1.81). The enlargement becomes more accentuated with age, especially at puberty. This disproportionate growth continues until the patient's overall growth ceases, resulting in permanent asymmetry.

The changes may involve all the tissues on the affected side, including the underlying bone. Often the skin is thickened and may demonstrate increased pigmentation, hypertrichosis, telangiectasias, or nevus flammeus (see page 551). About 20% of those affected are intellectually disabled. One of the most significant features is an increased prevalence of abdominal tumors, especially Wilms tumor, adrenal cortical carcinoma, and hepatoblastoma. These tumors have been reported in 5.9% of patients with isolated hemihyperplasia, and they do not necessarily occur on the same side as the somatic enlargement.

Unilateral **macroglossia,** featuring prominent tongue papillae, is common. Enlargement of other oral soft tissues and bone can occur. The mandibular canal may be increased in size on radiographs. The crowns of the teeth on the affected side, especially the permanent cuspids, premolars, and first molars, can be larger. Premature development of these teeth, along with precocious eruption, may be obvious. The roots also may be larger, but some reports have described root resorption. Malocclusion with open bite is not unusual.

Histopathologic Features

Microscopic examination shows an increase in thickness of the epithelium with hyperplasia of the underlying connective tissues.

Treatment and Prognosis

A complete workup should be undertaken to rule out other possible causes of unilateral growth, such as Beckwith-Wiedemann syndrome, Proteus syndrome, and neurofibromatosis type I (see page 551), which can exhibit hemihyperplasia. During childhood, periodic ultrasound examination should be performed to rule out development of abdominal tumors. After the patient's growth has ceased, cosmetic surgery can be performed, including soft tissue debulking, face lifts, and orthognathic surgery. Orthodontic therapy also frequently is needed.

◆ PROGRESSIVE HEMIFACIAL ATROPHY (PROGRESSIVE FACIAL HEMIATROPHY; ROMBERG SYNDROME; PARRY-ROMBERG SYNDROME)

Progressive hemifacial atrophy is an uncommon and poorly understood degenerative condition characterized by atrophic changes affecting one side of the face. The cause

dentlearn.ir

of these changes remains obscure. Etiologic theories include an autoimmune disorder, neurovasculitis involving branches of the trigeminal nerve, or hyperactivity and dysregulation of the sympathetic nervous system. A history of trauma has been documented in some cases, and other reports have considered *Borrelia* spp. infection (Lyme disease) in the cause. Usually, the condition is sporadic, but a few familial cases have been reported, suggesting a possible hereditary influence. Progressive hemifacial atrophy exhibits many features similar to a localized form of **scleroderma** (see page 801), indicating a close relationship between these two disorders.

Clinical and Radiographic Features

The onset of the syndrome is usually during the first two decades of life. The condition begins as atrophy of the skin and subcutaneous structures in a localized area of the face (Fig. 1.82). This atrophy progresses at a variable rate and affects the dermatome of one or more branches of the trigeminal nerve. Hypoplasia of the underlying bone also may occur. Osseous hypoplasia is more common when the condition begins during the first decade. Occasionally, bilateral facial atrophy may occur, or the condition may affect one side of the entire body. Females are affected more often than males.

The overlying skin often exhibits dark pigmentation. Some patients have a sharp line of demarcation, resembling a large linear scar, between normal and abnormal skin near the midline of the forehead, known as *linear scleroderma "en coup de sabre"* (i.e., "strike of the sword"). Ocular involvement is common, and the most frequent manifestation is enophthalmos because of loss of periorbital fat. Local alopecia may occur. Occasionally, trigeminal neuralgia, facial paresthesia, migraine, or epilepsy may develop. MRI studies may reveal a variety of central nervous system abnormalities.

The mouth and nose are deviated toward the affected side. Atrophy of the upper lip may expose the maxillary teeth. Unilateral atrophy of the tongue also can occur. Unilateral posterior open bite often develops as a result of mandibular hypoplasia and delayed eruption of the teeth. The teeth on the affected side may exhibit deficient root development or root resorption.

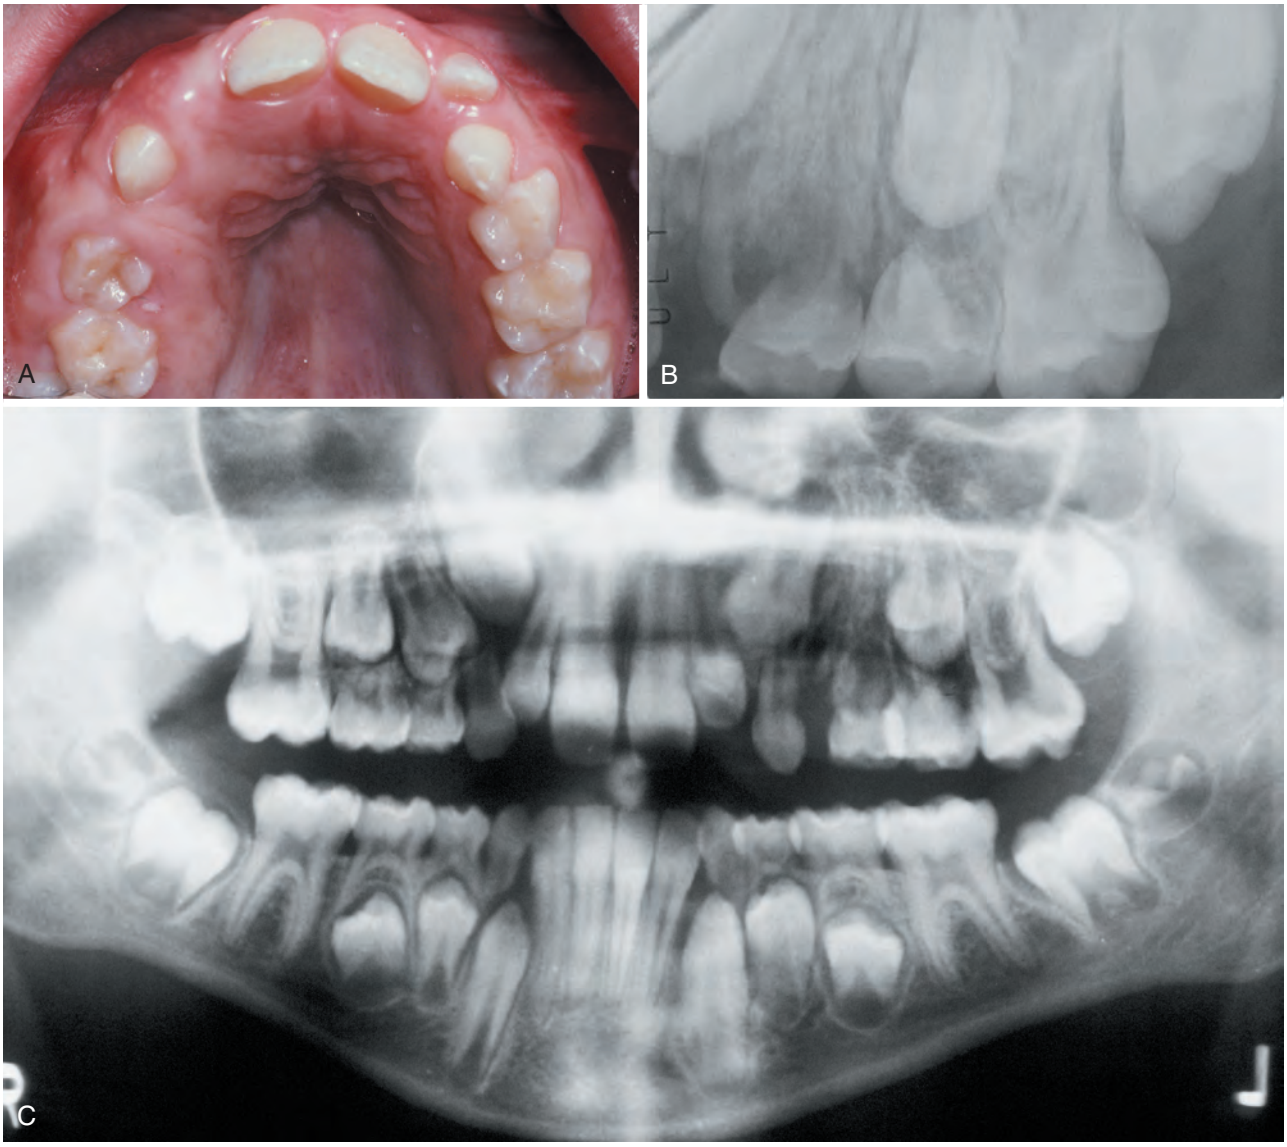
• **Fig. 1.82 Progressive Hemifacial Atrophy**. Young girl with right-sided facial atrophy.

Histopathologic Features

Microscopic examination of the affected skin reveals atrophy of the epidermis and a variable perivascular infiltrate of lymphocytes and monocytes. In cases showing clinical features of linear scleroderma, dermal fibrosis can be seen. Degenerative changes in the vascular endothelium can be identified with electron microscopy.

Treatment and Prognosis

The atrophy typically progresses slowly for 2 to 20 years and then becomes stable. Active disease can be managed medically with methotrexate and systemic corticosteroids. Plastic surgery may be utilized to correct the cosmetic deformity, and orthodontic therapy may be helpful to treat any associated malocclusion.



◆ SEGMENTAL ODONTOMAXILLARY DYSPLASIA (HEMIMAXILLOFACIAL DYSPLASIA)

Segmental odontomaxillary dysplasia is a recently recognized developmental disorder that affects the jaw and (sometimes) the overlying facial tissues. The cause is unknown. Clinically, it is frequently mistaken for craniofacial fibrous dysplasia or hemifacial hyperplasia, but it represents a distinct and separate entity.

Clinical and Radiographic Features

Segmental odontomaxillary dysplasia usually is discovered during childhood and is characterized by painless, unilateral enlargement of the maxillary bone, along with fibrous hyperplasia of the overlying gingival soft tissues (Fig. 1.83). Mild facial asymmetry may be evident, often described as prominence of the upper lip. One or both maxillary premolars frequently are missing or impacted, and the primary teeth in the affected area may be hypoplastic or show enamel defects. Radiographic examination reveals thickened trabeculae that often are vertically oriented, which results in a relatively radiopaque, granular appearance. The maxillary sinus may be smaller on the affected side. Several cases have been associated with hypertrichosis, hyperpigmentation, or rough erythema of the overlying facial skin.

dentlearn.ir

• **Fig. 1.83 Segmental Odontomaxillary Dysplasia**. **A,** Unilateral enlargement of the maxilla and overlying gingival soft tissues. **B,** Periapical radiograph showing coarse trabecular pattern with absence of the first premolar. **C,** Panoramic radiograph showing irregular bone pattern of the left maxilla expanding into the maxillary sinus.

Histopathologic Features

The gingival soft tissues may show nonspecific fibrosis. The affected maxillary bone consists of irregular trabeculae with a woven appearance. This bone shows numerous resting and reversal lines, but it lacks significant osteoblastic and osteoclastic activity. Deciduous teeth in the involved area may exhibit irregular dentinal tubules, a focally deficient odontoblastic layer, and external resorption.

Treatment and Prognosis

Once diagnosed, segmental odontomaxillary dysplasia remains relatively stable and may not require surgical intervention. Although the lesion can show gradual enlargement, the increase in size is proportional to the overall growth of the patient. When necessary, surgical recontouring can be performed for cosmetic purposes, to improve access for oral hygiene, or to facilitate tooth eruption. Both successful orthodontic therapy and placement of dental implants have been reported.

◆ CROUZON SYNDROME (CRANIOFACIAL DYSOSTOSIS)

Crouzon syndrome is one of a rare group of syndromes characterized by craniosynostosis, or premature closing of the cranial sutures. It is believed to be caused by one of a variety of mutations of the fibroblast growth factor receptor 2 *(FGFR2)* gene on chromosome 10q26. The condition occurs in about 1 of every 62,500 births and is inherited as an

dentlearn.ir

autosomal dominant trait. A significant number of cases, however, represent new mutations, often apparently related to increased paternal age.

Clinical and Radiographic Features

Crouzon syndrome exhibits a wide variability in expression. The premature sutural closing leads to cranial malformations, such as **brachycephaly** (short head), **scaphocephaly** (boat-shaped head), or **trigonocephaly** (triangle-shaped head). The most severely affected patients can demonstrate a "cloverleaf" skull (*kleeblattschädel* deformity). The orbits are shallow, resulting in characteristic ocular proptosis (Fig. 1.84). Visual impairment or total blindness and a hearing deficit may occur. Some patients report headaches, attributable to increased intracranial pressure. Marked mental deficiency is rarely seen. Skull radiographs typically show increased digital markings (i.e., "beaten-metal" pattern).

The maxilla is underdeveloped, resulting in midface hypoplasia and airway obstruction. Often the maxillary teeth are crowded, and occlusal disharmony usually occurs. Some patients will exhibit one or more congenitally missing teeth. Cleft lip and cleft palate are rare, but lateral palatal swellings may produce a midline maxillary pseudocleft.

Treatment and Prognosis

The clinical defects of Crouzon syndrome can be treated surgically, but multiple procedures may be necessary. Early craniectomy often is needed to alleviate the raised intracranial pressure. Fronto-orbital advancement can be performed to correct the ocular defects, with midfacial advancement used to correct the maxillary hypoplasia. Distraction osteogenesis can be a useful adjunct for these surgical procedures.

◆ APERT SYNDROME (ACROCEPHALOSYNDACTYLY)

Like Crouzon syndrome, **Apert syndrome** is a rare condition that is characterized by craniosynostosis. It occurs in about 1 of every 65,000 births and usually is caused by one of two point mutations in the *FGFR2* gene, which is located on chromosome 10q26. Although it is inherited as an autosomal dominant trait, most cases represent sporadic new mutations, which are thought to be exclusively of paternal origin and often associated with increased paternal age.

Clinical and Radiographic Features

Craniosynostosis typically produces **acrobrachycephaly** (tower skull); severe cases may demonstrate the *kleeblattschädel* deformity (cloverleaf skull). The occiput is flattened, and a tall appearance to the forehead is noted. Ocular proptosis is a characteristic finding, along with hypertelorism and downward-slanting lateral palpebral fissures (Fig. 1.85). Visual loss can result from the following:

- Chronic exposure of the unprotected eyes
- Increased intracranial pressure
- Compression of the optic nerves

Skull films may demonstrate digital impressions similar to those of Crouzon syndrome (Fig. 1.86). Fusion of two or more cervical vertebrae occurs in 68% of affected individuals.

The middle third of the face is significantly retruded and hypoplastic, resulting in a relative mandibular prognathism. The reduced size of the nasopharynx and narrowing of the posterior choanae can lead to respiratory distress in the young child. To compensate for this, most infants become mouth breathers, contributing to an "open-mouth" appearance. Sleep apnea may develop. Middle-ear infections are common, as is conductive hearing loss.

• **Fig. 1.86 Apert Syndrome**. Radiograph showing "tower skull," midface hypoplasia, and digital markings. Similar digital impressions are apparent in people with Crouzon syndrome. (Courtesy of Dr. Robert Gorlin.)

Characteristic limb defects help distinguish Apert syndrome from other craniosynostosis syndromes. Syndactyly of the second, third, and fourth digits of the hands and feet always is observed (Fig. 1.87). Associated synonychia also may occur. The first and fifth digits may be separate or joined to the middle digits. Synostosis of adjacent

• **Fig. 1.87 Apert Syndrome**. Syndactyly of the hand.

• **Fig. 1.88 Apert Syndrome**. Abnormal shape of the maxilla, with swellings of the posterior lateral hard palate, resulting in pseudocleft formation.

phalanges may be observed on radiographs. The average height of affected patients is below that of the general population.

Intellectual disability is reported in a large proportion of patients with Apert syndrome. An unusual acnelike eruption develops in most of the patients and involves the forearms.

Specific oral manifestations include a trapezoid-shaped appearance to the lips when they are relaxed, resulting from the midface hypoplasia and mouth breathing. Approximately 30% of patients exhibit either a cleft of the soft palate or a bifid uvula. The maxillary hypoplasia leads to a V-shaped arch and crowding of the teeth. Class III malocclusion typically occurs and may be associated with anterior open bite plus anterior and posterior crossbite. Swellings are observed along the lateral hard palate from the accumulation of glycosaminoglycans, especially hyaluronic acid (Fig. 1.88). These swellings often enlarge with age to produce a pseudocleft of the hard palate. Gingival thickening may be associated with delayed eruption of the teeth. One study showed that 35% of patients with Apert syndrome were missing one or two permanent teeth, especially maxillary lateral incisors or mandibular second premolars.

dentlearn.ir

Treatment and Prognosis

The cosmetic and functional defects of Apert syndrome can be treated by an interdisciplinary approach using multiple surgical procedures. Although this condition historically has been associated with intellectual disability, early surgical intervention to allow for brain growth may contribute to greater intellectual and social development. Craniectomy often is performed during the first year of life to treat the craniosynostosis. Frontofacial advancement and midface advancement can be done later to correct the proptosis and midface hypoplasia. Coordinated orthodontic therapy often is necessary to bring unerupted teeth into place and to improve occlusion. Surgery also can be used to separate the fused fingers. Due to limitations in hand mobility, maintenance of proper oral hygiene may be difficult. Therefore, parental assistance with oral hygiene should be encouraged, as well as utilization of electric toothbrushes, floss holders, and fluoride rinses.

◆ MANDIBULOFACIAL DYSOSTOSIS (TREACHER COLLINS SYNDROME; FRANCESCHETTI-ZWAHLEN-KLEIN SYNDROME)

Mandibulofacial dysostosis is a rare syndrome that is characterized primarily by defects of structures derived from the first and second branchial arches. It usually is inherited as an autosomal dominant trait and occurs with a frequency of 1 in 50,000 live births. However, even rarer autosomal recessive forms have been identified. The condition has variable expressivity, and the severity of the clinical features often tends to be greater in subsequent generations of the same family. Approximately 60% of cases represent new mutations, and these often are associated with increased paternal age. Mutations of the *TCOF1* gene account for over 90% of autosomal dominant forms of mandibulofacial dysostosis, but occasional examples are associated with mutations of *POLR1D*. Rare autosomal recessive cases may be related to pathogenic variants of *POLR1C* or *POLR1D*.

Clinical and Radiographic Features

Individuals with mandibulofacial dysostosis exhibit a characteristic facies (Fig. 1.89), although the features occasionally can be so mild that they are easily overlooked. The zygomas are hypoplastic, resulting in a narrow face with depressed cheeks and downward-slanting palpebral fissures. In 75% of patients, a **coloboma,** or notch, occurs on the outer portion of the lower eyelid. Approximately half of the patients have no eyelashes medial to the coloboma. Often the sideburns show a tongue-shaped extension toward the cheek.

The ears may demonstrate a number of anomalies. The pinnae frequently are deformed or misplaced, and extra ear tags may be seen. Ossicle defects or absence of the external auditory canal often result in conductive hearing loss.

The mandible is underdeveloped, resulting in a markedly retruded chin. Radiographs often demonstrate hypoplasia of the condylar and coronoid processes with prominent antegonial notching. The mouth is downturned, and about 15% of patients have lateral facial clefting (see page 2) that produces macrostomia. Cleft palate is seen in about one-third of cases. The parotid glands may be hypoplastic or may be totally absent (see page 460).

• **Fig. 1.89 Mandibulofacial Dysostosis**. Patient exhibits a hypoplastic mandible, downward-slanting palpebral fissures, and ear deformities. (Courtesy of Dr. Tom Brock.)

dentlearn.ir

A number of infants may experience respiratory and feeding difficulties because of hypoplasia of the nasopharynx, oropharynx, and hypopharynx. Choanal atresia may be present, and the larynx and trachea are often narrow. Combined with the mandibular hypoplasia and resultant improper tongue position, these defects can lead to the infant's death from respiratory complications.

Treatment and Prognosis

Patients with mild forms of mandibulofacial dysostosis may not require treatment. In more severe cases the clinical appearance can be improved with cosmetic surgery. Because of the extent of facial reconstruction required, multiple surgical procedures usually are necessary. Individual operations may be needed for the eyes, zygomas, jaws, ears, and nose. Combined orthodontic therapy is needed along with the orthognathic surgery.

2
Abnormalities of Teeth

◆ GENERAL CONSIDERATIONS

Abnormalities of the teeth can be divided into those that are influenced by environmental forces and those that are idiopathic and appear hereditary in nature. Environmental alterations are discussed first, and later parts of this chapter delineate the idiopathic and hereditary alterations of teeth.

ENAMEL DEVELOPMENT

The enamel develops in three major stages: (1) **matrix formation,** (2) **mineralization,** and (3) **maturation.** During matrix formation that also is known as the *secretory phase*, the enamel proteins are laid down. In the next stage that is termed the *transition phase*, minerals are deposited and the majority of the original proteins are removed. During the final maturation period, the enamel undergoes final mineralization and the remnants of the original proteins are removed. In the early stage of mineralization, the enamel is dull, white, and relatively soft. During the late stage of maturation, the final hard translucent enamel replaces this diffuse opaque enamel.

Dental enamel is unique in that remodeling or repair does not occur after initial formation. Therefore, abnormalities in enamel formation are etched permanently on the tooth surface and the timing of the ameloblastic damage has a great effect on the location and appearance of the defect in the enamel. Deciduous enamel contains a neonatal ring, and the rate of enamel apposition is estimated to be 0.023 mm/day. Using this knowledge, the clinician can estimate accurately the timing of an insult to the deciduous teeth to within 1 week. In the permanent dentition, the position of the enamel defects provides a rough estimate of the time of damage; however, available data on the chronology of tooth development are derived from a relatively small sample size, and the ranges of normal values are wide. In addition, gender and racial variations are not established thoroughly.

Both systemic and local factors can result in enamel defects (Box 2.1), and many different local and systemic stimuli may result in defects that have similar clinical appearances. When multiple factors are active simultaneously, the severity of the enamel defects is worse. The ameloblasts in the developing tooth germ are extremely sensitive to external stimuli; environmental effects on enamel and other tooth structures are discussed in the following section. In addition, hereditary enamel defects may occur—either as an isolated finding (see **amelogenesis imperfecta** on page 98) or as part of a heritable syndrome.

ENVIRONMENTAL ALTERATIONS OF TEETH

Box 2.2 lists the major categories of tooth alteration that can be affected by environmental influences. In many cases, the cause and effect are obvious; in others, the primary nature of the problem is less distinct.

◆ ENVIRONMENTAL EFFECTS ON TOOTH STRUCTURE DEVELOPMENT

ENAMEL HYPOPLASIA, DIFFUSE OPACITIES, AND DEMARCATED OPACITIES

Clinical and Radiographic Features

Almost all visible environmental enamel defects can be classified into one of three patterns:

1. Hypoplasia
2. Diffuse opacities
3. Demarcated opacities

Subtle enamel defects can be masked by saliva, plaque, or poor illumination. When attempting to detect areas of altered enamel, the dentition should be cleaned thoroughly and dried with gauze. Dental operatory lights are an ideal light source (direct sunlight should be avoided). Plaque-disclosing solution can be used to highlight small defects. The altered enamel may be localized or present on numerous teeth, and all or part of the surfaces of each affected tooth may be involved. **Enamel hypoplasia** is a quantitative defect and occurs in the form of pits, grooves, or larger areas of missing enamel. **Enamel opacities** are a qualitative defect that may be diffuse or demarcated and appear as variations in the translucency of the enamel. The affected enamel is of normal thickness. **Diffuse opacities** often are associated with fluorosis (see page 57), and the affected teeth demonstrate an increased white opacity with no clear boundary with the adjacent normal enamel. In contrast, **demarcated opacities**

dentlearn.ir

• BOX 2.1 Factors Associated With Enamel Defects

Systemic

- Birth-related trauma: Breech presentations, hypoxia, multiple births, premature birth, prolonged labor
- Chemicals: Amoxicillin, antineoplastic chemotherapy, cigarette smoke, fluoride, lead, tetracycline, thalidomide, vitamin D
- Chromosomal abnormalities: Trisomy 21
- Infections: Chicken pox, cytomegalovirus (CMV), gastrointestinal infections, measles, pneumonia, otitis media, respiratory infections, rubella, syphilis, tetanus, urinary tract infections
- Inherited diseases: Amelo-cerebro-hypohidrotic syndrome, amelo-onycho-hypohidrotic syndrome, epidermolysis bullosa, galactosemia, mucopolysaccharidosis IV, Nance-Horan syndrome, oculo-dento-osseous dysplasia, phenylketonuria, pseudohypoparathyroidism, tricho-dento-osseous syndrome, tuberous sclerosis, vitamin D–dependent rickets
- Malnutrition: Generalized malnutrition, vitamin D deficiency, vitamin A deficiency
- Medical conditions: Asthma, cardiac disease, celiac disease, gastrointestinal malabsorption, gastrointestinal lymphangiectasia, hepatobiliary disease, hyperbilirubinemia, hypocalcemia, hypothyroidism, hypoparathyroidism, maternal diabetes, renal disease, toxemia of pregnancy
- Neurologic disorders: Cerebral palsy, intellectual disability, sensorineural hearing defects

Local

- Local acute mechanical trauma: Falls, gunshots, neonatal mechanical ventilation, ritual mutilation, surgery, vehicular accidents
- Electrical burn
- Irradiation
- Local infection: Acute neonatal maxillitis, periapical inflammatory disease

• BOX 2.2 Environmental Alterations of Teeth

- Developmental tooth defects
- Postdevelopmental structure loss
- Discolorations of teeth
- Localized disturbances in eruption

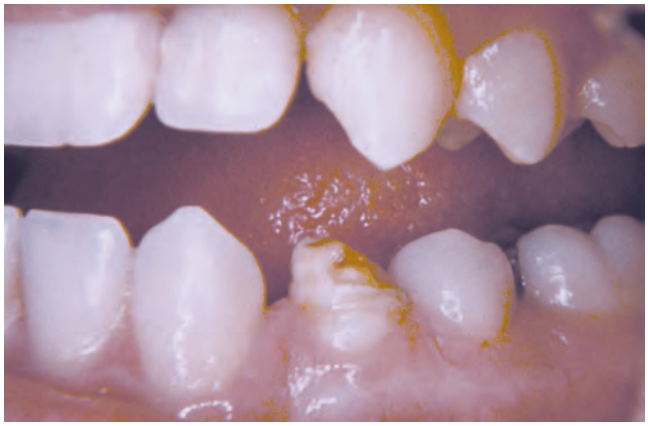
exhibit a sharp boundary with the adjacent enamel. These opacities may be white, cream, yellow, or brown. Yellow or brown examples typically are more porous than white opacities and are associated more strongly with posteruptive loss of enamel.

The site of coronal damage correlates with the area of ameloblastic activity at the time of the injury; the affected enamel is restricted to the areas in which secretory activity or active maturation of the enamel matrix was occurring. The crowns of the deciduous dentition begin to develop at approximately the fourteenth week of gestation and continue until the child is 12 months of age. Development of the

• **Fig. 2.1 Environmental Enamel Hypoplasia.** Bilaterally symmetrical pattern of horizontal enamel hypoplasia of the anterior dentition. Maxillary central incisors have been restored previously. (From Neville BW, Damm DD, White DK: *Color atlas of clinical oral pathology,* ed. 2, Hamilton, 1999, BC Decker.)

• **Fig. 2.2 Environmental Enamel Hypoplasia.** Same patient as depicted in Fig. 2.1. Note the lack of enamel damage on bicuspids. (From Neville BW, Damm DD, White DK: *Color atlas of clinical oral pathology,* ed. 2, Hamilton, 1999, BC Decker.)

crowns of the permanent dentition occurs from approximately 6 months to 15 years of age.



Environmental enamel abnormalities are extremely common with a wide range of reported prevalence. In one review of more than 1500 children from 12 to 15 years of age in an industrialized nation, the prevalence of enamel defects in the permanent dentition was 68.4%. Within this group, 67.2% demonstrated opacities, 14.6% revealed hypoplasia, and both patterns were seen in 13.4% of the children. The average number of affected teeth per individual was 3.6, with greater than 10% of the children having 10 or more teeth involved.

A common pattern is seen as a result of systemic influences, such as exanthematous fevers, that occur during the first 2 years of life. Horizontal rows of pits or diminished enamel are present on the anterior teeth and first molars (Figs. 2.1 and 2.2). The enamel loss is bilaterally symmetric, and the location of the defects correlates well with the

dentlearn.ir

• **Fig. 2.3 Environmental Enamel Hypoplasia.** Horizontal enamel hypoplasia of the bicuspids and second molars. Note sparing of the first molars. (From Neville BW, Damm DD, White DK: *Color atlas of clinical oral pathology,* ed. 2, Hamilton, 1999, BC Decker.)

• **Fig. 2.4 Turner Hypoplasia.** Extensive enamel hypoplasia of mandibular first bicuspid secondary to previous inflammatory process associated with overlying first deciduous molar. (From Halstead CL, Blozis GG, Drinnan AJ, et al: *Physical evaluation of the dental patient,* St Louis, 1982, Mosby.)

developmental stage of the affected teeth. A similar pattern of enamel defects can be seen in the cuspids, bicuspids, and second molars when the inciting event occurs around the age of 4–5 years (Fig. 2.3).

In patients without fluorosis, demarcated opacities may demonstrate increased surface porosity and caries susceptibility. One study reported more than twice prevalence of decay in patients with localized enamel hypoplasia or hypomineralization compared to those without such defects. The areas prone to caries demonstrated full-thickness enamel defects.

Aesthetically or functionally defective teeth can be restored through a variety of cosmetically pleasing techniques, such as the following:

- Acid-etched composite resin restorations
- Labial veneers
- Full crowns

Turner Hypoplasia

Another pattern of enamel defects seen in permanent teeth is caused by traumatic injury or periapical inflammatory disease of the overlying deciduous tooth. The altered tooth is called a **Turner tooth** (after the clinician whose publications allowed this problem to be widely recognized). The appearance of the affected area varies according to the timing and severity of the insult. The enamel defects vary from focal areas of white, yellow, or brown discoloration to extensive hypoplasia, which can involve the entire crown.

When the process occurs secondary to periapical inflammatory disease, the permanent bicuspids are affected most frequently because of their relationship to the overlying deciduous molars (Figs. 2.4 and 2.5). Anterior teeth are involved less often because crown formation usually is complete before the development of any apical inflammatory disease in the relatively caries-resistant anterior deciduous dentition. Factors that determine the degree of damage to the permanent tooth by the overlying infection include the stage of tooth development, length of time the infection

• **Fig. 2.5 Turner Hypoplasia.** Radiograph of the same tooth depicted in Fig. 2.4. Note the lack of significant enamel and irregularity of the dentin surface. (From Halstead CL, Blozis GG, Drinnan AJ, et al: *Physical evaluation of the dental patient,* St Louis, 1982, Mosby.)

remains untreated, the virulence of the infective organisms, and the host resistance to the infection.

In addition to classic Turner teeth, an increased prevalence of demarcated opacities has been reported in the permanent successors of carious primary teeth. In one report, if the primary tooth developed caries, the successor was twice as likely to demonstrate a circumscribed enamel defect. In addition, if the primary tooth was extracted for any reason other than trauma, then the prevalence of a demarcated enamel defect increased fivefold.

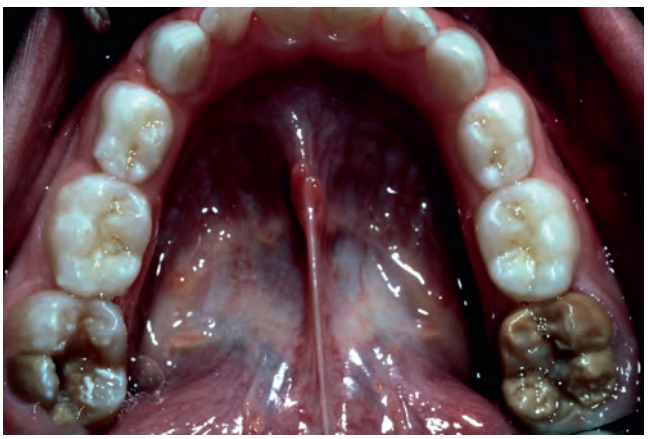
dentlearn.ir

Formation of Turner teeth secondary to traumatic injury of deciduous teeth is not uncommon because up to 45% of all children sustain injuries to their primary teeth. In a prospective study of 114 children with 255 traumatized primary teeth, 23% of the corresponding permanent teeth demonstrated developmental disturbances. The maxillary central incisors are affected in the majority of the cases; the maxillary lateral incisors are altered less frequently (Fig. 2.6). In several large reviews, the prevalence of involvement of the posterior teeth or mandibular incisors was less than 10% of all cases.

The frequency of traumatic damage to the anterior maxillary dentition is not surprising, considering the common occurrence of trauma to the deciduous dentition of the prominent anterior maxilla and the close anatomic relationship between the developing tooth bud and the apices of the overlying primary incisors. As would be expected, the clinical appearance of the alteration varies according to the timing and severity of the damage. Avulsion and intrusive luxation are the types of trauma most strongly associated with formation of Turner teeth.

Because of the position of the primary apices relative to the tooth bud, the facial surface of the maxillary incisors is the location most frequently affected. Typically, the affected area appears as a zone of white or yellowish-brown discoloration with or without an area of horizontal enamel hypoplasia. The trauma also can cause displacement of the already formed hard-tooth substance in relation to the soft tissue of the remaining developing tooth. This results in a bend of the tooth known as **dilaceration** and can affect either the crown or the root of a tooth (see page 94). Dilaceration of the crown occurs most frequently between 1.5 and 3.5 years of age, whereas dilaceration of the root usually is seen in association with trauma that occurs between 4 and 5 years of age. Severe trauma early in the development of the tooth can result in such disorganization of the bud that the resultant product may resemble a complex odontoma (see page 729). Similar levels of damage late in the formative process can lead to partial or total arrest in root formation.

Molar-Incisor Hypomineralization



Molar-incisor hypomineralization (MIH) is a condition that presents with demarcated qualitative enamel defects involving one or more first permanent molars with or without involvement of incisors. The clinical pattern is asymmetrical and can involve one or more teeth with varying severity within the same patient. Although not described until the 1970s and not widely recognized in the United States beyond pediatric dentists, the disorder has proven to be very common; a study of 337 children in Indiana demonstrated a prevalence of 13%, a finding in agreement with a meta-analysis revealing an almost identical global prevalence of 13.1%.

The etiology of MIH remains unclear. Due to the timing of enamel maturation, involvement of the deciduous teeth most likely arises from prenatal or perinatal disorders such as maternal illness, medications used during pregnancy, prematurity, or birth complications; in contrast, involvement limited to the permanent teeth appears more strongly associated with early childhood illnesses, particularly those with fever, asthma, or pneumonia.

Patients affected with MIH have enamel defects of one or more first permanent molars, which demonstrate normal surface contour unless posteruptive enamel breakdown is present. The altered enamel may be white, yellow, or brown, with a sharp demarcation between the defective and surrounding normal enamel (Fig. 2.7). Yellow or brown opacities appear to be more porous and often are associated with posteruptive enamel loss. On a microscopic level, the enamel is the demarcated opacities has larger interprismatic spaces that provide bacterial access to the underlying dentin, frequently resulting in chronic inflammation of the adjacent pulp. Affected teeth with or without posteruptive enamel loss often are highly sensitive, leading to avoidance of proper oral hygiene with rapid caries development. During attempts at dental therapy, these teeth often are very difficult to anesthetize. There appears to be a spectrum of the disease in which only the molars may be affected or the incisors also may be

• **Fig. 2.6 Turner Hypoplasia.** Extensive coronal hypoplasia of permanent maxillary left central incisor secondary to previous trauma to deciduous central incisor.

• **Fig. 2.7 Molar-incisor hypomineralization (MIH).** First permanent mandibular molars demonstrating brown hypomaturation with areas of coronal breakdown.

dentlearn.ir

involved. Affected incisors usually demonstrate only white opacities that primarily create aesthetic problems.

Similar alterations in primary cuspids and second molars have been termed *hypomineralized primary canines* (HPC) and *hypomineralized second primary molars* (HSPM). These alterations demonstrate a strong association with MIH in the permanent dentition. This association is not surprising because enamel maturation of the primary canines and second molars demonstrates significant overlap with enamel formation of the first permanent molar.

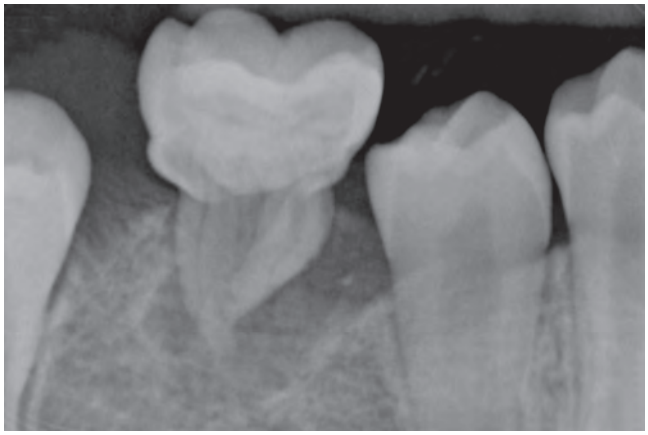
In a systematic review of **molar-incisor hypomineralizaion**, 27.4% of patients needed intervention due to pain, hypersensitivity, posteruptive breakdown, or caries. Casein phosphopeptide-amorphous calcium phosphate (CPP-ACP) can be used in mild cases to remineralize enamel and reduce sensitivity. Therapy for more advanced cases include adhesive restorations or sealants, preformed metal crowns followed by permanent indirect full crowns, or extraction often combined with orthodontic space closure. Amalgams are not ideal due to the atypically shaped cavities noted in MIH. Adhesive restorations also can be problematic due to cohesive failure related to poor quality enamel.

Molar Root-Incisor Malformation (Molar-Incisor Malformation)

Molar root-incisor malformation (MRIM) shares a number of features with **molar-incisor hypomineralization** (see previous section). Although the pathogenesis of both processes is uncertain, they are thought to be related to environmental stress early in life. In addition, the mandibular first molars and incisors are the predominant sites of involvement in both disorders.

All cases of MRIM appear sporadic with no family history of similar dental problems and almost all patients have a history of serious systemic health problems at birth or within the first 2 years of life. Although the health issues vary widely, a significant number represent central nervous system-related diseases such as meningitis, spina bifida, hydrocephalus, and seizures. Despite this, the timing of the health problems and the defining dental malformation often do not match. The primary alteration involves the roots of the first molars, which do not develop until approximately 3 years of age. Investigators speculate the environmental stressors damage or disorganize Hertwig's epithelial root sheath, leading to an abnormal function at a later date. The possibility of a genetic predisposition also has been suggested, but without any confirming evidence.

The defining feature of MRIM is the presence of short, narrow, spiked roots on all first molars with relatively normal overlying crowns (Figs. 2.8 and 2.9). The pulp chambers exhibit a reduced coronal-to-apical height with an ectopic mineralized plate between the chamber and the root canals. The malformed teeth often develop pain, mobility, and abscess formation without associated dental caries or trauma. This loss of vitality is thought to be secondary to the malformed pulp chamber or an abnormal periodontal attachment that allows formation of a combined periodontal-periapical inflammatory lesion. Similar involvement of the



• **Fig. 2.8 Molar root-incisor malformation (MRIM).** Dentition exhibiting malformed roots on all permanent first molars with mineralized plates on the floor of the pulp chambers. Note involvement of the deciduous second molars and shallow dens invaginatus of the permanent maxillary central incisors. (Courtesy of Dr. Jeff Hall).

dentlearn.ir

deciduous second molars may be seen, with rare involvement of the deciduous first molars. In about half of affected patients, one of more incisors will demonstrate marked constriction in the crown with a notch in the cervical third of the enamel. Shallow dens invaginatus (see page 88) also is seen frequently (Fig. 2.8).

In patients with **MRIM**, the anterior teeth should be inspected closely clinically and radiographically upon eruption to allow any teeth with dens invaginatus to be restored or sealed as soon as possible. Due to the high frequency of associated abscess, affected permanent first molars usually are extracted. Endodontic therapy is difficult due to the abnormal pulpal anatomy and the mineralized bridge present on the floor of the pulp. Following extraction, the healthy second and third molars may be guided into the edentulous first molar space as they develop. Alternatively, a space maintainer can be placed until the patient reaches an age that would allow successful implant placement.

• **Fig. 2.9 Molar root-incisor malformation (MRIM).** Mandibular first molar exhibiting short spiky roots. (Courtesy of Dr. Michael Myers).

Hypoplasia Caused by Antineoplastic Therapy

As modern medicine improves the prognosis of childhood cancer, it has become evident that a number of developmental alterations arise secondary to use of therapeutic radiation or chemotherapy. It has been reported that greater than 90% of childhood cancer survivors will demonstrate at least one oral complication. As would be expected, developing teeth often are affected, with these antineoplastic therapies producing clinically obvious alterations most commonly in patients younger than 12 years and most extensively in those younger than 5 years. The degree and severity of the developmental alterations are related to the patient's age at treatment, the form of therapy, and the dose and field of radiation, if used.

Although both chemotherapeutic agents and radiation therapy can be responsible for developmental abnormalities, the most severe alterations are associated with radiation. A dose of 30 Gray (Gy) stops tooth development, and dental malformations are noted in patients with doses as low as 4 Gy. As the dose escalates, so does the effect on the developing dentition and jaws. Frequently observed alterations include hypodontia, microdontia, V-shaped hypoplastic roots, and enamel hypoplasia (Fig. 2.10). Tooth agenesis and microdontia are more common in patients exposed prior to 3 years of age, whereas radicular hypoplasia is more prevalent in older children. In addition, mandibular hypoplasia and a reduction of the vertical development of the lower third of the face are not rare. The mandibular hypoplasia may be caused by one or more of the following: direct effect of therapeutic radiation, reduced alveolar bone growth secondary to impaired root development, or growth failure due to pituitary hypofunction caused by therapeutic radiation involving the cranium. Chemotherapy can produce similar but less severe dental alterations including tooth agenesis, microdontia, root hypoplasia, and enamel hypoplasia.

• **Fig. 2.10 Hypoplasia Caused by Antineoplastic Therapy.** Multiple teeth demonstrating radicular hypoplasia secondary to radiation and chemotherapy for cancer. (Courtesy of Dr. Bret Johnson.)

dentlearn.ir

Dental Fluorosis

The ingestion of excess amounts of fluoride also can result in significant enamel defects known as **dental fluorosis.** Fluoride appears to create enamel defects through retention of the amelogenin proteins in the enamel structure. This leads to the formation of hypomineralized enamel that alters light reflection and creates the appearance of white, chalky areas. Most of the problems associated with dental fluorosis are aesthetic, particularly when the anterior teeth are affected.

The severity of dental fluorosis is dose dependent, with greater ingestion of fluoride during critical periods of tooth development causing more severe fluorosis. Interestingly, individuals who consume similar levels of fluoride may demonstrate varying degrees of dental fluorosis, suggesting a genetic influence. The affected teeth are caries resistant, and the altered tooth structure appears as areas of lusterless white and opaque enamel that may have zones of yellow to dark-brown discoloration (Figs. 2.11 and 2.12). In the past, areas of moderate-to-severe enamel fluorosis were termed **mottled enamel.** True enamel hypoplasia is uncommon but can occur as deep, irregular, and brownish pits. Because other factors can result in a similar pattern of enamel damage, a definitive diagnosis requires that the defects be present in a bilaterally symmetric distribution, plus evidence of prior excessive fluoride intake or elevated levels of fluoride in the enamel or other tissues should be found.

• **Fig. 2.11 Dental Fluorosis.** Dentition exhibiting lusterless, white, and opaque enamel with areas of chipping. Notice that the deciduous teeth are spared.

• **Fig. 2.12 Dental Fluorosis.** Diffuse white opaque alteration of the dentition with areas of brown enamel mottling. Patient spent his childhood in Kenya.

Initially, fluoride's ability to reduce caries was thought to be secondary to its incorporation into developing enamel, resulting in a stronger and more acid-resistant fluorapatite crystal. Most investigators now agree that the posteruptive effects of fluoride are predominant and control caries by altering the demineralization and remineralization process that occurs at the tooth/bacterial biofilm interface. Nevertheless, fluoridated water remains an important topical source of application. Even though fluoride is present in numerous dental products, foods, and beverages, studies have shown that cessation of water fluoridation has been associated with an approximately 18% increase in dental caries. Consumption of optimally fluoridated water has been associated with a low frequency of altered enamel, which usually is mild in degree. However, an increased prevalence of dental fluorosis has been noted in recent years. The US Centers for Disease Control and Prevention reported that from 1986 to 1987, 22.6% of adolescents demonstrated some degree of fluorosis, whereas a similar group from 1999 to 2004 revealed a prevalence of 40.7%. Water fluoridation typically aims for a concentration between 0.7 and 1.2 ppm. In warm climates, the recommended concentration is 0.7 ppm due to higher consumption of water, whereas regions with more temperate climates use a concentration of 1 ppm. In 2011, the US Department of Health and Human Services recommended a nationwide standardized level of 0.7 ppm of fluoride.

The crowns of the maxillary central incisors are the most cosmetically important and their development is completed by age 3. Therefore, close monitoring of all sources of fluoride intake during the first 3 years of life is recommended strongly. Fluoride ingestion occurs primarily through four sources: drinking water, fluoride toothpaste, fluoride supplements, and infant formula. It has been reported that ingestion of fluoride dentifrices is responsible for approximately two-thirds of cases of fluorosis in the United States. A significant reduction in dental fluorosis can be seen if brushing with fluoride toothpaste does not start until after 12 months of age. Once initiated, close parental supervision with use of a rice-sized amount of toothpaste is recommended for children under 3 years of age, whereas a pea-sized amount is appropriate for children 3–6 years of age. In addition, reconstitution of infant formula with fluoridated water should be avoided. Because of the dissemination of fluoride through the food supply, the need for supplements in nonfluoridated areas is declining in many industrialized countries. Fluoride supplements are recommended only in nonfluoridated areas for children who are at high risk for rampant caries.

Although teeth affected by fluorosis have been treated with external bleaching, microabrasion, dental veneers or crowns, enamel infiltration with a low-viscosity light-cured

dentlearn.ir

resin has proven to be a successful approach to mask the altered enamel. Mild fluoride-associated opacities often fade over time, possibly due to surface tooth wear associated with daily activities.

Syphilitic Hypoplasia

Congenital syphilis (see page 181) results in a pattern of enamel hypoplasia that is well known but currently so rare that lengthy discussion is not warranted. Anterior teeth altered by syphilis are termed **Hutchinson incisors** and exhibit crowns that are shaped like straight-edge screwdrivers, with the greatest circumference present in the middle one-third of the crown and a constricted incisal edge. The middle portion of the incisal edge often demonstrates a central hypoplastic notch. Altered posterior teeth are termed **mulberry molars** and demonstrate constricted occlusal tables with a disorganized surface anatomy that resembles the bumpy surface of a mulberry.

◆ POSTDEVELOPMENTAL LOSS OF TOOTH STRUCTURE

Tooth structure can be lost after its formation by a variety of influences beyond the obvious cases related to caries or traumatic fractures. Destruction can begin on the enamel surface of the crown through abrasion, attrition, erosion, or abfraction. In addition, loss of tooth structure can begin on the dentin or cemental surfaces of the teeth by external or internal resorption.

TOOTH WEAR

Tooth wear, also termed *tooth surface loss,* is a normal physiologic process that occurs with aging but must be considered pathologic when the degree of destruction creates functional, aesthetic, or dental sensitivity problems. Although the four causes of tooth wear (i.e., **attrition, abrasion, erosion,** and **abfraction**), often are discussed as independent pathoses, most of these types of tooth loss are the result of a combination of influences. Many cases of attrition are accelerated by the presence of abrasive materials in the mouth. Erosion or abrasion often further damages areas of dentin exposed by attrition or abfraction. Areas softened by erosion are more susceptible to attrition, abrasion, and abfraction. The clinician should appreciate that acquired environmental loss of tooth structure often is multifactorial.

Most researchers agree that the reported prevalence of tooth wear is increasing. This is explained partly by a greater awareness among clinicians and by the adult population retaining more natural teeth as they age. In addition, younger individuals appear to exhibit an increased tooth surface loss that many believe may be caused by a more acidic diet (e.g., acidic soft drinks, diet foods, and fresh fruits). This belief is supported by the knowledge that consumption of acidic soft drinks in the United States has increased 300% over the past 20 years.

Attrition is the loss of tooth structure caused by tooth-to-tooth contact during occlusion and mastication. The term comes from the Latin verb *attritum,* which refers to the action of rubbing against another surface. Some degree of attrition is physiologic, and the process becomes more noticeable with age. When the amount of tooth loss is extensive and begins to affect aesthetic appearance and function, the process must be considered pathologic.

The following factors can accelerate tooth destruction:

- Poor-quality or absent enamel (e.g., fluorosis, environmental or hereditary enamel hypoplasia, or dentinogenesis imperfecta)
- Premature contacts (edge-to-edge occlusion)
- Intraoral abrasives, erosion, and grinding habits
- Medications or illicit drugs that induce bruxism

Abrasion is the pathologic wearing away of tooth structure or restorations secondary to the mechanical action of an external agent. The term arises from the Latin verb *abrasum,* which literally means *to scrape off* and implies wear or partial removal through a mechanical process. The most common cause of abrasion is toothbrushing that combines abrasive toothpaste with heavy pressure and a horizontal brushing stroke. Other items frequently associated with dental abrasion include pencils, toothpicks, pipe stems, and bobby pins. Chewing tobacco, cracking nuts and seeds, biting fingernails or thread, and using dental floss inappropriately also can cause clinically significant abrasion. When tooth wear is accelerated by chewing an abrasive substance between opposing teeth, the process has been termed **demastication** and exhibits features of both attrition and abrasion.

Erosion is the loss of tooth structure caused by a nonbacterial chemical process. The term is derived from the Latin verb *erosum,* which literally means *to corrode* and implies gradual destruction of a surface by a chemical or electrolytic process. Typically, exposure to an acid is to blame, but chelating agents are occasionally the primary cause. Although saliva aids remineralization and contains bicarbonate with a significant buffering ability, the bicarbonate level of saliva is directly correlated to salivary flow, with the buffering capability reduced in situations with low flow rates. Causes for salivary gland hypofunction include salivary gland aplasia, dehydration, therapeutic radiation, medications, and systemic conditions such as Sjögren syndrome, bulimia nervosa, and diabetes. The acidic source often is foods or drinks (especially acidic and carbonated soft drinks), but other causes include some medications and illicit drugs, swimming pools with poorly monitored pH, chronic involuntary regurgitation (e.g., hiatal hernia, esophagitis, chronic alcoholism, and pregnancy), voluntary regurgitation (e.g., psychologic problems, bulimia, and occupations that require low body weight), industrial environmental exposure, and occupations such as sommeliers. Erosion from dental exposure to gastric secretions is termed **perimolysis.** Because saliva has the ability to remineralize tooth surfaces exposed to acid, it appears that areas of erosive damage must have some abrasive component that removes the softened enamel before

dentlearn.ir

remineralization. The susceptibility to erosion varies among individuals and appears to be related to the quality of the enamel, the composition of the saliva, and the protective effect of the salivary pellicle.

Dental erosion appears associated strongly with both the frequency and duration of exposure to acidic foods and drinks. Due to the buffering abilities of saliva, acid clearance and pH stabilization typically occurs 2–13 minutes after exposure. Increased erosion is noted in individuals who ingest acidic foods in between meals or increase the exposure times by sipping drinks or slowly eating acidic fruits. Four or more daily dietary exposures to acid have been associated with a higher risk of erosive tooth wear. Use of straws positioned in the back of the mouth tend to bypass the teeth and reduce the erosive potential of acidic drinks, whereas straw placement in the labial vestibule increases the erosive effects. The erosive potential also is influenced by the calcium and phosphate concentration. Acidic foods with a significant calcium content, such as yogurt, demonstrate a low erosive potential.

Abfraction refers to the loss of tooth structure from occlusal stresses that create repeated tooth flexure with failure of enamel and dentin at a location away from the point of loading. The term is derived from the Latin words *ab* and *fractio,* which respectively translate into *away* and *breaking.* Dentin is able to withstand greater tensile stress than enamel. When occlusal forces are applied eccentrically to a tooth, the tensile stress is concentrated at the cervical fulcrum, leading to flexure that may produce disruption in the chemical bonds of the enamel crystals in the cervical areas. Once damaged, the cracked enamel can be lost or more easily removed by erosion or abrasion.

Agreement on the prevalence of abfraction does not exist. Some propose that abfraction causes most cervical tooth loss; others believe that little evidence exists to indicate that this sequence of events actually occurs in the mouth. A number of systematic reviews have found little support for occlusal forces being responsible for noncarious cervical tooth loss, bringing into question the validity of abfraction.

Clinical Features

Attrition

Attrition can occur in both the deciduous and the permanent dentitions. As would be expected, the surfaces predominantly affected are those that contact the opposing dentition. Most frequently, the incisal and occlusal surfaces are involved, in addition to the lingual of the anterior maxillary teeth and the labial of the anterior mandibular teeth. Large, flat, smooth, and shiny wear facets are found in a relationship that corresponds to the pattern of occlusion. The interproximal contact points also are affected from the vertical movement of the teeth during function. Over time, this interproximal loss can result in a shortening of the arch length. Pulp exposure and dentin sensitivity are rare because of the slow loss of tooth structure and the apposition of reparative secondary dentin within the pulp chamber (Fig. 2.13).

• **Fig. 2.13 Attrition.** Extensive loss of coronal tooth height without pulp exposure in patient with anterior edge-to-edge occlusion.

• **Fig. 2.14 Abrasion.** Horizontal cervical notches on the anterior mandibular dentition. Note visible pulp canals that have been filled with tertiary dentin.

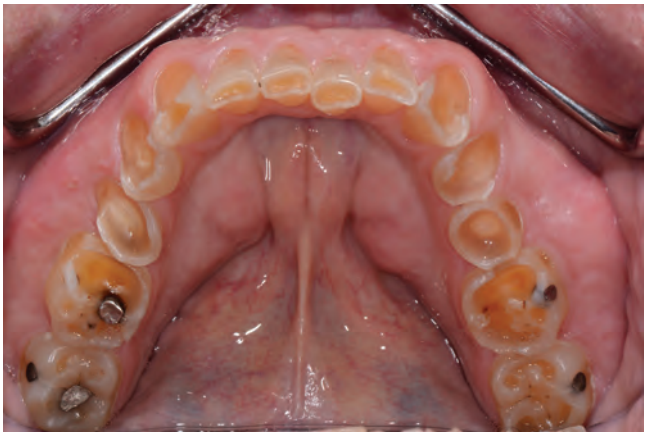
Abrasion

Abrasion has a variety of patterns, depending on the cause. Toothbrush abrasion typically appears as horizontal cervical notches on the buccal surface of exposed radicular cementum and dentin (Fig. 2.14). The defects usually have sharply defined margins and a hard, smooth surface. If acid also is present, then the lesions are more rounded and shallower. The degree of loss is greatest on prominent teeth (i.e., cuspids, bicuspids, and teeth adjacent to edentulous areas) and occasionally is more advanced on the side of the arch opposite the dominant hand. Thread biting or the use of pipes or bobby pins usually produces rounded or V-shaped notches in the incisal edges of anterior teeth (Fig. 2.15). The inappropriate use of dental floss or toothpicks results in the loss of interproximal radicular cementum and dentin.

Erosion

In patients with **erosion,** the tooth loss does not correlate with functional wear patterns or with those typically associated with known abrasives. The predominant sites of tooth loss appear to correlate closely with those areas not protected

dentlearn.ir



• **Fig. 2.15 Abrasion.** Notching of the anterior dentition on the right side caused by long-term use of tobacco pipe.

• **Fig. 2.16 Erosion.** Multiple cupped-out depressions corresponding to the cusp tips.

• **Fig. 2.17 Erosion.** Extensive tooth wear. Note spoon-shaped depressions in anterior teeth and depressed dentin adjacent to elevated ridges of enamel in more posterior teeth.

• **Fig. 2.18 Erosion.** Same patient as depicted in Fig. 2.17. Multiple mandibular teeth exhibiting depressions of dentin surrounded by elevated rims of enamel. Note the amalgam in the first molar that is raised above the surface of the surrounding depressed dentin.

by the serous secretions of the parotid and submandibular glands. The facial and palatal surfaces of the maxillary anterior teeth and the facial and occlusal surfaces of the mandibular posterior teeth are affected most frequently. Involvement of the lingual surfaces of the entire mandibular dentition is uncommon, possibly because of the protective buffering capacity of the submandibular serous saliva.

The classic pattern of dental erosion is the cupped lesion in which a central depression of dentin is surrounded by elevated enamel. Cupped areas are seen on the occlusal cusp tips, incisal edges, and marginal ridges (Fig. 2.16). In contrast to abrasion, erosion commonly affects the facial surfaces of the maxillary anteriors and appears as shallow spoon-shaped depressions in the cervical portion of the crown (Fig. 2.17). The posterior teeth frequently exhibit extensive loss of the occlusal surface, and the edges of metallic restorations subsequently may be above the level of the tooth structure (Fig. 2.18). After a portion of the cuspal enamel has been lost, the dentin is destroyed more rapidly than the remaining enamel, often resulting in a concave depression of the dentin surrounded by an elevated rim of enamel (see Fig. 2.18). The more rapid dissolution of the dentin can lead to undermined enamel that often is lost easily by chipping. Occasionally, entire buccal cusps are lost and replaced by ski slope–like depressions that extend from the lingual cusp to the buccal cementoenamel junction (Fig. 2.19). When palatal surfaces are affected, the exposed dentin has a concave surface and shows a peripheral white line of enamel (Fig. 2.20). Active erosion typically reveals a clean, unstained surface, whereas inactive sites become stained and discolored.

Erosion limited to the facial surfaces of the maxillary anterior dentition often is associated with dietary sources of acid. When the tooth loss is confined to the incisal portions of the anterior dentition of both arches, an external environmental source is suggested. When erosion is located on the palatal surfaces of the maxillary anterior teeth and the occlusal surfaces of the posterior teeth of both dentitions, regurgitation of gastric secretions is a probable cause. The location of the tooth structure loss may suggest the cause of the damage but is not completely reliable.

dentlearn.ir

• **Fig. 2.19 Erosion.** Extensive loss of enamel and dentin on the buccal surface of the maxillary bicuspids. The patient had sucked chronically on tamarinds (an acidic fruit).

• **Fig. 2.21 Abfraction.** Deep and narrow enamel cervical defects on the facial surface of the mandibular dentition. (From Neville BW, Damm DD, White DK: *Color atlas of clinical oral pathology,* ed 2, Hamilton, 1999, BC Decker.)

• **Fig. 2.20 Erosion.** Palatal surfaces of the maxillary dentition in which the exposed dentin exhibits a concave surface and a peripheral white line of enamel. The patient had bulimia.

Abfraction

Abfraction appears as wedge-shaped defects limited to the cervical area of the teeth and may closely resemble cervical abrasion or erosion. Clues to the diagnosis include defects that are deep, narrow, and V-shaped (which do not allow the toothbrush to contact the base of the defect) and often affect a single tooth with adjacent unaffected teeth (Fig. 2.21). In addition, occasional lesions are subgingival, a site typically protected from abrasion and erosion. The lesions predominantly affect the facial surfaces of the bicuspids and molars.

In all forms of tooth wear, the process typically proceeds at a slow rate that allows deposition of tertiary dentin and prevents pulp exposure, even when extensive loss of tooth structure is present (see Fig. 2.14). In some cases, especially in the deciduous dentition, the tooth loss can proceed at a more accelerated rate, which results in a near or frank exposure of the pulp.

Treatment and Prognosis

Normal levels of attrition require no therapy, with intervention reserved for those cases that create a pathologic degree of tooth loss. Early diagnosis and intervention may assist in preserving the permanent dentition. Before any definitive action, the clinician must remember that tooth wear almost invariably has a multifactorial cause. Failure to recognize the interrelationships of these pathoses can lead to inappropriate therapy and failure of any attempted repair. Intervention should emphasize detailed diagnosis, preventive measures, and long-term monitoring. Immediate therapy should be directed toward resolution of tooth sensitivity and pain, but identifying the causes of tooth structure loss and protecting the remaining dentition also are important goals.

In patients affected by dental erosion, preventive interventions should attempt not only to reduce the frequency and duration of acid exposure but also to improve the oral cavity's ability to resist the effects of acid. Upon exposure to an acid, the saliva has the ability to achieve remineralization with time, but teeth are vulnerable to abrasion before completion of this action. Although some investigators have recommended a minimum 1-hour interval between acid exposure and toothbrushing in an attempt to minimize abrasion of the weakened enamel, other studies have shown that a brushing delay is not warranted due to the inability of saliva to achieve complete remineralization. Low-abrasive toothpaste and professional guidance to prevent inappropriate, overzealous, or too frequent toothbrushing may assist in reducing associated abrasion. Consumption of buffering substances such as milk, cheese, and sugar-free antacids also is thought to be beneficial. Rinsing the mouth with water after acid exposure and proper hydration have been suggested to reduce the severity of demineralization and maintain sufficient salivary flow with appropriate buffering capability. A suspected common cause of tooth loss is decreased salivary flow secondary to dehydration, often associated with strenuous work or athletic activities and possibly complicated by use of acidic soft drinks or sports beverages in the place of water. Chewing xylitol gum has been suggested as a method for decreasing dental erosion by increasing salivary flow after acid exposure, but others have demonstrated that enamel softened by acid can be damaged by the adjacent soft tissues

dentlearn.ir

during the movements of chewing in this time of vulnerability. Patients should be informed of the potential for loss of tooth structure associated with the overuse of acidic foods and drinks (e.g., wine, carbonated beverages, foods pickled in acetic acid, and citrate-containing fruits, fruit juices, and candies), chronic regurgitation, and improper oral hygiene techniques. Mouth guards and occlusal adjustment can be used to slow nocturnal attrition and to protect the teeth from frequent exposure to acid from regurgitation or industrial sources. Dental sensitivity can be reduced through the use of varnishes, mouthwashes, or toothpastes containing strontium chloride, stannous fluoride, or monofluorophosphate. If initially unsuccessful, these agents can be combined with iontophoresis.

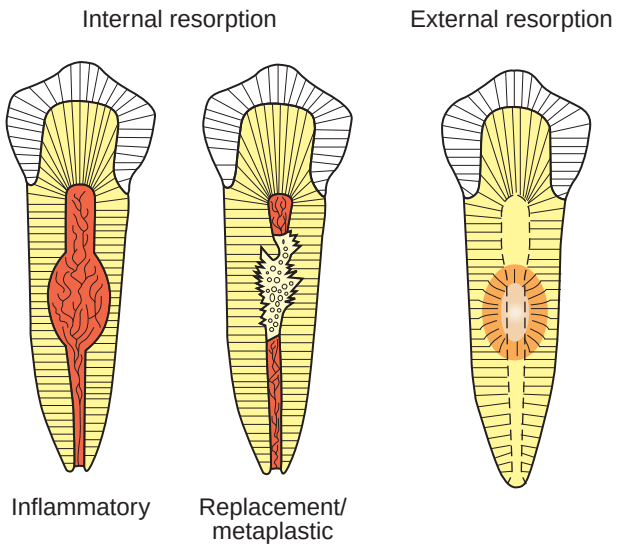
Active restorative therapy is premature in the presence of ongoing tooth wear and should be postponed until the patient expresses strong aesthetic concerns, exhibits dental sensitivity that is nonresponsive to conservative interventions, or demonstrates progressive and uncontrollable wear. Once indicated, the minimum treatment necessary to solve the problem should be implemented. In lesions thought to represent abfraction, glass ionomer materials are recommended because of their greater resilience that allows the material to flex with the tooth. In areas of abrasion, a material with optimum resistance to the abrasive process should be chosen. Replacement of lost posterior teeth and avoidance of edge-to-edge occlusion limit the effects of attrition. Lost tooth structure can be restored with composite resins, veneers, onlays, or full crowns. Restorative procedures that do not involve significant removal of remaining tooth structure are preferable in patients demonstrating extensive tooth wear.

INTERNAL AND EXTERNAL RESORPTION

In addition to loss of tooth structure that begins on the exposed coronal surfaces, destruction of teeth also can occur through resorption, which is accomplished by cells located in the dental pulp (i.e., **internal resorption**) or in the periodontal ligament (PDL) (i.e., **external resorption**). Internal resorption is a relatively rare occurrence, and most cases develop after injury to pulpal tissues, such as physical trauma or caries-related pulpitis. The resorption can continue as long as vital pulp tissue remains and may result in communication of the pulp with the PDL.

In contrast, external resorption is extremely common; with close examination, all patients are most likely to have root resorption on one or more teeth. In one radiographic review of 13,263 teeth, all patients showed evidence of root resorption, and 86.4% of the examined teeth demonstrated external resorption, with an average of 16 affected teeth per patient. Most areas of resorption are mild and of no clinical significance, but 10% of patients exhibit unusual amounts of external resorption.

The potential for resorption is inherent within the periodontal tissue of each patient, and this individual susceptibility to resorption is the most important factor in the degree of resorption that will occur after a stimulus. The factors reported to increase the severity of external resorption are delineated in Box 2.3. Many cases have been termed *idiopathic* because no factor could be found to explain the accelerated resorption. Although local factors may exert a strong influence, many researchers believe genetic predisposition plays a strong role. One investigation demonstrated a 5.6-fold increase in root resorption during orthodontics in patients demonstrating homozygosity for the interleukin-1 beta (IL-1B) allele. In addition, examples of families with generalized idiopathic root resorption and monozygotic twins presenting with identical patterns of root resorption have been reported. Genetics appears to be a modifying factor that can increase the severity of external resorption when triggered by a secondary influence. When pretreatment radiographs of a given patient exhibit a degree of resorption beyond that which is normally seen, the clinician should realize the potential risks involved in initiating procedures (e.g., orthodontics) that are known to be associated with an increased risk of external resorption.



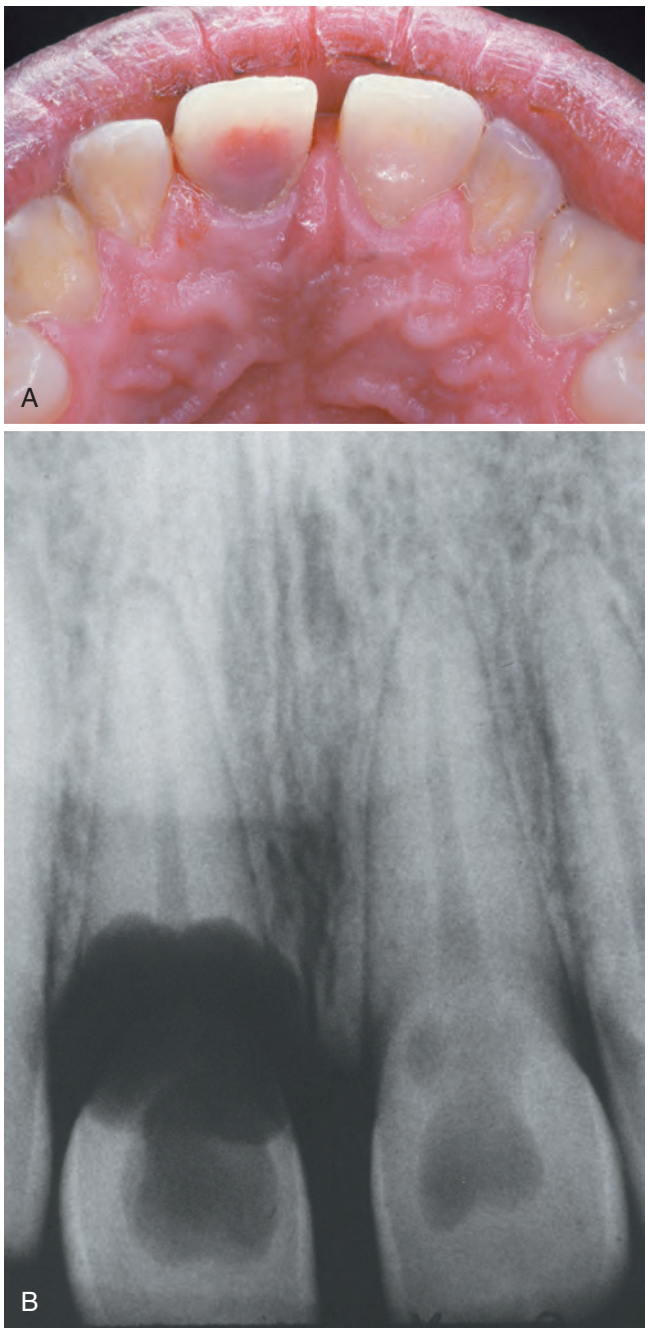
• BOX 2.3 Factors Associated With External Resorption

- Cysts
- Dental trauma
- Excessive mechanical forces (e.g., orthodontic therapy)
- Excessive occlusal forces
- Grafting of alveolar clefts
- Hormonal imbalances
- Hyperparathyroidism
- Intracoronal bleaching of pulpless teeth
- Local involvement by herpes zoster
- Paget disease of bone
- Periodontal treatment
- Periradicular inflammation
- Pressure from impacted teeth
- Reimplantation of teeth
- Tumors

Clinical and Radiographic Features

Resorption of dentin or cementum can occur at any site that contacts vital soft tissue. **Internal resorption** usually is asymptomatic and discovered through routine radiographs. Pain may be reported if the process is associated with significant pulpal inflammation. Two main patterns are seen: (1) **inflammatory resorption** and (2) **replacement** or **metaplastic resorption** (Fig. 2.22). In inflammatory resorption, the resorbed dentin is replaced by inflamed granulation tissue. Although this pattern may involve any portion of the canal, the cervical zone is affected most frequently (and the pulpal inflammation usually is caused by bacterial invasion). The resorption continues as long as vital pulp remains; typically, the coronal pulp is necrotic with the apical portion remaining vital. The results of pulp testing are variable. In this pattern, the area of destruction usually appears as a uniform, well-circumscribed symmetric radiolucent enlargement of the

dentlearn.ir



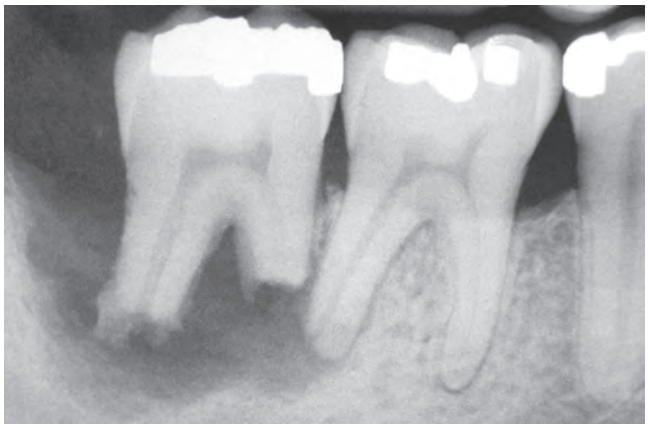
• **Fig. 2.22 Tooth Resorption.** Illustration contrasting the common patterns of internal and external tooth resorption. Internal resorption will result in a radiolucent enlargement of the pulp chamber or canal. In external resorption, the radiolucency is superimposed on the pulp canal, which should not be enlarged.

pulp chamber or canal. When it affects the coronal pulp, the crown can display a pink discoloration **(pink tooth of Mummery)** as the vascular resorptive process approaches the surface (Fig. 2.23). When it occurs in the root, the original outline of the canal is lost and a balloon-like radiographic dilation of the canal is seen (Fig. 2.24). If the process continues, the destruction eventually can perforate the lateral root surface, which may be difficult to distinguish from external root resorption. Internal resorption secondary to infectious pulpitis may cease upon necrosis of the responsible cells within the pulp. Although many cases are progressive, some cases are self-limiting and usually arise in traumatized teeth or those that have recently undergone orthodontic or periodontal therapy.

In *replacement* or *metaplastic resorption*, portions of the pulpal dentinal walls are resorbed and replaced with bone or cementum-like bone (see Fig. 2.22). Radiographically, replacement resorption appears as an enlargement of the canal, which is filled with a material that is less radiodense than the surrounding dentin. Because a central zone of the pulp is replaced with bone, the radiographic appearance often demonstrates partial obliteration of the canal. The outline of destruction is less defined than that seen in inflammatory resorption.

External resorption demonstrates a wider variety of patterns and includes inflammatory, surface, replacement, and cervical resorption. **External inflammatory resorption** arises secondary to an inflammatory process, usually periapical inflammatory disease or periodontitis (Fig. 2.25). The affected teeth will demonstrate loss of root length, often with ragged apices. The results of vitality testing depend on the origin of the inflammatory process, and the resorption often ceases with elimination of the focus of infection.

• **Fig. 2.23 Internal Resorption (Pink Tooth of Mummery). A,** Pink discoloration of the maxillary central incisor. **B,** Radiograph of same patient showing extensive resorption of both maxillary central incisors.



A variation of inflammatory resorption that occurs following luxation injuries is termed **transient apical breakdown** and presents with focal resorption of the root tip in association with widening of the apical periodontal ligament and loss or blurry appearance of the lamina dura encircling the apex. Vitality testing is variable and creates confusion with early periapical inflammatory disease. The resorption is followed quickly by repair, with the process resolving spontaneously within 12 months.

External surface resorption occurs secondary to pressure applied to the root surface. Orthodontic tooth movement,

dentlearn.ir

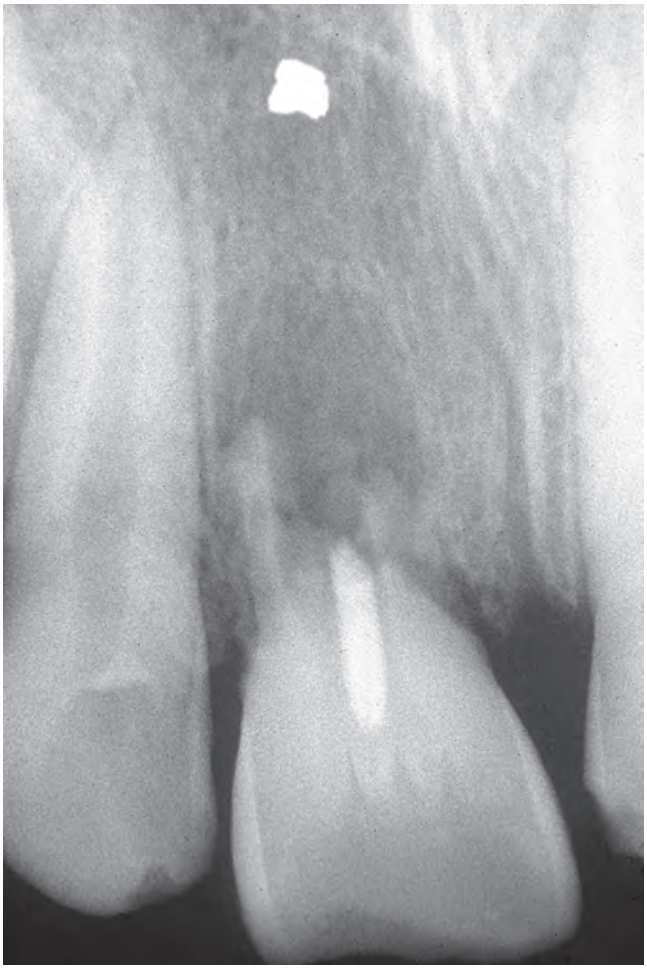
• **Fig. 2.25 External Inflammatory Resorption.** Extensive irregular destruction of both roots of the mandibular second molar associated with chronic periodontitis. (Courtesy of Dr. Tommy Shimer.)

adjacent impacted teeth, enlarging cysts, and tumors are common causes. Teeth affected by orthodontic treatment may demonstrate blunted or shortened roots (Fig. 2.26). Resorption secondary to impacted teeth, cysts, and tumors often will exhibit irregular or saucer-shaped area of tooth loss.

External resorption occurring during orthodontics appears to be influenced most strongly by the patient's individual susceptibility. However, heavy forces have been shown to induce a greater degree of resorption, and compressive forces appear more strongly related than tensile forces. The single most important local factor is the distance a tooth is moved during therapy. The maxillary anterior teeth typically are the most severely affected, particularly in patients who have been treated with premolar extractions. Movement



• **Fig. 2.26 External Surface Resorption.** Diffuse external resorption of radicular dentin of maxillary dentition. This process arose after initiation of orthodontics.

of teeth with an abnormal root shape (such as, dilaceration) also has been associated with an increased severity of external resorption. In patients who have demonstrated significant resorption during therapy, a 2- to 3-month treatment pause has been shown to reduce the final amount of treatment-associated external resorption.

External replacement resorption refers to osteoclastic removal of cementum and dentin with replacement by alveolar bone. This process usually occurs secondary to severe luxation or avulsion of the tooth. In reimplanted avulsed teeth, extensive external resorption of the root is extremely common without rapid and appropriate intervention (see Fig. 2.27). If the tooth remains outside of the socket without being placed in a proper storage medium, then the periodontal ligament cells undergo necrosis. Without vital periodontal ligament cells, the surrounding bone views the tooth as a foreign object and initiates resorption with replacement by bone. Affected teeth often will demonstrate ankylosis, with many surviving for years until almost the entire root is lost.

Invasive cervical resorption is an uncommon but rather troublesome pattern of external resorption that begins in the cervical cementum usually apical to the epithelial attachment (Fig. 2.28). Although the process may begin as a small perforation, the resorption often extends circumferentially into the dentin of the crown and a larger portion of the root. The destruction often will encircle the pulp chamber but typically will not invade the pulp until late in the course of tooth destruction. The pulp is surrounded by a protective resorption-resistant sheet containing a significant layer of predentin, a material that resists attachment of osteoclastic cells. As the process proceeds, portions of the granulation

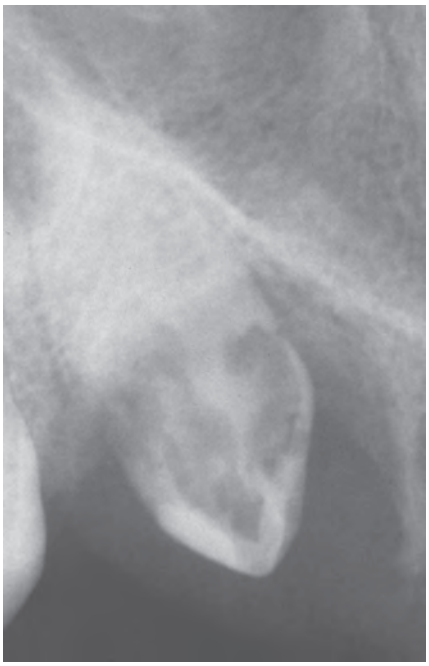
dentlearn.ir

• **Fig. 2.27 External Replacement Resorption.** Complete loss of the root leaving only the metallic retrofill of the root tip. The tooth had been reimplanted after traumatic avulsion. (Courtesy of Dr. Lawrence Bean.)

• **Fig. 2.28 Invasive Cervical Resorption.** Extensive cervical resorption of several anterior mandibular teeth. (Courtesy of Dr. Keith Lemmerman.)

tissue within the areas of resorption often are replaced by metaplastic bone. When the process involves more than three teeth, it is termed **multiple idiopathic cervical root resorption.** This condition typically exhibits an aggressive clinical course.

Although the cause of invasive cervical resorption is not known, it is believed that an initial injury leads to localized damage to the periodontal ligament with focal loss of cementum and exposure of the underlying dentin. With continued inflammation, granulation tissue forms and begins the resorptive process. As would be expected, the possible causes of the initial injury are diverse with orthodontic treatment, traumatic injury, removal of an adjacent tooth, periodontitis, malocclusion, and bruxism frequently mentioned as possible triggers. Cats develop a similar process termed *feline odontoclastic resorptive lesions* that has been associated with a feline herpes virus. It has been suggested that some cases of invasive cervical resorption in humans may arise secondary to transmission of the feline virus from their cats, with reports of owners shown to demonstrate positive titers of neutralizing antibodies against the feline virus. Often, a combination of factors appears to be involved in the initiation and propagation of the resorptive process. In addition to invasive cervical resorption, generalized and progressive external resorption also can affect the apical portion of the roots. Although this pattern can occur secondary to an endocrine disturbance or one of a small number of systemic conditions, many of these cases are idiopathic and difficult to arrest. On occasion, the idiopathic apical resorption demonstrates a bilaterally symmetrical pattern that suggests the possibility of occlusal interferences triggering resorption in a genetically predisposed patient (Fig. 2.29).



External resorption typically appears as a "moth-eaten" loss of tooth structure in which the radiolucency is less well defined and demonstrates variations in density. If the lesion overlies the pulp canal, then close examination demonstrates the retention of the unaltered canal through the area of the defect. Most cases involve the apical or midportions of the root. External resorption can create significant defects in the crowns of teeth before eruption (see Fig. 2.30). This pattern frequently is misdiagnosed as preeruptive caries and is thought by some investigators to be caused by defects in the enamel epithelium that allow connective tissue to come into direct contact with the enamel.

If difficulty arises in distinguishing external from internal resorption, then the mesial-buccal-distal rule can be used through two radiographic exposures. Although use of plain film techniques remains valid, the diagnostic accuracy of

dentlearn.ir

• **Fig. 2.29 Idiopathic External Resorption.** First molars in all four quadrants demonstrate extensive radicular external resorption.

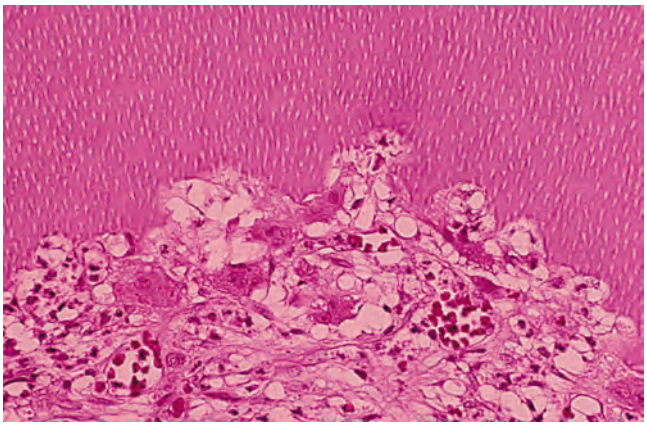
• **Fig. 2.30 External Resorption.** Extensive external resorption of the crown of the impacted right maxillary cuspid. Histopathologic examination revealed resorption without bacterial contamination or caries.

cone beam computed tomography (CBCT) has been shown to be superior and should be considered the standard of care for evaluation of the nature and extent of significant internal and external resorption.

Histopathologic Features

In patients with internal inflammatory resorption, the pulp tissue in the area of destruction is vascular and exhibits increased cellularity and collagenization. Immediately adjacent to the dentinal wall are numerous multinucleated dentinoclasts, which are histologically and functionally identical to osteoclasts (Fig. 2.31). An inflammatory infiltrate characterized by lymphocytes, histiocytes, and polymorphonuclear leukocytes is not uncommon. In replacement resorption, the normal pulp tissue is replaced by woven bone that fuses with the adjacent dentin. External resorption is similar in appearance, with numerous multinucleated dentinoclasts located in the areas of structure loss. Areas of resorption often are repaired through deposition of osteodentin. In large defects, external inflammatory resorption results in deposition of inflamed granulation tissue, and areas of replacement with woven bone may also be seen. Extensive bony replacement in areas of external resorption can lead to ankylosis.

dentlearn.ir



Treatment and Prognosis

The treatment of internal and external resorption centers on the removal of all soft tissue from the sites of dental destruction. Internal resorption can be stopped consistently if endodontic therapy successfully removes all vital pulp tissue before the process perforates into the PDL. Once perforation occurs, therapy becomes more difficult, and the prognosis is poor. In such cases, initial placement of calcium hydroxide paste occasionally may result in remineralization of the site of perforation and stop the resorptive process. If remineralization of cervical sites of perforation is not successful, then surgical exposure and restoration of the defect may halt the process. Extraction often is necessary for radicular perforations that do not respond to therapy.

The first step in treating external resorption is the identification and elimination of any accelerating factor. Apically located sites cannot be approached without significant damage created by attempts at access. Because the cells responsible for the resorption are located within the PDL, endodontic therapy is not effective in stopping the process.

Treatment of invasive cervical resorption is difficult and varies according to the extent and location of the resorptive defects. Therapies include external repair with or without endodontics, internal repair with root canal therapy, repair with intentional reimplantation, periodic review without intervention, and extraction. In contrast to the isolated variant, therapy of multiple idiopathic cervical root resorption is unsatisfactory with the vast majority of reported cases demonstrating repeated recurrences of the resorptive process with ultimate loss of the affected teeth.

For avulsed teeth, the best way to prevent resorption is to maintain PDL vitality by immediate reimplantation or short-term use of a physiologic storage solution. Teeth reimplanted with an open apex should be monitored monthly; for teeth with a closed apex, endodontic therapy is necessary. Avulsed teeth with an open apex and nonvital PDL cells should not be implanted.

• **Fig. 2.31 Internal Resorption.** Resorption of the inner dentinal wall of the pulp. Note cellular and vascular fibrous connective tissue, which exhibits an adjacent inflammatory infiltrate and numerous dentinoclasts within resorptive lacunae.

◆ ENVIRONMENTAL DISCOLORATION OF TEETH

The color of normal teeth varies and depends on the shade, translucency, and thickness of the enamel. In primary teeth, the normal color is bluish white, whereas permanent teeth tend to be grayish white or yellowish white. With aging, the enamel thins and the dentin thickens, leading to teeth that are more yellow or grayish yellow. Abnormal colorations may be **extrinsic** or **intrinsic.** Extrinsic stains occur from surface accumulation of an exogenous pigment and typically can be removed with a surface treatment, whereas intrinsic discolorations arise from an endogenous material that is incorporated into the enamel or dentin and cannot be removed by prophylaxis with toothpaste or pumice. Box 2.4 lists the most frequently documented causes of tooth discolorations.

Dental fluorosis is discussed in the section on environmental effects on the structural development of the teeth (see page 57). The alterations associated with **amelogenesis imperfecta** (see page 98) and **dentinogenesis imperfecta (DGI)** (see page 104) are presented later in this chapter in the text devoted to primary developmental alterations of the teeth.

Clinical Features

Extrinsic Stains

Bacterial stains are a common cause of surface staining of exposed enamel, dentin, and cementum. Chromogenic bacteria can produce colorations that vary from green or black-brown to orange. The discoloration occurs most frequently in children and usually is seen initially on the labial surface of the maxillary anterior teeth in the gingival one-third. In contrast to most plaque-related discolorations, the black-brown stains most likely are not primarily of bacterial origin

• BOX 2.4 Tooth Discolorations

dentlearn.ir

but are secondary to the formation of ferric sulfide from an interaction between bacterial hydrogen sulfide and iron in the saliva or gingival crevicular fluid.

Extensive use of **tobacco** products, betel quid, **tea,** or **coffee** often results in significant brown discoloration of the surface enamel (Fig. 2.32). The tar within the tobacco dissolves in the saliva and easily penetrates the pits and fissures of the enamel. Smokers (of tobacco or marijuana) most frequently exhibit involvement of the lingual surface of the mandibular incisors; users of smokeless tobacco often demonstrate involvement of the enamel in the area of tobacco placement. Stains from beverages also often involve the lingual surface of the anterior teeth, but the stains are usually more widespread and less intense. In addition, foods that contain abundant chlorophyll can produce a green discoloration of the enamel surface.

The green discoloration associated with chromogenic bacteria or the frequent consumption of chlorophyll-containing foods can resemble the pattern of green staining seen secondary to **gingival hemorrhage.** As would be expected, this pattern of discoloration occurs most frequently in patients with poor oral hygiene and erythematous, hemorrhagic, and enlarged gingiva. The color results from the breakdown of hemoglobin into green biliverdin.

A large number of **medications** may result in surface staining of the teeth. In the past, use of products containing high amounts of iron or iodine was associated with significant black pigmentation of the teeth. Exposure to sulfides, silver nitrate, or manganese can cause stains that vary from gray to yellow to brown to black. Copper, nickel, or ciprofloxacin may produce a green stain; cadmium, essential oils, doxycycline, linezolid, glibenclamide, and amoxicillin-clavulanic acid may be associated with a yellow to brown discoloration.

More recently, the most frequently reported culprits include **stannous fluoride** and **chlorhexidine.** Fluoride staining may be associated with the use of 8% stannous fluoride and is thought to be secondary to the combination of the stannous (tin) ion with bacterial sulfides. This black stain occurs predominantly in people with poor oral hygiene in areas of a tooth previously affected by early carious involvement. The labial surfaces of anterior teeth and the occlusal surfaces of posterior teeth are the most frequently affected. Chlorhexidine is associated with a yellow-brown stain that predominantly involves the interproximal surfaces near the gingival margins. The degree of staining varies with the concentration of the medication and the patient's susceptibility. Although an increased frequency has been associated with the use of tannin-containing beverages, such as tea and wine, effective brushing and flossing or frequent gum chewing can minimize staining. Chlorhexidine is not alone in its association with tooth staining; many oral antiseptics, such as Listerine and sanguinarine, also may produce similar changes.

Silver diamine fluoride has become a popular therapy for arresting and preventing caries in young children with childhood caries, especially for individuals with problems that interfere with routine dental care. Application of silver diamine fluoride is inexpensive and easy to apply, but it is associated with noticeable black discoloration. Although parents often will tolerate the discoloration on posterior teeth, the altered aesthetics limit its use on anterior teeth.

Intrinsic Stains

Congenital erythropoietic porphyria (Günther disease) is an autosomal recessive disorder of porphyrin metabolism that results in the increased synthesis and excretion of porphyrins and their related precursors. Significant diffuse discoloration of the dentition is noted as a result of the deposition of porphyrin in the teeth (Fig. 2.33). Affected teeth demonstrate a marked red-brown coloration that exhibits a red fluorescence when exposed to a Wood's ultraviolet (UV) light. The deciduous teeth demonstrate a more intense coloration because porphyrin is present in the enamel and the dentin; in the permanent teeth, only the dentin is affected. The discoloration is most intense along the cervical margin and decreases in intensity toward the occlusal surface. Excess porphyrins also are present in the urine, which typically is reddish-brown with a similar fluorescence when exposed to a Wood's light. Affected patients

• **Fig. 2.32 Tobacco Discoloration.** Extrinsic brown stains of the enamel on the lingual surfaces of the anterior mandibular dentition secondary to long-term tobacco abuse.

• **Fig. 2.33 Erythropoietic Porphyria–Related Discoloration.** Red-brown discoloration of the maxillary dentition.

dentlearn.ir

also will demonstrate areas of cutaneous hyper- and hypopigmentation with bullae and vesicles on sun-exposed skin.

Another autosomal recessive metabolic disorder, **alkaptonuria,** is associated with a blue-black discoloration termed *ochronosis* that occurs in connective tissue, tendons, and cartilage. On rare occasions, a blue discoloration of the dentition may be seen in patients who also are affected with Parkinson disease.

Bilirubin is a breakdown product of red blood cells, and excess levels can be released into the blood in a number of conditions. The increased amount of bilirubin can accumulate in the interstitial fluid, mucosa, serosa, and skin, resulting in a yellow-green discoloration known as **jaundice** (see page 823). During periods of **hyperbilirubinemia,** developing teeth also may accumulate the pigment and become stained intrinsically. In most cases, the deciduous teeth are affected as a result of hyperbilirubinemia during the neonatal period. The two most common causes are **erythroblastosis fetalis** and **biliary atresia.** Other diseases that less frequently display intrinsic staining of this type include the following:

- Premature birth
- ABO incompatibility
- Neonatal respiratory distress
- Significant internal hemorrhage
- Congenital hypothyroidism
- Cholestasis
- Biliary hypoplasia
- Metabolic diseases (tyrosinemia, α1-antitrypsin deficiency)
- Neonatal hepatitis

The extent of the dental changes correlates with the period of hyperbilirubinemia, and most patients exhibit involvement limited to the primary dentition. Occasionally, the cusps of the permanent first molars may be affected. In addition to enamel hypoplasia, the affected teeth frequently demonstrate a green discoloration (**chlorodontia**). The color is the result of the deposition of biliverdin (the breakdown product of bilirubin that causes jaundice). Although the teeth often are dark green initially, the discoloration typically fades and becomes a less intense yellow-green or grayish (Fig. 2.34). The color of tooth structure formed after the resolution of the hyperbilirubinemia appears normal. The teeth often demonstrate a sharp dividing line, separating green portions (formed during hyperbilirubinemia) from normal-colored portions (formed after normal levels of bilirubin were restored).

Coronal discoloration is a frequent finding after **trauma,** especially in the deciduous dentition. Posttraumatic injuries may create pink, yellow, or dark-gray discoloration. Temporary pink discoloration that arises 1–3 weeks after trauma may represent localized vascular damage and often returns to normal in 1–3 weeks. In these instances, periapical radiographs are warranted to rule out internal resorption that may produce a similar clinical presentation. A yellow discoloration is indicative of pulpal obliteration, termed **calcific metamorphosis,** and is discussed more fully in Chapter 3 (see page 120). Occasionally, during a postmortem examination, a pink discoloration of teeth is found. The crowns and necks of the teeth are affected most frequently, and the process is thought to arise from hemoglobin breakdown within the necrotic pulp tissue in patients in whom blood has accumulated in the head.

• **Fig. 2.34 Hyperbilirubinemia-Related Discoloration.** Diffuse grayish-blue discoloration of the dentition. Cervical portions are stained most intensely. (Courtesy of Dr. John Giunta.)

A similar pink or red discoloration of the maxillary incisors has been reported in living patients with **lepromatous leprosy** (see page 188). Although controversial, some investigators believe these teeth are involved selectively because of the decreased temperature preferred by the causative organism. This process is thought to be secondary to infection-related necrosis and the rupture of numerous small blood vessels within the pulp, with a secondary release of hemoglobin into the adjacent dentinal tubules.

Dental **restorative materials,** especially amalgam, can result in black-gray discolorations of teeth. This most frequently arises in younger patients who presumably have more open dentinal tubules. Large Class II proximal restorations of posterior teeth can produce discoloration of the overlying facial surface. In addition, deep lingual metallic restorations on anterior incisors can significantly stain underlying dentin and produce visible grayish discoloration on the labial surface. To help reduce the possibility of discoloration, the clinician should not restore endodontically treated anterior teeth with amalgam (Fig. 2.35).

Regenerative endodontic therapy refers to treatment of permanent teeth with necrotic pulps and open apices, which are filled with a variety of materials to promote continued root maturation and apical closure. Discoloration of the treated tooth is a common complication that appears to be affected by the choice of filling materials. Significant discoloration has been noted with use of mineral trioxide aggregate or triple antibiotic paste containing minocycline, whereas calcium hydroxide or double antibiotic paste with metronidazole and ciprofloxacin has proven to be less problematic.

Several different **medications** can become incorporated into the developing tooth and result in clinically evident discoloration. The severity of the alterations is dependent on the time of administration, the dose, and the duration of the

dentlearn.ir

• **Fig. 2.35 Amalgam Discoloration.** Green-gray discoloration of mandibular central incisor, which had endodontic access preparation restored with amalgam.

• **Fig. 2.36 Tetracycline-Related Discoloration.** Diffuse brownish discoloration of the permanent dentition.

drug's use. The most infamous is **tetracycline,** with the affected teeth varying from bright yellow to dark brown and, in UV light, showing a bright yellow fluorescence (Fig. 2.36). After chronic exposure to ambient light, the fluorescent yellow discoloration fades over months to years into a nonfluorescent brown discoloration. Often the facial surfaces of the anterior teeth will darken while the posterior dentition and lingual surfaces remain a fluorescent yellow. The drug and its homologues can cross the placental barrier; therefore, administration should, if possible, be avoided during pregnancy and in children up to 8 years of age. All homologues of tetracycline are associated with discoloration and include chlortetracycline (gray-brown discoloration) and demethylchlortetracycline and oxytetracycline (yellow).

One semisynthetic derivative of tetracycline, **minocycline hydrochloride,** has been shown to produce significant discoloration of the dentition and also may affect teeth that are fully developed. Minocycline is a widely used medication for the treatment of acne and also is prescribed occasionally to treat rheumatoid arthritis. Its prevalence of use is increasing (and, presumably, so will the number of patients affected with discolored teeth and bone).

• **Fig. 2.37 Minocycline-Related Discoloration.** Dentition demonstrating grayish discoloration predominantly noted on the incisal half of the teeth. Note the horizontal bands of bluish alteration of the maxillary and mandibular alveolar ridges. (Courtesy of Dr. Roger Miller.)

Although the mechanism is unknown, minocycline appears to bind preferentially to certain types of collagenous tissues (e.g., dental pulp, dentin, bone, and dermis). Once in these tissues, oxidation occurs and may produce the distinctive discoloration. Some investigators believe supplementation with ascorbic acid (an antioxidant) can block formation of the discoloration. No matter the cause, once the pulp tissues are stained, the coloration can be seen through the overlying translucent dentin and enamel. The staining is not universal; only 3%–6% of long-term users become affected. In those affected, the period of time before discoloration becomes evident can range from just 1 month to several years.

In susceptible individuals, minocycline creates discoloration in the skin, oral mucosa (see page 307), nails, sclera, conjunctiva, thyroid, bone, and teeth. Coloration of the bone occasionally results in a distinctive blue-gray appearance of the palate, mandibular tori, or anterior alveolar mucosa, which represents the black bone showing through the thin, translucent oral mucosa (Fig. 2.37). Several patterns of staining are noted in the dentition. Fully erupted teeth typically reveal a blue-gray discoloration of the incisal three-fourths, with the middle one-third being maximally involved (see Fig. 2.37). The exposed roots of erupted teeth demonstrate a dark-green discoloration, although the roots of developing teeth are stained dark black.

Another antibiotic, ciprofloxacin, is given intravenously to infants for *Klebsiella* spp. infections. Although less notable than tetracycline, this medication also has been associated with intrinsic tooth staining—usually a greenish discoloration.

Treatment and Prognosis

Careful polishing with fine pumice can remove most extrinsic stains on the teeth; typically, normal prophylaxis paste is insufficient. Stubborn stains often are resolved by mixing 3% hydrogen peroxide with the pumice or by using bicarbonate spray solutions. The use of jet prophylactic devices with a

dentlearn.ir

mild abrasive is the most effective. Recurrence of the stains is not uncommon unless the cause is reduced or eliminated. Improving the level of oral hygiene often minimizes the chance of recurrence.

Intrinsic discoloration is much more difficult to resolve because of the frequent extensive involvement of the dentin. Suggested aesthetic remedies include external bleaching of vital teeth, internal bleaching of nonvital teeth, bonded restorations, composite buildups, laminate veneer crowns, and full crowns. The treatment must be individualized to fulfill the unique needs of each patient and his or her specific pattern of discoloration.

◆ LOCALIZED DISTURBANCES IN ERUPTION

DELAYED ERUPTION

Eruption is the movement of a tooth from its position of development within the bone to its functional location in the mouth. After the tooth is in full occlusion, slight eruption continues in order to compensate for normal attrition and continued vertical growth of the face. Although delayed eruption is not a rare problem, few well-written reviews have been published on the subject.

Emergence is the moment of eruption when the first part of the cusp or crown is visible through the gingiva. This process normally occurs when the dental root is approximately two-thirds its final length. Emergence occurs over a broad chronologic age range and differs according to a number of influences, such as racial and gender variations. Eruption is considered delayed if emergence has not occurred within 12 months of the normal range or by the time 75% root formation is complete. Box 2.5 lists local conditions reported in the literature that can be associated with delayed eruption; Box 2.6 highlights systemic disorders associated with delayed eruption.

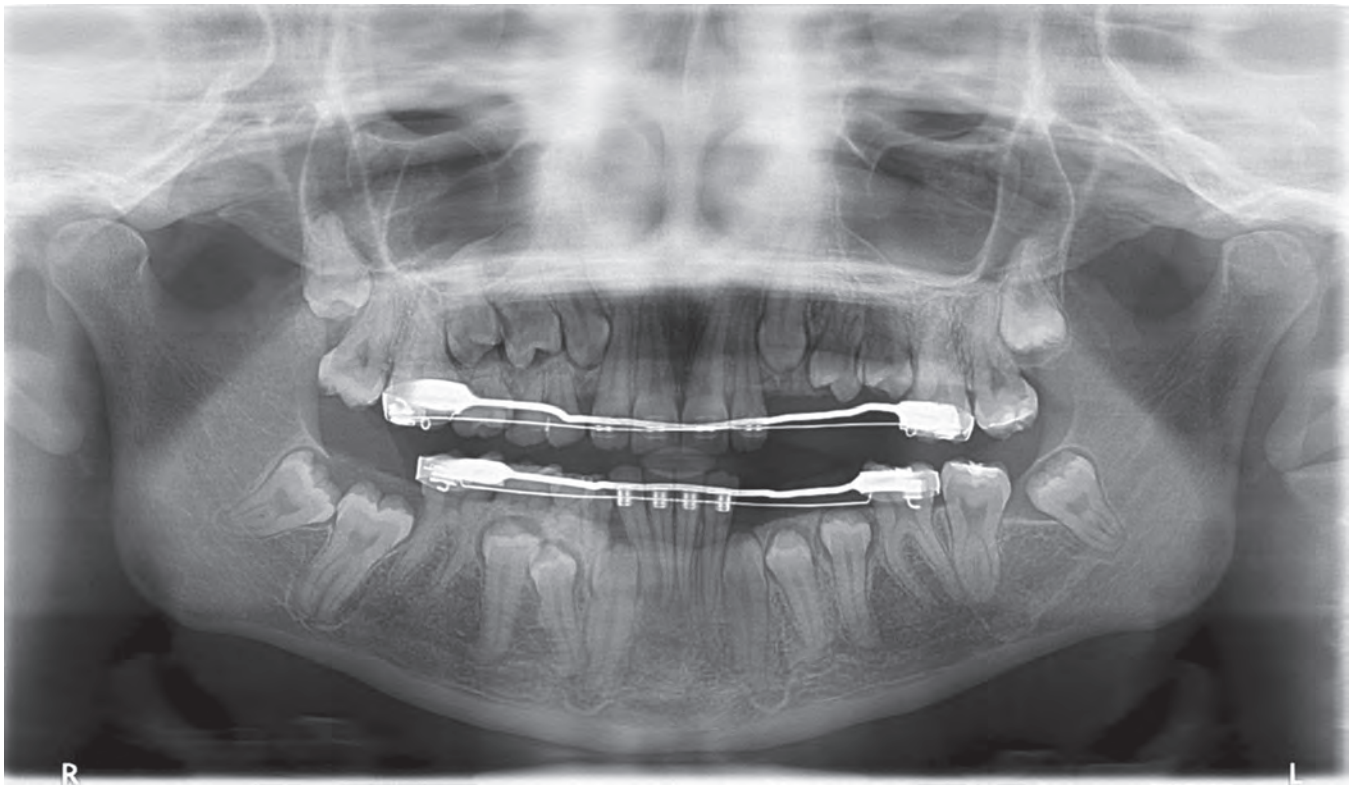
• BOX 2.5 Local Conditions Associated With Delayed Eruption

- Ankylosis of deciduous tooth
- Arch-length deficiency
- Ectopic eruption
- Enamel pearls
- Failure of resorption of deciduous tooth
- Gingival fibromatosis or hyperplasia
- Impaction of deciduous tooth
- Injury or infection of deciduous tooth
- Mucosal barriers, such as scar tissue
- Oral clefts
- Premature loss of deciduous tooth
- Radiation damage
- Regional odontodysplasia
- Segmental odontomaxillary dysplasia
- Supernumerary teeth
- Tumors, odontogenic and non-odontogenic

• BOX 2.6 Systemic Conditions Associated With Delayed Eruption

- Anemia
- Celiac disease
- Cerebral palsy
- Chemotherapy
- Dysosteosclerosis
- Drugs, such as phenytoin
- Endocrine disorders (e.g., hypothyroidism, hypopituitarism, hypoparathyroidism, pseudohypoparathyroidism)
- Genetic disorders
- Heavy metal intoxication
- Human immunodeficiency virus (HIV) infection
- Hypobaria
- Ichthyosis
- Inadequate nutrition
- Low birth weight
- Renal failure
- Tobacco smoke
- Vitamin D–resistant rickets

Clinical and Radiographic Features



The failure of eruption may be localized or diffuse. In many localized examples, the cause is readily apparent upon radiographic examination when objects are discovered in the path of eruption. In other cases, the cause is not obvious and may be discovered after surgical exploration (such as a small intramural odontogenic hamartoma within the follicular sac). Diffuse delayed eruption often is more problematic and frequently is associated with a systemic disorder (Fig. 2.38). An excellent example is presented during the discussion of hypothyroidism in Chapter 17 (see page 835).

Primary failure of eruption is a rare disease in which incomplete tooth eruption occurs despite a clear eruption pathway. The process most commonly affects the posterior teeth, and all teeth distal to the most mesially affected teeth will demonstrate lack of full eruption. Although the majority of cases are limited to the molars, the premolars also may be affected. The most common presentation is infraocclusion of the posterior teeth, with bilateral involvement noted frequently. Studies have demonstrated an association with a mutation in the *PTH1R* gene.

Treatment and Prognosis

For localized delayed emergence, removal of any pathosis in the path of eruption may be sufficient to allow eruption to occur. If eruption does not proceed, surgical exposure accompanied by orthodontic traction has been shown to be successful. In patients with primary failure of eruption localized to the posterior teeth, mild infraocclusion requires no treatment, whereas extraction with implant replacement is recommended for severely affected teeth. When the delayed eruption is generalized, the patient should be evaluated for systemic diseases known to be associated with the

dentlearn.ir

• **Fig. 2.38 Delayed Eruption.** Adult patient presenting with multiple unerupted permanent teeth without obvious causation. (Courtesy of Dr. Mark Lingen.)

process. Successful resolution of the underlying disorder often is followed by completion of eruption.

IMPACTION

Teeth that cease to erupt before emergence are **impacted.** Some authors subdivide these nonerupted teeth into those that are obstructed by a physical barrier (impacted) and those that appear to exhibit a lack of eruptive force (embedded). In many cases a tooth may appear to be embedded; however, on removal, a previously undetected overlying odontogenic hamartoma or neoplasm is discovered. Therefore, it appears appropriate to classify all these teeth as impacted.

Clinical and Radiographic Features

Impaction of deciduous teeth is extremely rare; when seen, it most commonly involves second molars. Analysis of cases suggests that ankylosis plays a major role in the pathogenesis. In the permanent dentition, the most frequently impacted teeth are the mandibular third molars, followed by maxillary third molars and maxillary cuspids. In decreasing order of frequency, impaction also may occur with mandibular premolars, mandibular canines, maxillary premolars, maxillary central incisors, maxillary lateral incisors, and mandibular second molars. First molars and maxillary second molars are rarely affected.

Lack of eruption most frequently is caused by crowding and insufficient maxillofacial development. Procedures that create more space, such as removal of bicuspids for orthodontic purposes, are associated with a decreased prevalence of third molar impaction. Impacted teeth are frequently diverted or angulated and eventually lose their potential to erupt (on completion of root development). Other factors known to be associated with impaction include the following:

- Overlying cysts or tumors
- Trauma
- Reconstructive surgery
- Thickened overlying bone or soft tissue
- A host of systemic disorders, diseases, and syndromes

Impacted teeth may be partially erupted or completely encased within the bone (i.e., full bony impaction). In addition, the impaction may be classified according to the angulation of the tooth in relationship to the remaining dentition: mesioangular, distoangular, vertical, horizontal, or inverted. On occasion, a small spicule of nonvital bone may be seen radiographically or clinically overlying the crown of partially erupted permanent posterior tooth (Fig. 2.39). The process is termed an **eruption sequestrum** and occurs when the osseous fragment becomes separated from the contiguous bone during eruption of the associated tooth. On occasion, mild sensitivity is noted in the area, especially during eating.

dentlearn.ir

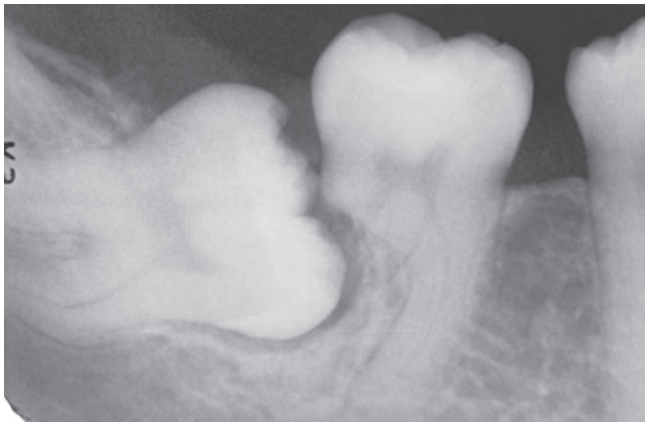
• **Fig. 2.39 Eruption Sequestrum.** A radiopaque fragment of sequestrating bone can be seen overlying an impacted third molar.

Treatment and Prognosis

The choices of treatment for impacted teeth include the following:

- Long-term observation
- Orthodontically assisted eruption
- Transplantation
- Surgical removal

Considerable evidence exists to support removal of impacted teeth associated with symptoms or the presence of clinically or radiographically obvious disease. The primary controversy surrounds appropriate therapy for asymptomatic and disease-free impactions. The British National Health Service instituted a restrictive policy toward removal of asymptomatic impacted third molars. This resulted in an initial decrease in third molar removal that was followed promptly by an increased need for extractions due to the development of caries, periodontal disease, and pericoronitis. If early prophylactic removal is discontinued, the number removed in elderly patients certainly will increase. Studies have demonstrated that removal in patients over the age of 65 is associated with significant increased morbidity and substantially worse surgical outcomes.



A 2016 Cochrane review found insufficient evidence to determine whether or not asymptomatic disease-free impacted teeth should be removed and stated that well-designed randomized controlled trials are unlikely to be feasible. The review stated that patient values and clinical expertise should be used to guide a shared decision. Patients deciding to retain their impacted teeth should obtain clinical assessment at regular intervals to prevent undesirable complications.

The risks associated with nonintervention include the following:

- Crowding of dentition
- Resorption, caries, and worsening of the periodontal status of adjacent teeth (Fig. 2.40)
- Development of pathologic conditions, such as infections, cysts, and tumors

The risks of intervention include the following:

- Transient or permanent sensory loss
- Alveolitis
- Trismus

• **Fig. 2.40 Impaction-Related Tooth Resorption.** Mesioangular impaction of the right mandibular third molar associated with significant resorption of the distal root of the second molar. (Courtesy of Dr. Richard Brock.)

- Infection
- Fracture
- Temporomandibular joint (TMJ) injury
- Periodontal injury
- Injury to adjacent teeth

The eruption sequestrum requires no therapy and usually undergoes spontaneous resorption or exfoliation.

ANKYLOSIS

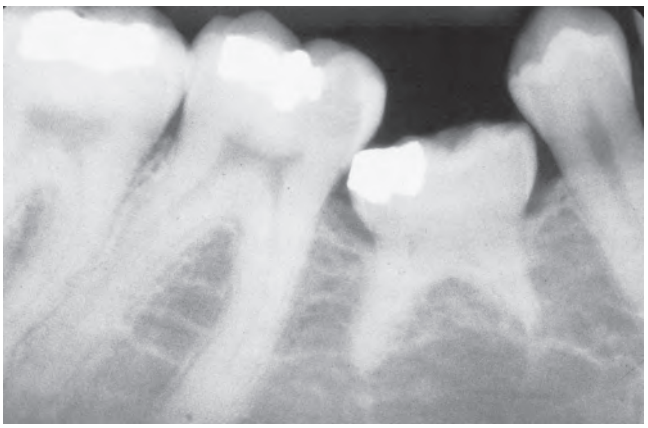
Eruption continues after the emergence of the teeth to compensate for masticatory wear and the growth of the jaws. The cessation of eruption after emergence is termed **ankylosis** and occurs from an anatomic fusion of tooth cementum or dentin with the alveolar bone. The process can be difficult to separate from primary failure of eruption (see page 71). Although the areas of union may be too subtle to be detected clinically and radiographically, histopathologic examination demonstrates fusion between the affected tooth and the adjacent bone in almost all cases. Other terms for this process within the literature include **infraocclusion, secondary retention, submergence, reimpaction,** and **reinclusion.** *Secondary retention* is an acceptable term but may be confused with *retained primary teeth,* which maintain their emergence. *Submergence, reimpaction,* and *reinclusion* connote an active depression, and this is not the case.

The pathogenesis of ankylosis is unknown and may be secondary to one of many factors. Disturbances from changes in local metabolism, trauma, injury, chemical or thermal irritation, local failure of bone growth, and abnormal pressure from the tongue have been suggested. The periodontal ligament (PDL) might act as a barrier that prevents osteoblasts from applying bone directly onto cementum. Ankylosis could arise from a variety of factors that result in a deficiency of this natural barrier. Such loss could arise from trauma or a genetically decreased PDL gap. Other theories point to a disturbance between normal root resorption and hard tissue repair. Several investigators believe genetic predisposition has a significant influence and point to

dentlearn.ir

monozygotic twins who demonstrate strikingly similar patterns of ankylosis to support this hypothesis.

Clinical and Radiographic Features



Ankylosis may occur at any age; however, clinically the condition is most obvious if the fusion develops during the first two decades of life. Most patients reported in the literature with obvious alterations in occlusion are between the ages of 7 and 18 years, with a peak prevalence occurring in 8- to 9-year-old children. The reported prevalence of clinically detectable ankylosis in children varies from 1.3% to 8.9% and has been reported to be as high as 44% in siblings of those affected.

Although any tooth may be affected, the most commonly involved teeth in order of frequency are the mandibular primary first molar, the mandibular primary second molar, the maxillary primary first molar, and the maxillary primary second molar. Ankylosis of permanent teeth is uncommon. In the deciduous dentition, mandibular teeth are affected ten times as often as the maxillary dentition. The occlusal plane of the involved tooth is below that of the adjacent dentition (infraocclusion) in a patient with a history of previous full occlusion (Fig. 2.41). A sharp, solid sound may be noted on percussion of the involved tooth but can be detected only when more than 20% of the root is fused to the bone. Radiographically, absence of the PDL space may be noted; however, the area of fusion is often in the bifurcation and interradicular root surface, making radiographic detection most difficult in plain films (Fig. 2.42). Cone beam computed tomography (CBCT) has proven to be a useful diagnostic adjunct and typically will demonstrate a focal loss of the periodontal ligament adjacent to a small area of external replacement resorption (page 64) on the adjacent tooth.

Ankylosed teeth that are allowed to remain in position can lead to a number of dental problems. The adjacent teeth often incline toward the affected tooth, frequently with the development of subsequent occlusal and periodontal problems. In addition, the opposing teeth often exhibit overeruption. Occasionally, the ankylosed tooth leads to a localized deficiency of the alveolar ridge or impaction of the underlying permanent tooth. An increased frequency of lateral open bite and crossbite is seen.

• **Fig. 2.41 Ankylosis.** Deciduous molar well below the occlusal plane of the adjacent teeth.

• **Fig. 2.42 Ankylosis.** Radiograph of an ankylosed deciduous molar. Note the lack of periodontal ligament (PDL) space.

Treatment and Prognosis

Because they are fused to the adjacent bone, ankylosed teeth fail to respond to normal orthodontic forces, with attempts to move the ankylosed tooth occasionally resulting in intrusion of the anchor teeth. Recommended therapy for ankylosis of primary molars is variable and often is determined by the severity and timing of the process. When an underlying permanent successor is present, extraction of the ankylosed primary molar should not be performed until it becomes obvious that exfoliation is not proceeding normally or adverse occlusal changes are developing. After extraction of an ankylosed molar, the permanent tooth will erupt spontaneously in the majority of cases. In permanent teeth or primary teeth without underlying successors, prosthetic buildup can be placed to augment the occlusal height. Severe cases in primary teeth are treated best with extraction and space maintenance. Luxation of affected permanent teeth may be attempted with extraction forceps in an effort to break the ankylosis. It is hoped that the subsequent inflammatory reaction results in the formation of a new fibrous ligament in the area of previous fusion. In these cases, reevaluation in 6 months is mandatory. Finally, several reports have documented successful repositioning of an ankylosed permanent tooth with a combination of orthodontics, segmental osteotomy, and distraction osteogenesis.

DEVELOPMENTAL ALTERATIONS OF TEETH

Numerous developmental alterations of teeth can occur. Box 2.7 delineates the major reported alterations, and the following text pertains to these entities. These alterations may be

primary or arise secondary to environmental influences (e.g., concrescence, hypercementosis, and dilaceration). For the sake of convenience, both the primary and the environmental forms will be discussed together.

◆ DEVELOPMENTAL ALTERATIONS IN THE NUMBER OF TEETH

Variations in the number of teeth that develop are common. Several terms are useful in the discussion of the numeric variations of teeth. **Tooth agenesis** refers to the failure of a tooth to develop. Varying degrees of severity are noted. **Hypodontia** denotes lack of development of one to five teeth, **oligodontia** indicates the developmental absence of six or more teeth (excluding third molars), and **anodontia** refers to a total lack of tooth development. **Hyperdontia** is the development of an increased number of teeth, and the additional teeth are termed **supernumerary.** Terms such as *partial anodontia* are oxymorons and should be avoided. In addition, these terms pertain to teeth that failed to develop and should not be applied to teeth that developed but are impacted or have been removed.

Genetic control appears to exert a strong influence on the development of teeth. Tooth agenesis and hyperdontia have been noted in patients with a variety of syndromes (Boxes 2.8 and 2.9). In all of these syndromes, an increased prevalence of tooth agenesis or hyperdontia exists, but the strength of the association varies. Furthermore, the actual genetic contribution to the increased or decreased number of teeth may be unclear in some of these conditions. In addition to these syndromes, an increased prevalence of tooth agenesis is noted in patients with nonsyndromic cleft lip (CL) or cleft palate (CP).

Genetic influences still may affect nonsyndromic numeric alterations of teeth, because more than 200 genes are known to play a role in odontogenesis. Because of the complexity of the system, variations in tooth number arise in a wide variety of patterns. A large percentage of primary tooth agenesis cases appear to be inherited in an autosomal dominant fashion, with incomplete penetrance and variable expressivity, whereas a minority of examples presents an autosomal recessive or sex-linked pattern. The environment is not without its influence, with occasional examples suggesting multifactorial inheritance. Several investigators have reported variable expression of hypodontia in monozygotic twins (confirmed by DNA fingerprinting). This discordance confirms the occasional multifactorial nature of the process. Overall, dental agenesis most likely represents a variety of disorders caused by variable genetic and epigenetic factors.

Research has identified a gene mutation in only a small percentage of nonsyndromic tooth agenesis cases. Although this list will continue to lengthen over time, the most frequently implicated genes include the *WNT10A, PAX9*, *MSX1*, *EDA*, and the *AXIN2* genes, with one of these five genes involved in 50% of tooth agenesis in humans when the genetic mutation is known. Although variable expressivity is common, most of these examples represent oligodontia and exhibit numerous missing teeth. Interestingly, the affected gene tends to correlate to the pattern of missing teeth. It must be stressed that these genes are involved in only a very small number of affected patients with dental agenesis, and the genetic basis for the vast majority of missing teeth remains elusive.

Less information is available on the genetics of hyperdontia; however, like tooth agenesis, almost every possible pattern of inheritance has been suggested. In all likelihood, many cases are multifactorial and arise from a combination of genetics and environmental influences. Despite this, studies on certain kindreds have suggested an autosomal dominant pattern of inheritance with incomplete penetrance, autosomal recessive inheritance with lesser penetrance in females, and X-linked inheritance. Unlike dental agenesis, mutations of only a few genes have been linked to hyperdontia. Two of the best known examples are mutations in *RUNX2* (associated with cleidocranial dysplasia; see page 623) and *APC* (associated with Gardner syndrome; see page 656).

Some investigators have implied that tooth agenesis is a normal variant, suggesting that humans are in an intermediate stage of dentitional evolution. A proposed future dentition would contain one incisor, one canine, one premolar, and two molars per quadrant. Conversely, others have suggested that hyperdontia represents atavism—the reappearance of an ancestral condition. The latter hypothesis is difficult to accept because some patients have had as many as four premolars in one quadrant, a situation that has never

been reported in other mammals. The most widely accepted theory is that hyperdontia is the result of a localized and independent hyperactivity of dental lamina.

In contrast, tooth agenesis correlates with the absence of appropriate dental lamina. As discussed, the loss of the developing tooth buds in most instances appears to be genetically controlled. Despite this, the environment most likely influences the final result or, in some cases, may be responsible completely for the lack of tooth formation. The dental lamina is extremely sensitive to external stimuli, and damage before tooth formation can result in hypodontia. Trauma, infection, radiation, chemotherapeutic medications, endocrine disturbances, and severe intrauterine disturbances have been associated with missing teeth.

Clinical Features

Tooth Agenesis

Failure of teeth to form is one of the most common dental developmental abnormalities, with a reported prevalence of 3% to 10% in permanent teeth when absence of third molars is excluded. The prevalence increases to 23% if third molars are considered. A female predominance of approximately 1.5:1 is reported. Anodontia is rare, and most cases occur in the presence of hereditary hypohidrotic ectodermal dysplasia (see page 747). Indeed, when the number of missing teeth is high or involves the most stable teeth (i.e., maxillary central incisors or first molars), the patient should be evaluated for ectodermal dysplasia. Tooth agenesis is uncommon in the deciduous dentition with a prevalence of less than 1%. Absence of a deciduous tooth is associated strongly with an increased prevalence of a missing successor. Missing teeth in the permanent dentition are not rare, with third molars being the most commonly affected. After the third molars, the second premolars and lateral incisors are absent most frequently (Fig. 2.43). The teeth least likely to be missing are the maxillary central incisors and mandibular first molars and canines. In Caucasians with missing teeth, approximately 80% demonstrate loss of only one or two teeth. Ethnic differences have been documented, with Japanese and Chinese populations more frequently having absent mandibular central incisors when compared to Caucasians. In contrast, when compared to Caucasians, American blacks demonstrate a significantly decreased prevalence of tooth agenesis and a reduced average number of missing teeth per individual. In the deciduous dentition, 90% of missing teeth involve the maxillary lateral incisors and mandibular incisors. Tooth agenesis is associated positively with microdontia (see page 81), dental transposition (see page 79), reduced alveolar development, increased freeway space, anterior malocclusion, and retained primary teeth (Fig. 2.44).

Mutation of *PAX9* creates an autosomal dominant pattern of oligodontia that can involve various teeth but most commonly affects most of the permanent molars. In severe cases, loss of the primary molars, second premolars, and permanent mandibular central incisors also may be seen. Mutation of *MSX1* also is inherited as an autosomal dominant trait. Those affected tend to demonstrate loss of the distal tooth of each type, with more severely affected individuals also revealing anterior progression of the agenesis. In these patients, the most commonly missing teeth are the second premolars and third molars. In more severe cases, often the maxillary first premolars and maxillary lateral incisors also are missing. With the *MSX1* mutation, the degree of oligodontia is severe with an average of approximately 12 missing teeth per patient. *EDA* is associated with a nonsyndromic X-linked pattern of missing teeth, which primarily affects

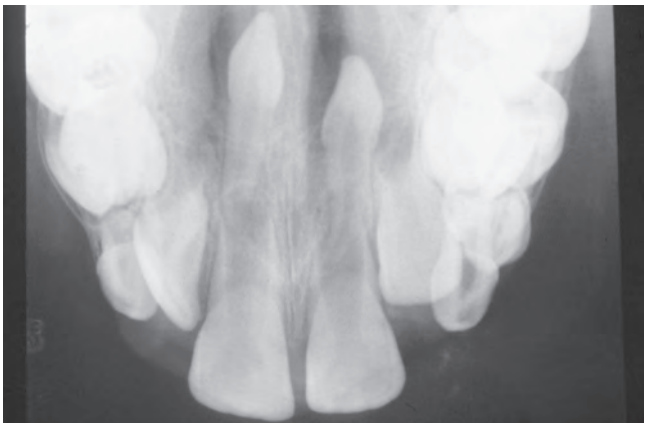
• **Fig. 2.43 Hypodontia.** Developmentally missing maxillary lateral incisors. Radiographs revealed no underlying teeth, and there was no history of trauma or extraction.

• **Fig. 2.44 Oligodontia. A,** Multiple developmentally missing permanent teeth and several retained deciduous teeth in a female adult. **B,** The panoramic radiograph shows no unerupted teeth in either jaw.

dentlearn.ir

the maxillary and mandibular central incisors, lateral incisors, cuspids, and premolars. Tooth agenesis associated with nonsyndromic mutation of *WNT10A* appears limited to maxillary and mandibular lateral incisors and second premolars.

For dentists and their patients, the most critical discovery related to tooth agenesis revolves around the mutation of *AXIN2*. This pattern of oligodontia is inherited as an autosomal dominant disorder, with the most commonly missing teeth being the permanent second and third molars, second premolars, lower incisors, and maxillary lateral incisors. The maxillary central incisors always are present and usually accompanied by the canines, first premolars, and first molars. However, the number and type of missing teeth are highly variable, a typical finding of inheritable oligodontia. Although the missing teeth can produce a significant oral problem, the presence of the *AXIN2* mutation in these kindreds also has been associated with development of adenomatous polyps of the colon and colorectal carcinoma. This suggests that patients with similar examples of oligodontia should be questioned closely for a family history of colon cancer, with further medical evaluation recommended for those possibly at risk. An association between tooth agenesis and ovarian cancer also has been suggested, but no single mutation has been found that could explain the simultaneous occurrence of both conditions. In addition, close examination of affected patients often reveals two separate mutations that are independently responsible for the ovarian cancer and tooth agenesis.



Even in kindreds with an obviously inherited pattern of hypodontia or oligodontia, it must be stressed that, in the majority of the cases, the genes are yet to be discovered.

Hyperdontia

The prevalence of supernumerary permanent teeth in whites is between 0.1% and 3.8%, with a slightly higher rate seen in Asian populations. Although limited data is available, the prevalence in American blacks appears significantly higher with reports documenting an increased frequency up to nine times that seen in whites. The frequency in the deciduous dentition is much lower and varies from 0.3% to 0.8%. Approximately 76%–86% of cases represent single-tooth **hyperdontia,** with two supernumerary teeth noted in 12%–23%, and three or more extra teeth noted in less than 1% of cases. Single-tooth hyperdontia occurs more frequently in the permanent dentition, and approximately 95% present in the maxilla, with a strong predilection for the anterior region. However, these widely accepted data appear to be associated with a strong racial bias. Limited prevalence studies in American blacks reveal that fourth molars are the most common extra teeth, with a comparatively low frequency of supernumerary incisors. When all prevalence studies are combined, the most common site is the maxillary incisor region, followed by maxillary fourth molars and mandibular fourth molars, premolars, canines, and lateral incisors (Fig. 2.45). Supernumerary mandibular incisors are very rare. Although supernumerary teeth may be bilateral, most occur unilaterally (Fig. 2.46). In contrast to single-tooth hyperdontia, nonsyndromic multiple supernumerary teeth occur most frequently in the mandible. These multiple supernumerary teeth occur most often in the premolar region, followed by the molar and anterior regions, respectively (Fig. 2.47).

• **Fig. 2.45 Hyperdontia (Mesiodens).** Erupted supernumerary, rudimentary tooth of the anterior maxilla.

• **Fig. 2.46 Hyperdontia (Mesiodens).** Bilateral inverted supernumerary teeth of the anterior maxilla.

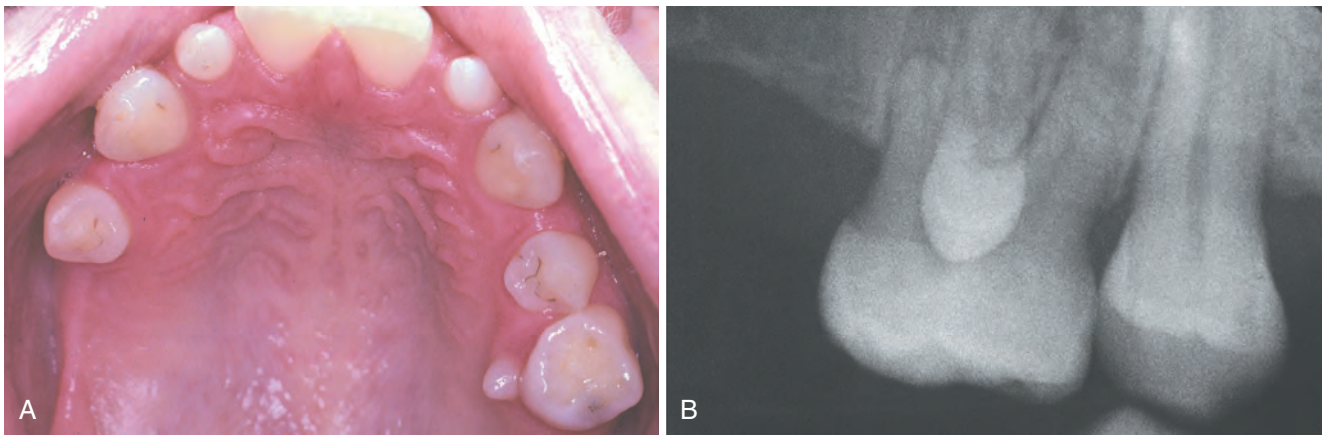
• **Fig. 2.47 Hyperdontia.** Right mandibular dentition exhibiting four erupted bicuspids.

dentlearn.ir

Although most supernumerary teeth occur in the jaws, examples have been reported in the gingiva, maxillary tuberosity, soft palate, maxillary sinus, sphenomaxillary fissure, nasal cavity, and between the orbit and the brain. The eruption of accessory teeth is variable and dependent on the degree of space available; 75% of supernumerary teeth in the anterior maxilla fail to erupt. Unlike hypodontia, hyperdontia is positively correlated with macrodontia (see page 81) and exhibits a 2:1 male predominance. Although examples may be identified in older adults, most supernumerary teeth develop during the first two decades of life.

Several terms have been used to describe supernumerary teeth, depending on their location. A supernumerary tooth in the maxillary anterior incisor region is termed a **mesiodens** (see Fig. 2.45); an accessory fourth molar is often called a **distomolar** or **distodens** (Fig. 2.48). A posterior supernumerary tooth situated lingually or buccally to a molar tooth is termed a **paramolar** (Fig. 2.49).

Supernumerary teeth are divided into **supplemental** (normal size and shape) or **rudimentary** (abnormal shape and smaller size) types. Rudimentary supernumerary teeth are classified further into **conical** (small, peg-shaped), **tuberculate** (barrel-shaped anterior with more than one cusp), and **molariform** (small premolar-like or molar-like). Although odontomas are considered hamartomas and could be placed within this classification, these lesions traditionally are included in the list of odontogenic neoplasms and are discussed in Chapter 15 (page 685). The conical mesiodens represents one of the more common supernumerary teeth and can erupt spontaneously, whereas tuberculate examples are less frequent and rarely erupt.



• **Fig. 2.48 Hyperdontia (Distodens).** Supernumerary maxillary fourth molar.

On rare occasions, an affected patient can present with both hypodontia and hyperdontia, which has been termed **hypohyperdontia.** The process most commonly involves missing mandibular incisors followed by second premolars; in contrast, supernumerary teeth are seen most frequently in the anterior maxilla followed by supplemental canines or maxillary premolars.

Occasionally, normal teeth may erupt into an inappropriate position (e.g., a canine present between two premolars). This pattern of abnormal eruption is called **dental transposition.** Such misplaced teeth have been confused with supernumerary teeth; but in reality, patients exhibiting dental transposition have been reported to exhibit an increased prevalence of hypodontia, not hyperdontia. The teeth involved most frequently in transposition are the maxillary canines and first premolars (Fig. 2.50). Crowding or malocclusion of these normal teeth may dictate reshaping, orthodontics, or extraction.

Accessory teeth may be present at or shortly after birth. Historically, teeth present in newborns have been called **natal teeth;** those arising within the first 30 days of life are designated **neonatal teeth.** The ratio of natal teeth to neonatal teeth is 3:1. The reported prevalence of such teeth ranges from 1:2000 to 1:3500 live births. (Fig. 2.51). Although some authors have suggested that these teeth may represent predeciduous supernumerary teeth, 90% are prematurely erupted deciduous teeth (not supernumerary teeth). Approximately 85% of natal teeth are mandibular

• **Fig. 2.49 Paramolar. A,** Rudimentary tooth situated palatal to a maxillary molar in a patient who also exhibits hypodontia. **B,** Radiograph of the same patient showing a fully formed tooth overlying the crown of the adjacent molar.

dentlearn.ir

• **Fig. 2.51 Natal Teeth.** Mandibular central incisors that were erupted at birth.

incisors, 11% are maxillary incisors, and 4% are canines or posterior teeth. Often, the natal teeth erupt in pairs.

Treatment and Prognosis

Sequelae associated with tooth agenesis include abnormal spacing of teeth, delayed tooth formation, delayed deciduous tooth exfoliation, late permanent tooth eruption, and altered dimension of the associated gnathic regions. The management of the patient with missing teeth depends on the severity of the case. No treatment may be required for a single missing tooth; prosthetic replacement often is needed when multiple teeth are absent. Therapeutic options include removable partial dentures, traditional fixed prosthodontics, resin-bonded bridges, or osseointegrated implants with associated prosthetic crowns. Use of fixed prosthodontics typically is not recommended for children because of the risk of pulp exposure during abutment preparation and because further growth can lead to infraocclusion and ankylosis of teeth held together by the prosthesis. Likewise, because implants act more like ankylosed teeth than erupting teeth, their use is not recommended before completion of skeletal growth except for patients with anodontia. For these reasons, a removable appliance or resin-bonded bridge often is appropriate in children and young adults while waiting for full dental and skeletal maturation.

In some cases of hypodontia and oligodontia, orthodontic therapy may improve the restorative treatment or even negate its need in selected patients. Patients with oligodontia exhibit an increased prevalence of orthodontics-associated external root resorption. This may be due to the altered root anatomy or to the extensive tooth movement that is required in some patients. Follow-up radiographs are recommended after 6–9 months of therapy to evaluate the root morphology for evidence of excessive resorption.

The presence of supernumerary teeth should be suspected if a significant delay is observed in the eruption of a localized portion of the dentition. Because of the decreased clarity in the anterior portion of a panoramic radiograph, this image should be combined with occlusal and periapical radiographs to fully visualize the area. Supernumerary teeth may develop long after eruption of the permanent dentition. Several publications have documented supernumerary bicuspids arising up to 11 years after completion of normal teeth development. In patients previously diagnosed with supernumerary teeth, or in those genetically predisposed, long-term monitoring for additional tooth development is warranted.

Early diagnosis and treatment often are crucial in minimizing the aesthetic and functional problems of the adjacent teeth. Because only 7% to 20% of supernumerary teeth exist without clinical complications, the standard of care is removal of the accessory tooth during the time of the early mixed dentition. Complications created by anterior supernumerary teeth tend to be more significant than those associated with extra teeth in the posterior regions. Reports have documented spontaneous eruption of the adjacent dentition in 75% of the cases if the supernumerary tooth is removed early. After removal of the supernumerary tooth, full eruption typically occurs within 18 months to 3 years. Impacted permanent teeth having closed apices or those associated with a tuberculate mesiodens may show a reduced tendency for spontaneous eruption. Permanent teeth that fail to erupt are treated best by surgical exposure with orthodontic eruption. Removal of unerupted deciduous teeth is not recommended, because most will erupt spontaneously.

A consequence of late therapy may include the delayed eruption, resorption of the adjacent teeth, displacement of the teeth with associated crowding, dilaceration, malocclusion, diastema formation, or eruption into the nasal cavity. Supernumerary teeth also predispose the area to subacute pericoronitis, gingivitis, periodontitis, abscess formation, and the development of any one of a large number of odontogenic cysts and tumors. In selected cases, clinical judgment may not dictate surgical removal, or patient resistance to therapy may be present. In these instances, regular monitoring is appropriate.

A study attempting to determine the optimum time for removal of mesiodens in a pediatric population suggested that removal after age 10 was associated with a higher

dentlearn.ir

prevalence of developmental defects of the adjacent permanent teeth such as dilaceration and root resorption. Although a cautious surgical approach is necessary to avoid damage to the adjacent developing incisor, removal of mesiodens prior to 6–7 years of age appears advantageous in decreasing local developmental complications.

Natal teeth must be approached individually with sound clinical judgment guiding appropriate therapy. Radiographs may be difficult to obtain but could be helpful in distinguishing premature eruption of a deciduous tooth from a supernumerary tooth. As stated, the erupted teeth in most cases represent the deciduous dentition, and removal should not be performed hastily. If the teeth are mobile and at risk for aspiration, removal is indicated. The surgical procedure must ensure complete removal of the associated dental papilla and epithelial root sheath to prevent formation of residual root fragments. If mobility is not a problem and the teeth are stable, then they should be retained. Traumatic ulcerations of the adjacent soft tissue **(Riga-Fede disease)** (see page 274) may occur during breast feeding but often can be resolved through use of a breastfeeding splint or grinding/smoothing of the incisal edges of the natal tooth. If the tooth is surgically removed during the first 10 days of life, vitamin K administration is advocated, because the infant's coagulation system may not be established sufficiently.

◆ DEVELOPMENTAL ALTERATIONS IN THE SIZE OF TEETH

Tooth size is variable among different races and between the sexes. The presence of unusually small teeth is termed **microdontia;** the presence of teeth larger than average is termed **macrodontia.** Although heredity is the major factor, both genetic and environmental influences affect the size of developing teeth. The deciduous dentition appears to be affected more by maternal intrauterine influences; the permanent teeth seem to be more affected by environment.

Clinical Features

Although the size of teeth from person to person is variable, the teeth on two sides of the jaws usually are symmetrical. Despite this, when significant size variation is present, the entire dentition rarely is affected. Typically, only a few teeth are altered significantly in size. Differences in tooth sizes may be related to other concurrent oral developmental anomalies. Microdontia is associated strongly with tooth agenesis (see page 75); macrodontia often is seen in association with hyperdontia (see page 75). Females demonstrate a higher frequency of microdontia and tooth agenesis; males have a greater prevalence of macrodontia and hyperdontia.

Microdontia

The term **microdontia** should be applied only when the teeth are physically smaller than usual. Normal-sized teeth may appear small when widely spaced within jaws that are larger than normal. This appearance has been historically termed **relative microdontia,** but it represents **macrognathia** (not microdontia). Diffuse true microdontia is uncommon but may occur as an isolated finding in Down syndrome, in pituitary dwarfism, and in association with a small number of rare hereditary disorders that exhibit multiple abnormalities of the dentition (Fig. 2.52).

• **Fig. 2.52 Diffuse Microdontia.** Dentition in which the teeth are smaller than normal and widely spaced within the arch.

• **Fig. 2.53 Isolated Microdontia (Peg Lateral).** Small, cone-shaped right maxillary lateral incisor.

Isolated microdontia within an otherwise normal dentition is not uncommon. The maxillary lateral incisor is affected most frequently and typically appears as a peg-shaped crown overlying a root that often is of normal length (Fig. 2.53). The mesiodistal diameter is reduced, and the proximal surfaces converge toward the incisal edge. The reported prevalence varies from 0.8% to 8.4% of the population, and the alteration appears to be autosomal dominant with incomplete penetrance. In addition, isolated microdontia often affects third molars. Interestingly, the maxillary lateral incisors and the third molars are among the most frequent teeth to be congenitally missing. When a peg-shaped tooth is present, the remaining permanent teeth often exhibit a slightly smaller mesiodistal size.

dentlearn.ir

Macrodontia

Analogous to microdontia, the term **macrodontia (megalodontia, megadontia)** should be applied only when teeth are physically larger than usual and should not include normal-sized teeth crowded within a small jaw (previously termed **relative macrodontia**). In addition, the term *macrodontia* should not be used to describe teeth that have been altered by fusion or gemination. Diffuse involvement is rare, and typically only a few teeth are abnormally large. Diffuse macrodontia has been noted in association with pituitary gigantism (see page 834), otodental syndrome, XYY males, and pineal hyperplasia with hyperinsulinism. Macrodontia with unilateral premature eruption is not rare in hemifacial hyperplasia (see page 37). Authors have postulated that the unilateral bone growth resulting from this condition may also affect developing teeth on the altered side. Isolated macrodontia is reported to occur most frequently in incisors or canines but also has been seen in second premolars and third molars (Fig. 2.54). In such situations, the alteration often occurs bilaterally.

In one distinctive pattern of macrodontia, the affected teeth demonstrate an extreme elongation of the roots known as **radiculomegaly**. The most commonly affected tooth is the cuspid with the roots often extending to the inferior border of the mandible and/or the floor of the orbit. Although radiculomegaly may be nonsyndromic, this finding is strongly suggestive of **oculo-facio-cardio-dental (OFCD) syndrome**. This X-linked dominant syndrome is characterized by ocular alterations (congenital cataracts, secondary glaucoma, microphthalmia) distinctive facies (narrow face, high nasal bridge, broad nasal tip, cleft palate), cardiac abnormalities (atrial or ventricular septal defects), and dental alterations (radiculomegaly, hypodontia, delayed eruption, retained deciduous teeth). The radiculomegaly is the most distinctive findings and does not become evident until the age of 15 due to the associated maturation time of the cuspid roots. The syndrome only occurs in females and is thought to demonstrate embryonic lethality in males. A novel mutation of the BCL-6 interacting corepressor gene (BCOR) is noted in affected patients.

• **Fig. 2.54 Macrodontia.** The patient's left maxillary central incisor is abnormally large. (Courtesy of Dr. Peter Fam.)

Treatment and Prognosis

Treatment of the dentition is not necessary unless desired for aesthetic considerations. Maxillary peg laterals often are restored to full size by porcelain crowns.

◆ DEVELOPMENTAL ALTERATIONS IN THE SHAPE OF TEETH

GEMINATION, FUSION, AND CONCRESCENCE

Double teeth (connate teeth, conjoined teeth) are two separate teeth exhibiting union by dentin and (perhaps) their pulps. The union may be the result of fusion of two adjacent tooth buds or the partial splitting of one into two. The development of isolated large or joined (i.e., double) teeth is not rare, but the literature is confusing when the appropriate terminology is presented. Historically, *gemination* was defined as an attempt of a single tooth bud to divide, with the resultant formation of a tooth with a bifid crown and, usually, a common root and root canal. Conversely, *fusion* was considered the union of two normally separated tooth buds with the resultant formation of a joined tooth with confluence of dentin. Finally, *concrescence* was the union of two teeth by cementum without confluence of the dentin.

Many investigators have found these definitions confusing and open to debate. A double tooth found in the place of a maxillary permanent central incisor is a good example of the controversy. If the joined tooth is counted as one and the tooth number is correct, then the anomaly could result from the division of a single tooth bud or the fusion of the permanent tooth bud with the bud of an adjacent mesiodens. Some have suggested that the terms *gemination, fusion,* and *concrescence* should be discontinued, and all of these anomalies should be termed *twinning.* This also is confusing because other investigators use *twinning* to refer to the development of two separate teeth that arose from the complete separation of one tooth bud (this also is arguable).

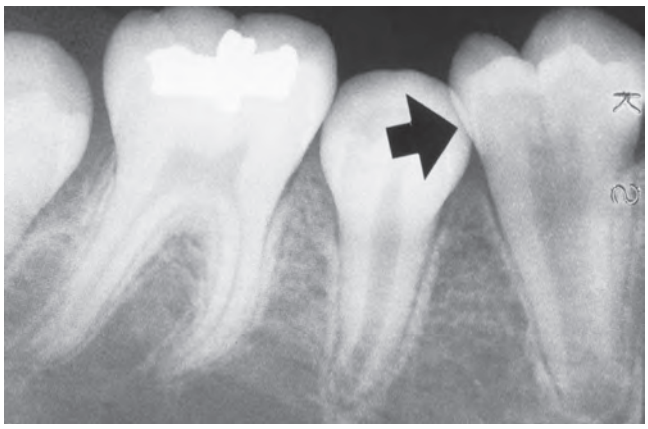
Because of this confusion in terminology, the use of the term *twinning* cannot be recommended. Extra teeth are termed **supernumerary,** and another name is not necessary. Even though the exact pathogenesis may be questionable in some cases (whether caused by fusion of adjacent buds or partial split of one bud), the terms *gemination, fusion,* and *concrescence* serve a useful purpose because they are the most descriptive of the clinical presentation. **Gemination** is defined as a single enlarged tooth or joined (i.e., double) tooth in which the tooth count is normal when the anomalous tooth is counted as one. **Fusion** is defined as a single enlarged tooth or joined (i.e., double) tooth in which the tooth count reveals a missing tooth when the anomalous tooth is counted as one. **Concrescence** is union of two adjacent teeth by cementum alone, without confluence of the underlying dentin. Unlike fusion and gemination, concrescence may be developmental or post-inflammatory. When

dentlearn.ir

two teeth develop in close proximity, developmental union by cementum is possible. In addition, areas of inflammatory damage to the roots of teeth are repaired by cementum once the inciting process resolves. Concrescence of adjacent teeth may arise in initially separated teeth in which cementum deposition extends between two closely approximated roots in a previous area of damage.

Clinical Features

Gemination and Fusion



Double teeth (**gemination** and **fusion**) occur in both the primary and the permanent dentitions, with a higher frequency in the anterior and maxillary regions (Figs. 2.55–2.59). In the permanent dentition, the prevalence of double teeth in whites is approximately 0.3%–0.5%, whereas the frequency in deciduous teeth is greater, with a reported prevalence from 0.5% to 2.5%. Asian populations tend to

• **Fig. 2.55 Bilateral Gemination.** Two double teeth. The tooth count was normal when each anomalous tooth was counted as one.

• **Fig. 2.56 Gemination.** Mandibular bicuspid exhibiting bifid crown.

• **Fig. 2.57 Gemination.** Same patient as depicted in Fig. 2.56. Note the bifid crown and shared root canal.

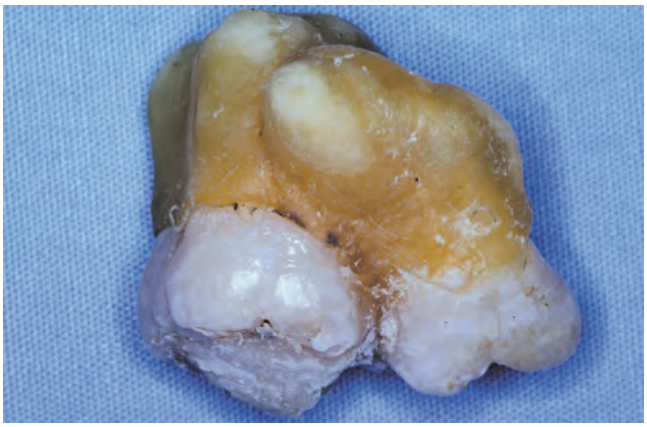
• **Fig. 2.59 Fusion.** Radiographic view of double tooth in the place of the mandibular central and lateral incisors. Note separate root canals.

dentlearn.ir

demonstrate a higher occurrence that exceeds 5% in some studies. In both dentitions, incisors and canines are the most commonly affected teeth. Involvement of posterior primary teeth, premolars, and permanent molars also can occur. Gemination is more common in the maxilla, whereas fusion tends to occur more frequently in the mandible. Bilateral cases are uncommon (Fig. 2.60).

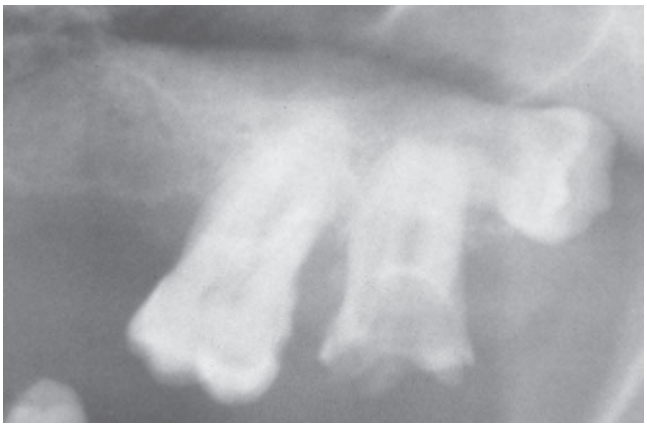
Gemination and fusion appear similar and may be differentiated by assessing the number of teeth in the dentition. Some authors have suggested that gemination demonstrates a single root canal whereas separate canals are present in fusion; but this does not hold true in all cases (Fig. 2.61). Fusion and gemination can be seen in one of four major patterns: a bifid crown with a single root, a large crown with a large root, two conjoined crowns with a double conical root, and two connected crowns with two linked roots.

• **Fig. 2.60 Fusion.** Bilateral double teeth in the place of the mandibular lateral incisors and cuspids.



• **Fig. 2.61 Fusion.** Radiograph of the same patient depicted in Fig. 2.60. Note the bifid crown overlying the single root canal; the contralateral radiograph revealed a similar pattern.

Concrescence



Concrescence is two fully formed teeth, joined along the root surfaces by cementum. The process is noted more frequently in the posterior and maxillary regions. The developmental pattern often involves a second molar tooth in which its roots closely approximate the adjacent impacted third molar (Fig. 2.62). The post-inflammatory pattern frequently involves carious molars in which the apices overlie the roots of horizontally or distally angulated third molars. This latter pattern most frequently arises in a carious tooth that exhibits large coronal tooth loss. The resultant large pulpal exposure often permits pulpal drainage, leading to a resolution of a portion of the intrabony pathosis. Cemental repair then occurs (Figs. 2.63 and 2.64).

Treatment and Prognosis

The presence of double teeth (i.e., gemination or fusion) in the deciduous dentition can result in crowding, abnormal spacing, and delayed or ectopic eruption of the underlying permanent teeth. When detected, the progression of

• **Fig. 2.62 Concrescence.** Union by cementum of adjacent maxillary molars.

• **Fig. 2.63 Concrescence.** Union by cementum of maxillary second and third molars. Note the large carious defect of the second molar.

dentlearn.ir

eruption of the permanent teeth should be monitored closely by careful clinical and radiographic observation. When appropriate, extraction may be necessary to prevent an abnormality in eruption. Occasionally, fusion in the primary dentition is associated with absence of the underlying permanent successor.

Several approaches are available for the treatment of joined teeth in the permanent dentition, and the treatment of choice is determined by the patient's particular needs. Cone beam computed tomography (CBCT) often proves beneficial during treatment planning due to its ability to define the level of the tooth union, the number of the roots, and the anatomy of the involved pulp chambers and canals more clearly. In gemination, if the double teeth have separate pulps, hemisection may be successful without root canal therapy. The separation may be done intraorally or require extraction with extraoral sectioning if the union extends close to the apex. If extraction is necessary, immediate (within 5 minutes) replantation of the desirable half may result in preservation of vitality and long-term survival of the tooth. In double teeth that share a common pulp, endodontic therapy is necessary if sectioning is considered. Selected shaping with or without placement of full crowns has been used in many cases. Other patients exhibit pulpal or coronal anatomic features that are resistant to reshaping and require surgical removal with prosthetic replacement. Double teeth often will demonstrate a pronounced labial or lingual groove that may be prone to develop caries. In such cases, placement of a fissure sealant or composite restoration is appropriate if the tooth is to be retained.

• **Fig. 2.64 Concrescence.** Gross photograph of the same teeth depicted in Fig. 2.63. Histopathologic examination revealed that union occurred in the area of cemental repair previously damaged by a periapical inflammatory lesion.

Patients with concrescence often require no therapy unless the union interferes with eruption; then surgical removal may be warranted. Post-inflammatory concrescence must be kept in mind whenever extraction is planned for nonvital teeth with apices that overlie the roots of an adjacent tooth. Significant extraction difficulties can be experienced on attempted removal of a tooth that is unexpectedly joined to its neighbor. Surgical separation often is required to complete the procedure without loss of a significant portion of the surrounding bone.

ACCESSORY CUSPS

The cuspal morphology of teeth exhibits minor variations among different populations; of these, three distinctive patterns deserve further discussion: (1) **cusp of Carabelli,** (2) **talon cusp,** and (3) **dens evaginatus.** When an accessory cusp is present, the other permanent teeth often exhibit a slightly increased tooth size.

Clinical and Radiographic Features

Cusp of Carabelli

The **cusp of Carabelli** is an accessory cusp located on the palatal surface of the mesiolingual cusp of a maxillary molar (Fig. 2.65). The cusp may be seen in the permanent or deciduous dentitions and varies from a definite cusp to a small indented pit or fissure. When present, the cusp is most pronounced on the first molar and is increasingly less obvious on the second and third molars. When a cusp of Carabelli is present, the remaining permanent teeth often are larger than normal mesiodistally, but a similar association in deciduous tooth size typically is not noted. A significant variation exists among different populations, with the prevalence reported to be as high as 90% in whites and rare in Asians. An analogous accessory cusp is seen occasionally on the mesiobuccal cusp of a mandibular permanent or deciduous molar and is termed a *protostylid.*

Talon Cusp

A **talon cusp** is a well-delineated additional cusp that is located on the surface of an anterior tooth and extends at least half the distance from the cementoenamel junction to

• **Fig. 2.65 Cusp of Carabelli.** Accessory cusp on the mesiolingual surface of the maxillary first molar.

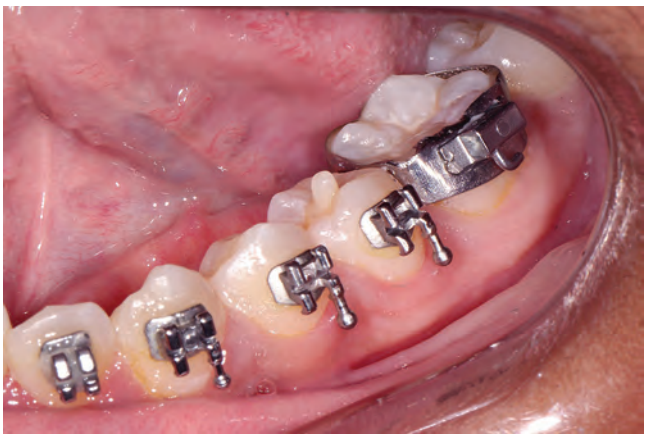
dentlearn.ir

• **Fig. 2.66 Talon Cusp.** Accessory cusp present on the palatal surface of a maxillary lateral incisor. (Courtesy of Dr. S. Gabrielle Shuler).

the incisal edge. A talon cusp is thought to represent the end of a continuum that extends from a normal cingulum, to an enlarged cingulum, to a small accessory cusp, and, finally, to a full-formed talon cusp. Investigators have muddied the literature associated with this spectrum by categorizing all enlarged cingula as talon cusps and developing a classification system for the degree of enlargement. These classification systems make prevalence data difficult to evaluate and should be discouraged.

Three-fourths of all reported talon cusps are located in the permanent dentition. The cusps predominantly occur on permanent maxillary lateral (55%) or central (33%) incisors but have been seen less frequently on mandibular incisors (6%) and maxillary canines (4%) (Fig. 2.66). Their occurrence in the deciduous dentition is very rare, with the vast majority noted on maxillary central incisors. In almost all cases, the accessory cusp projects from the lingual surface of the affected tooth and forms a three-pronged pattern that resembles an eagle's talon. On rare occasions, the cusp may project from the facial surface or from both surfaces of a single tooth. A deep developmental groove may be present where the cusp fuses with the underlying surface of the affected tooth. Most, but not all, talon cusps contain a pulpal extension. Radiographically, the cusp is seen overlying the central portion of the crown and includes enamel and dentin (Fig. 2.67). Only a few cases demonstrate visible pulpal extensions on dental radiographs.

Talon cusps appear to occur more frequently in Asians, Native Americans, the Inuit, and those of Arab descent. Both sexes may be affected, and the occurrence may be unilateral or bilateral. In isolated cases, genetic influences appear to have an effect, because identical talon cusps occasionally have been documented in twins. Talon cusps also have been seen in patients with Rubinstein-Taybi syndrome, Mohr syndrome, Ellis-van Creveld syndrome, incontinentia pigmenti achromians, Berardinelli-Seip syndrome, and Sturge-Weber angiomatosis. Although the strength of association between the presence of talon cusps and these syndromes generally is not clear, Rubinstein-Taybi syndrome is correlated strongly as demonstrated by a study of 45 affected patients in which 92% demonstrated talon cusps.



• **Fig. 2.67 Talon Cusp.** Radiograph of same patient shown in Fig. 2.66. Note the enamel and dentin layers within the accessory cusp. (Courtesy of Dr. Gabrielle Shuler).

Dens Evaginatus

Dens evaginatus (central tubercle, tuberculated cusp, accessory tubercle, occlusal pearl, evaginated odontome, Leong premolar, tuberculated premolar) is a cusplike elevation of enamel located in the central groove or lingual ridge of the buccal cusp of premolar or molar teeth (Fig. 2.68). Although this pattern of accessory cusps has been reported on molars, dens evaginatus typically occurs on premolar teeth, usually is bilateral, and demonstrates a marked mandibular predominance. Deciduous molars are affected infrequently. The accessory cusp normally consists of enamel and dentin, with pulp present in about half of the cases. Although the prevalence is variable, most reviews suggest a frequency between 1% and 4%. The anomaly is encountered most frequently in Asians, the Inuit, and Native Americans but is rare in whites. Researchers expect an increased prevalence of this anomaly in the United States secondary to immigration by Asians and by Hispanics of mestizo heritage (i.e., those of mixed European and Native American ancestry). Radiographically, the occlusal surface exhibits a

dentlearn.ir

• **Fig. 2.68 Dens Evaginatus.** Cusplike elevation located in the central groove of mandibular second bicuspid. (Courtesy of Dr. Jason Latham).

• **Fig. 2.69 Shovel-Shaped Incisors.** Chinese patient exhibiting maxillary incisors with prominent lateral margins, which create a hollowed lingual surface.

cusp-like structure often with a pulpal extension. The accessory cusp frequently creates occlusal interferences that are associated with significant clinical problems. In one large study, more than 80% of the tubercles were worn or fractured, with pulpal pathosis noted in more than 25% of patients. Pulpal necrosis is common and may occur through a direct exposure or invasion of patent, immature dentinal tubules. In addition to abnormal wear and pulpal pathosis, the accessory cusp also may result in dilaceration, displacement, tilting, or rotation of the tooth.

Frequently, dens evaginatus is seen in association with another variation of coronal anatomy, **shovel-shaped incisors.** This alteration also occurs predominantly in Asians, with a very high prevalence also noted in Native Americans and the Inuit. Affected incisors demonstrate prominent lateral margins, creating a hollowed lingual surface that resembles the scoop of a shovel (Fig. 2.69). Typically, the thickened marginal ridges converge at the cingulum; not uncommonly, a deep pit, fissure, or dens invaginatus is found at this junction. Maxillary lateral and central incisors most frequently are affected, with mandibular incisors and canines less commonly reported.

Treatment and Prognosis

Patients with cusps of Carabelli require no therapy unless a deep groove is present between the accessory cusp and the surface of the mesiolingual cusp of the molar. These deep grooves should be sealed to prevent carious involvement.

Patients with talon cusps on mandibular teeth often require no therapy; talon cusps on maxillary teeth frequently interfere with occlusion and should be removed. Other complications include compromised aesthetics, displacement of teeth, caries, periodontal problems, and irritation of the adjacent soft tissue (e.g., tongue or labial mucosa). Because many of these cusps contain pulp, rapid removal often results in pulpal exposure. Cone beam computed tomography (CBCT) can be used to determine the extent of pulp tissue within the cusp and assist in treatment planning. Often, removal without the loss of vitality may be accomplished through periodic grinding of the cusp, with time allowed for tertiary dentin deposition and pulpal recession. Successful reduction may be achieved with three visits spaced 6–8 weeks apart. At the end of each grinding session, the exposed dentin should be coated with a desensitizing agent such as fluoride varnish, which also may speed the rate of pulpal recession. Even with slow reduction and no direct pulp exposure, loss of vitality is possible when large numbers of immature dentin tubules are exposed. After successful removal of the cusp, the exposed dentin can be covered with calcium hydroxide, the peripheral enamel etched, and a composite resin placed. Alternatively, for large talon cusps or those with significant pulp tissue, the cusp can be removed in a single session with an intentional partial pulpotomy being performed in an attempt to maintain long-term vitality of the tooth.

On eruption, the affected tooth should be inspected for the presence of a deep fissure at the junction between the talon cusp and the surface of the tooth. If a fissure is present, it should be restored to avoid early carious extension into the nearby dental pulp. Reports also have documented the continuation of this fissure down the surface of the root, with subsequent development of lateral radicular inflammatory lesions secondary to the access provided to oral flora by the deep groove. In these latter cases, further surgery is required to expose the groove for appropriate cleansing.

Dens evaginatus typically results in occlusal problems and often leads to pulpal death. In affected teeth, removal of the cusp often is indicated, but attempts to maintain vitality have met with only partial success. Slow, periodic grinding of the cusp exposes immature patent dentinal tubules and may lead to irreversible pulpitis without direct exposure. To reduce the chance of pulpal pathosis, elimination of opposing occlusal interferences combined with removal of minimal dentin and treatment of the area with stannous fluoride has been recommended. More rapid cuspal removal with indirect or direct pulp capping also has proven beneficial in some patients. Other investigators support removal of occlusal interferences, protection of the cusp from fracture by the placement of surrounding resin reinforcement, and delaying

dentlearn.ir

cuspal removal until evidence of significant dentinal maturation, pulpal recession, and apical root closure are present.

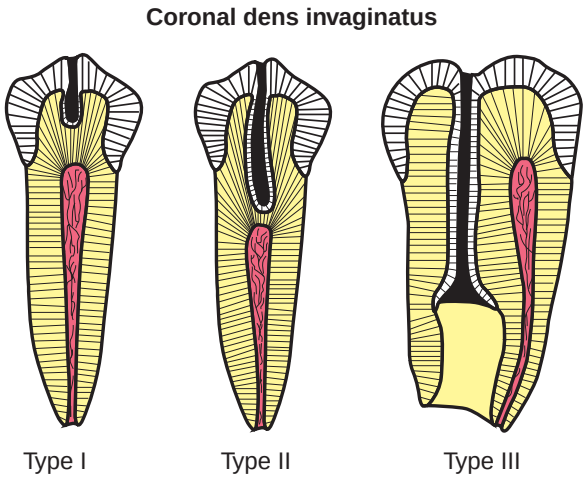
If pulpal necrosis occurs in a tooth with an immature open apex, regenerative endodontic procedures can be employed to induce apical growth and promote increased thickness of the radicular dentinal walls. Another option for necrotic teeth with an immature open apex is revascularization. In this technique, the purulent pulp tissue is removed with sodium hypochlorite irrigation, placement of antimicrobial agents, and no use of endodontic instruments. Over several appointments, the necrotic tissue is eliminated and replaced with healing vascular pulp tissue. When the tooth is asymptomatic without evidence of continued infection, a ceramic cement plug (such as mineral trioxide aggregate) is placed over the top of the healing radicular pulp tissue with the access cavity restored with a glass ionomer cement and composite resin.

Shovel-shaped incisors should be inspected for surface defects at the point where the marginal ridges converge. Any deep fissures or invaginations should be restored shortly after eruption to prevent carious exposure of the adjacent pulp.

DENS INVAGINATUS (DENS IN DENTE)

Dens invaginatus is a deep surface invagination of the crown or root that is lined by enamel. Oehlers described this condition thoroughly in three classic articles published from 1957 to 1958. Two forms, coronal dens invaginatus and radicular dens invaginatus, are recognized. By a great margin, coronal dens invaginatus is seen more frequently.

Clinical and Radiographic Features



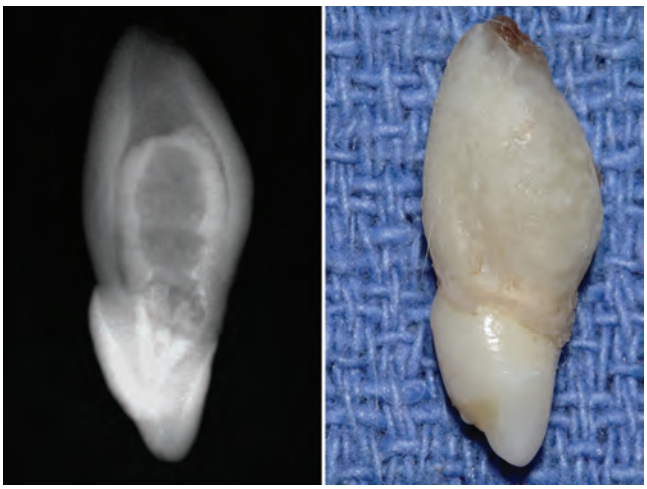
Coronal Dens Invaginatus

The reported prevalence of coronal dens invaginatus varies from 0.04% to 10% of all patients. In order of decreasing frequency, the teeth affected most often include the permanent lateral incisors, central incisors, premolars, canines, and molars. Involvement of deciduous teeth has been reported but is uncommon. A strong maxillary predominance is seen.

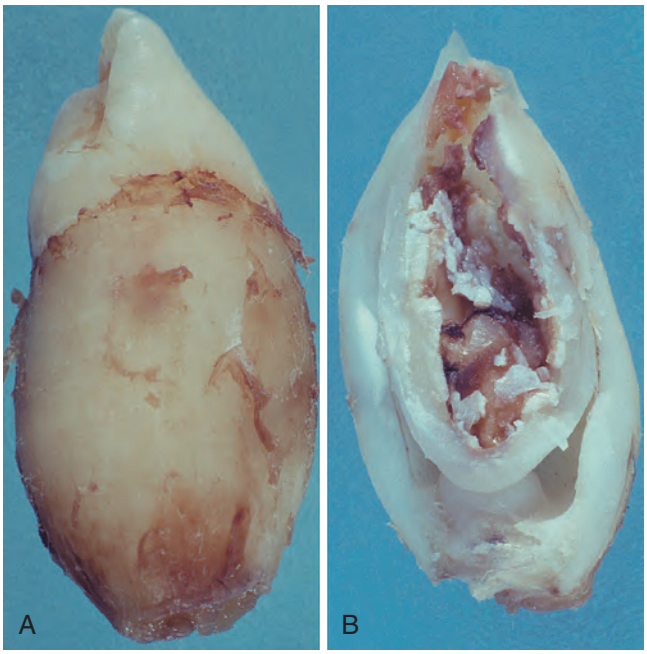
The crown of the affected tooth often will demonstrate clinical changes that suggest the need for radiographs to confirm the presence of an enamel-lined invagination. Suggestive clinical findings include a palatal pit or groove, a barrel or cone-shaped tooth, a crown that is dilated in comparison to the contralateral tooth, localized microdontia, a talon cusp, dens evaginatus, or a coronal labial groove.

The depth of the invagination varies from a slight enlargement of the cingulum pit to a deep infolding that extends to the apex. As would be expected, before eruption, the lumen of the invagination is filled with soft tissue similar to the dental follicle (i.e., reduced enamel epithelium with a fibrous connective tissue wall). On eruption, this soft tissue loses its vascular supply and becomes necrotic.

Historically, coronal dens invaginatus has been classified into three major types (Fig. 2.70). Type I exhibits an invagination that is confined to the crown. The invagination in type II extends below the cementoenamel junction and ends in a blind sac (Figs. 2.71 and 2.72). Large invaginations may become dilated and contain dystrophic enamel in the base of the dilatation (Fig. 2.73). In some cases, the enamel lining of the invagination is incomplete, and channels communicate between the invagination and the pulp. These connections can result in pulpal necrosis long before the apex has closed. Type III extends through the root and perforates in



• **Fig. 2.70 Dens Invaginatus.** Illustration depicting the three types of coronal dens invaginatus.



• **Fig. 2.71 Coronal Dens Invaginatus Type II.** Maxillary lateral incisor exhibiting invagination of the surface enamel that extends below the cementoenamel junction.

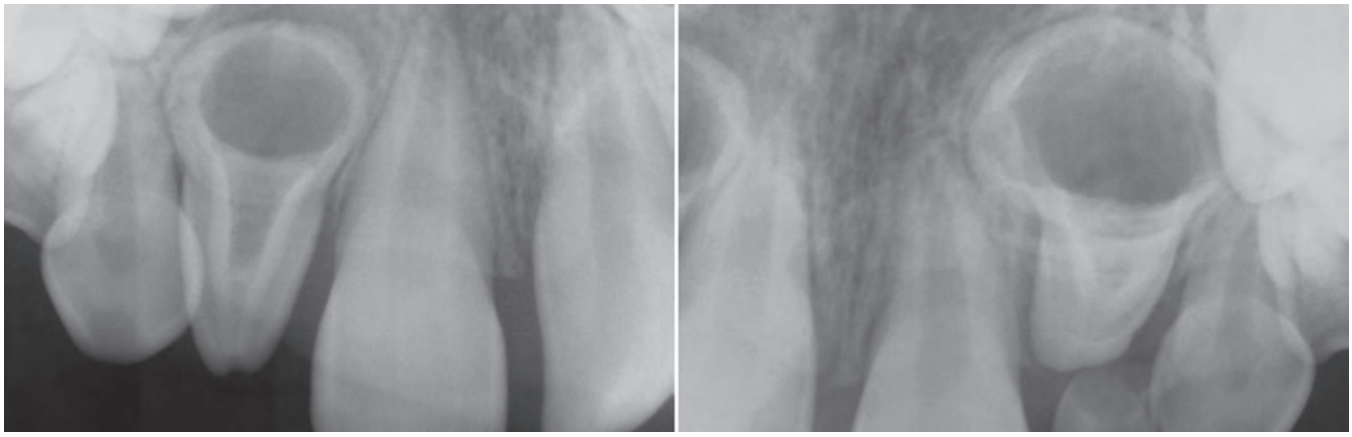
• **Fig. 2.72 Coronal Dens Invaginatus Type II. A,** Bulbous maxillary cuspid exhibiting a dilated invagination lined by enamel. **B,** Gross photograph demonstrating bulbous root and coronal notch.

• **Fig. 2.73 Coronal Dens Invaginatus Type II.** Gross photograph of a sectioned tooth. Note the dilated invagination with apical accumulation of dystrophic enamel.

the apical or lateral radicular area without any immediate communication with the pulp. In this latter type, the enamel that lines the invagination is often replaced by cementum close to the radicular perforation. This perforation provides direct communication from the oral cavity to the intraosseous periradicular tissues and often produces inflammatory lesions in the presence of a vital pulp (Figs. 2.74 and 2.75). Type I is by far the most common pattern (79%) followed by type II (15%) and type III (5%).

Occasionally, the invagination may be rather large and resemble a tooth within a tooth; hence the term **dens in dente.** In other cases, the invagination may be dilated and

• **Fig. 2.74 Coronal Dens Invaginatus Type III.** Parulis overlying vital maxillary cuspid and lateral incisor. The cuspid contained a dens invaginatus that perforated the mesial surface of its root.



• **Fig. 2.75 Coronal Dens Invaginatus Type III.** Maxillary cuspid exhibiting an enamel invagination that parallels the pulp canal and perforates the lateral root surface. (Courtesy of Dr. Brian Blocher.)

disturb the formation of the tooth, resulting in anomalous tooth development termed **dilated odontome** (Fig. 2.76). Involvement may be singular, multiple, or bilateral.

Radicular Dens Invaginatus

Radicular dens invaginatus is rare and thought to arise secondary to a proliferation of Hertwig root sheath, with the formation of a strip of enamel that extends along the surface of the root. This pattern of enamel deposition is similar to that frequently seen in association with radicular **enamel pearls** (see Ectopic Enamel, page 90). Rather than protrude from the surface (as seen in an enamel pearl), the altered enamel forms a surface invagination into the dental papilla. Cementum-lined invaginations of the root have been reported, but these represent a simple variation of root morphology and should not be included under the term *radicular dens invaginatus.*

dentlearn.ir

• **Fig. 2.76 Coronal Dens Invaginatus Type II.** Bilateral dilated dens invaginatus (dilated odontome) of the maxillary lateral incisors. (Courtesy of Dr. Mary Haigler).

Radiographically, the affected tooth demonstrates an enlargement of the root. Close examination often reveals a dilated invagination lined by enamel, with the opening of the invagination situated along the lateral aspect of the root.

Treatment and Prognosis

In small type I invaginations, the opening of the invagination should be restored after eruption in an attempt to prevent carious involvement and subsequent pulpal inflammation. If the invagination is not detected quickly, then pulpal necrosis frequently results. With larger type II invaginations, the contents of the lumen and any carious dentin must be removed; then a calcium hydroxide base may be placed to help treat any possible microcommunications with the adjacent pulp. In cases with obvious pulpal communication or signs of pulpal pathosis, both the invagination and the adjacent pulp canal require endodontic therapy. In teeth with open apices, regenerative endodontic procedures are recommended to obtain continued apexification.

Type III invaginations associated with periradicular inflammatory lesions require endodontic-like therapy of the perforating invagination. Once again, before final obturation with gutta-percha, temporary placement of calcium hydroxide helps to build dentinal bridges and maintain vitality of the adjacent pulp. If vitality is lost, endodontic therapy of the parallel root canal also becomes necessary. Some cases do not respond to conservative endodontic therapy and require periapical surgery and retrofill. Large and extremely dilated invaginations often have abnormal crowns and need to be extracted. Cone beam computed tomography (CBCT) has proven to be most beneficial in defining the complex anatomy of the invagination and the adjacent pulp, improving the accuracy of treatment planning decisions.

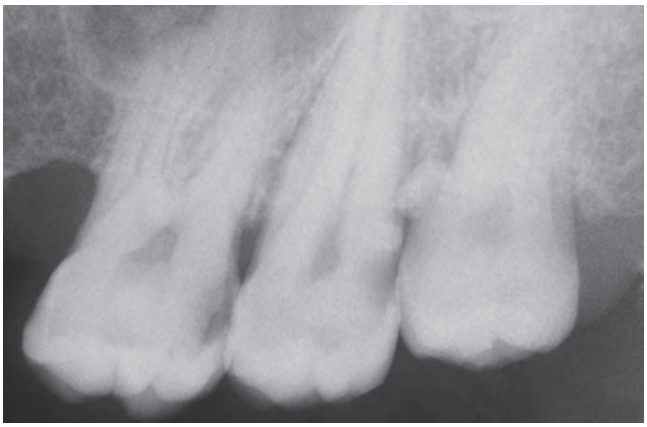
Among the few reported cases of true radicular dens invaginatus, the significantly altered anatomy has necessitated extraction in the vast majority.

ECTOPIC ENAMEL

Ectopic enamel refers to the presence of enamel in unusual locations, mainly the tooth root. The most widely known are **enamel pearls,** which are located on the external surface of the root apical to and separated from the cemento-enamel junction. Three patterns are seen: (1) *true enamel pearls* consisting entirely of enamel, (2) *composite pearls* demonstrating a core of dentin covered by enamel, and (3) *"E-D-P" pearls* containing enamel, dentin, and pulp. The vast majority of enamel pearls are the composite type. Instead of creating exophytic globes, ectopic enamel also may invaginate into the underlying radicular cementum and dentin, resulting in the extremely rare radicular form of dens invaginatus (see page 89).

In addition to enamel pearls, **cervical enamel extensions** also occur along the surface of dental roots. These extensions are thought to be more common than enamel pearls and represent a dipping of the enamel from the cementoenamel junction toward the bifurcation of molar teeth. This pattern of ectopic enamel forms a triangular extension of the coronal enamel that develops on the buccal surface of molar teeth directly overlying the bifurcation. The base of the triangle is continuous with the inferior portion of the coronal enamel; the leading point of the triangle extends directly toward the bifurcation of the tooth. These areas of ectopic enamel have been called *cervical enamel projections,* but this terminology is confusing because no significant exophytic projections are seen.

Clinical and Radiographic Features



Enamel Pearls

Enamel pearls usually develop on the roots of the maxillary permanent molars followed in prevalence by the mandibular permanent molars. Premolars and incisors rarely are affected. Involvement of deciduous molars has been reported but also is rare. The reported prevalence of enamel pearls varies (0.23%–4.82% of all patients) according to the population studied and is highest in Asians. In most cases, one pearl is found, but as many as four pearls have been documented on a single tooth. The majority occur on the roots at the furcation area or near the cementoenamel junction (Fig. 2.77). Radiographically, pearls appear as well-defined, radiopaque nodules along the root's surface (Fig. 2.78). Although they can be confused with dental calculus, cone beam computed tomography (CBCT) easily resolves this dilemma.

dentlearn.ir

• **Fig. 2.77 Enamel Pearl.** Mass of ectopic enamel located in the furcation area of a molar tooth. (Courtesy of Dr. Joseph Beard.)

• **Fig. 2.78 Enamel Pearl.** Radiopaque nodule on the mesial surface of the root of the maxillary third molar. Another less distinct enamel pearl is present on the distal root of the second molar.

The enamel surface of pearls precludes normal periodontal attachment with connective tissue, and a hemidesmosomal junction probably exists. This junction is less resistant to breakdown; once separation occurs, rapid loss of attachment is likely. In addition, the exophytic nature of the pearl is conducive to plaque retention and inadequate cleansing.

Cervical Enamel Extensions

As mentioned previously, **cervical enamel extensions** are located on the buccal surface of the root overlying the bifurcation (Fig. 2.79). Mandibular molars are affected slightly more frequently than maxillary molars. In reviews of extracted teeth in the lower 48 United States, the prevalence is surprisingly high, with approximately 20% of molars being affected. Similar studies demonstrate an even greater prevalence in other locations, such as Japan, China, and Alaska,

• **Fig. 2.79 Cervical Enamel Extension.** Flat V-shaped extension of enamel into the bifurcation of a maxillary molar. (Courtesy of Dr. Keith Lemmerman.)

with cervical enamel extensions discovered in 50%–78% of extracted molars. Cervical enamel extensions may occur on any molar, but they are seen less frequently on third molars. Because connective tissue cannot attach to enamel, these extensions have been correlated positively with localized loss of periodontal attachment with furcation involvement. On review of a large number of dentitions with periodontal furcation involvement, a significantly higher frequency of cervical enamel extensions was found compared with dentitions without furcation involvement. In addition, the greater the degree of cervical extension, the higher the frequency of furcation involvement.

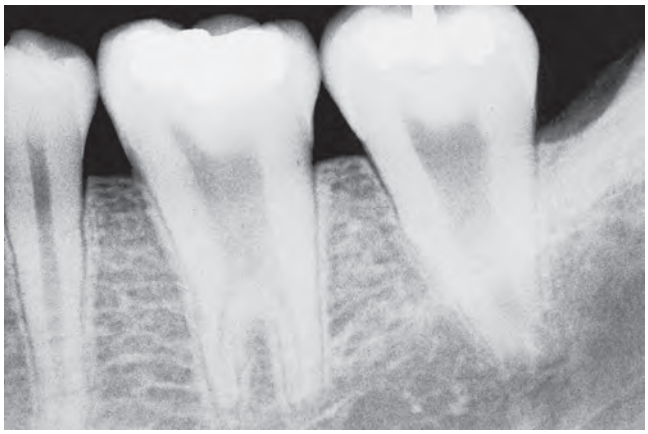
In addition to periodontal furcation involvement, cervical enamel extensions have been reported to be associated with the development of inflammatory cysts that are histopathologically identical to inflammatory periapical cysts. The cysts develop along the buccal surface over the bifurcation and most appropriately are called **buccal bifurcation cysts** (see page 704). The association between cervical enamel extensions and this unique inflammatory cyst is controversial.

Treatment and Prognosis

When enamel pearls are detected radiographically, most are incidental findings that require no therapy. Despite this, the area should be viewed as a weak point of periodontal attachment. Meticulous oral hygiene should be maintained in an effort to prevent localized loss of periodontal support and

dentlearn.ir

exposure of the enamel mass. If an enamel pearl becomes exposed and removal is contemplated, then the clinician must remember that the projection occasionally contains vital pulp tissue.



For teeth with cervical enamel extensions and associated periodontal furcation involvement, therapy is directed at achieving a more durable attachment and providing access to the area for appropriate cleaning. Reports have suggested that flattening or removing the enamel in combination with an excisional new attachment procedure and furcation plasty may accomplish this.

TAURODONTISM

Taurodontism is an enlargement of the body and pulp chamber of a multirooted tooth, with apical displacement of the pulpal floor and bifurcation of the roots. This pattern of molar formation was described initially by Keith in 1913 and has been found in earlier forms of prehistoric man such as the ancient Neanderthals. The morphologic pattern was termed taurodont due to its overall shape that resembles the molar teeth of cud-chewing animals (*tauro* = bull; *dont* = tooth).

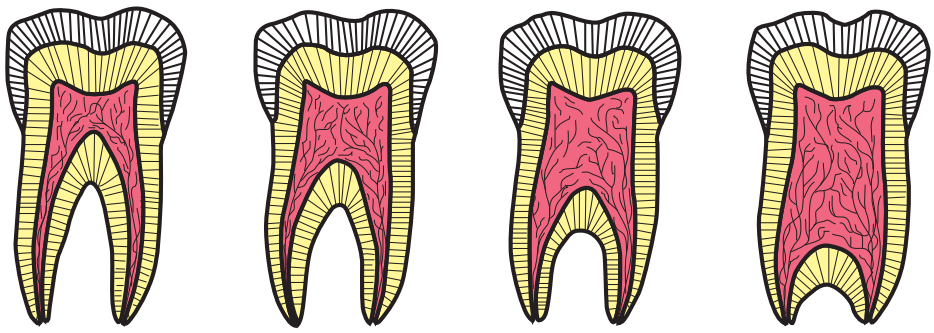
Clinical and Radiographic Features

Affected teeth tend to be rectangular and exhibit pulp chambers with a dramatically increased apico-occlusal height and a bifurcation close to the apex (Fig. 2.80). The diagnosis usually is made subjectively from the radiographic appearance. The degree of taurodontism has been classified into *mild* **(hypotaurodontism),** *moderate* **(mesotaurodontism),** and *severe* **(hypertaurodontism),** according to the degree of apical displacement of the pulpal floor (Fig. 2.81). Witkop and colleagues and Shifman and Chanannel presented useful biometric criteria for the determination of taurodontism. These reports contain information that is useful in epidemiologic studies of the process.

• **Fig. 2.80 Taurodontism.** Mandibular molar teeth exhibiting increased pulpal apico-occlusal height with apically positioned pulpal floor and bifurcation. (Courtesy of Dr. Michael Kahn.)

Patients with taurodonts often will demonstrate one or more additional molars with completely fused roots and a solitary enlarged canal. This developmental pattern is termed **pyramidal molars**. Some investigators believe taurodont molars represent an intermediate pattern on the continuum between normal and pyramidal molars.

Some authors include examples of taurodontism in premolar teeth; others argue that taurodontism is not shown by premolars. This argument is academic because the presence of taurodontism in premolars cannot be documented in situ. Investigations of taurodontism in premolar teeth require the examination of extracted teeth, because the necessary radiographs must depict the tooth in a mesiodistal orientation.



Taurodontism may be unilateral or bilateral and affects permanent teeth more frequently than deciduous teeth. There is no sex predilection. The reported prevalence is highly variable (0.5%–46%) and most likely is related to different diagnostic criteria and racial variations. In the United States, most reports indicate a prevalence of 2.5%–3.2% of the population. Some investigators believe the alteration is more of a variation of normal rather than a definitive pathologic anomaly. The process often demonstrates a field effect with the involvement of all molars. When this occurs, the first molar is usually affected least with increasing severity noted in the second and third molars, respectively.

Taurodontism may occur as an isolated trait or as a component of various syndromes (Box 2.10). An increased frequency of taurodontism has been reported in patients with hypodontia, cleft lip, and cleft palate. Investigations have shown that taurodontism may develop in the presence of any one of a large number of different genetic alterations. These findings suggest that chromosomal abnormalities may disrupt the development of the tooth's form and that taurodontism is not the result of a specific genetic abnormality.

Treatment and Prognosis

Patients with taurodontism require no specific therapy. Coronal extension of the pulp is not seen; therefore, the process does not interfere with routine restorative procedures. Some investigators have suggested the taurodontic shape may exhibit decreased stability and strength as an abutment tooth in prosthetic procedures due to decreased root surface area, but this hypothesis has not been verified. If endodontic therapy is required, the shape of the pulp chamber and the apically positioned pulpal floor frequently increase the difficulty of locating, instrumenting, and obturating the pulp canals. In addition, the presence of supernumerary roots and canals mandates careful exploration of all orifices and chamber grooves, with magnification being highly beneficial. Cone beam computed tomography (CBCT) has proven to be particularly useful in defining the highly variable canal morphologies encountered in taurodonts. One bit of good news is that patients have to demonstrate significant periodontal destruction before bifurcation involvement occurs.

HYPERCEMENTOSIS

Hypercementosis (cemental hyperplasia) is a nonneoplastic deposition of excessive cementum that is continuous with the normal radicular cementum.

Hypercementosis has been reported in association with a wide variety of disorders, Box 2.11 lists several of the most commonly mentioned local and systemic factors that have been associated with an increased frequency of the excessive cemental deposition. All of the listed systemic factors exhibit a weak association with hypercementosis except for **Paget disease of bone** (see page 628). Numerous authors have reported significant hypercementosis in patients with Paget disease, and this disorder should be considered whenever generalized hypercementosis is discovered in a patient of the appropriate age. Most localized cases of hypercementosis are not related to any systemic disturbance.

• BOX 2.11 Factors Associated With Hypercementosis

Local Factors

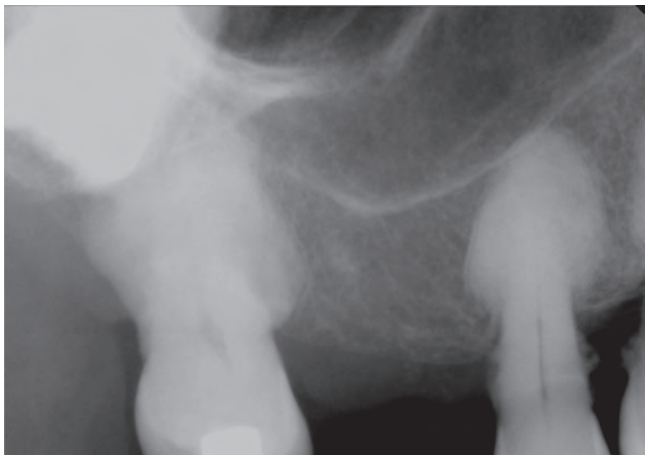
- Abnormal occlusal trauma
- Adjacent inflammation (e.g., pulpal, periapical, periodontal)
- Unopposed teeth (e.g., impacted, embedded, without antagonist)
- Repair of vital root fracture

Systemic Factors

- Acromegaly and pituitary gigantism
- Arthritis
- Calcinosis
- Paget disease of bone
- Rheumatic fever
- Thyroid goiter
- Gardner syndrome
- Vitamin A deficiency (possibly)

Clinical and Radiographic Features

Hypercementosis may be isolated, involve multiple teeth, or appear as a generalized process. The condition most frequently affects premolars and permanent molars with a mandibular predominance. Involvement of the deciduous dentition and permanent canines and incisors is uncommon.

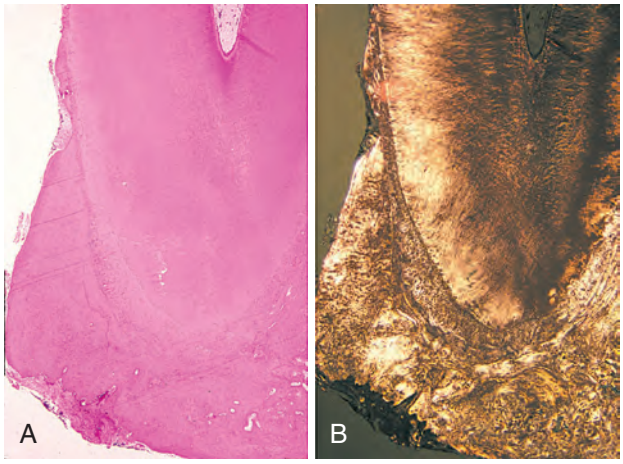


Hypercementosis typically is identified in adults, and the frequency increases with age, which is most likely secondary to cumulative exposure to causative influences. Its occurrence has been reported in younger patients, and many of these cases demonstrate a familial clustering, suggesting hereditary influence.

Radiographically, affected teeth demonstrate a thickening or blunting of the root, but the exact amount of increased cementum often is difficult to ascertain because cementum and dentin demonstrate similar radiodensities (Figs. 2.82 and 2.83). The enlarged root is surrounded by the radiolucent PDL space and the adjacent intact lamina dura. On occasion, the enlargement may be significant enough to suggest the possibility of a cementoblastoma (see page 659). However, the

dentlearn.ir

• **Fig. 2.82 Hypercementosis.** Gross photograph of a maxillary bicuspid that exhibits thickening and blunting of the apical portion of the root. (Courtesy of Dr. David Hicklin.)



• **Fig. 2.83 Hypercementosis.** Periapical radiograph of the tooth depicted in Fig. 2.82. Note the radiopaque enlargement of the apical portion of the tooth. (Courtesy of Dr. David Hicklin.)

cementoblastoma usually can be distinguished on the basis of age (75% arise under the age of 30 years), associated pain, cortical expansion, and continued enlargement.

Histopathologic Features

The periphery of the root exhibits deposition of an excessive amount of cementum over the original layer of primary cementum. The excessive cementum may be hypocellular

• **Fig. 2.84 Hypercementosis. A,** Dental root exhibiting excessive deposition of cellular and acellular cementum. The dividing line between dentin and cementum is indistinct. **B,** Polarized light demonstrating the sharp dividing line between the tubular dentin and osteocementum.

or exhibit areas of cellular cementum that resemble bone (osteocementum). Often the material is arranged in concentric layers and may be applied over the entire root or be limited to the apical portion. On routine light microscopy, distinguishing between dentin and cementum often is difficult, but viewing the section with polarized light helps to discriminate between the two different layers (Fig. 2.84).

Treatment and Prognosis

Patients with hypercementosis require no treatment. Because of a thickened root, occasional problems have been reported during the extraction of an affected tooth. Sectioning of the tooth may be necessary in certain cases to aid in removal. In addition, hypercementosis has been shown to alter the anatomy of the apical foramen and can complicate endodontic procedures.

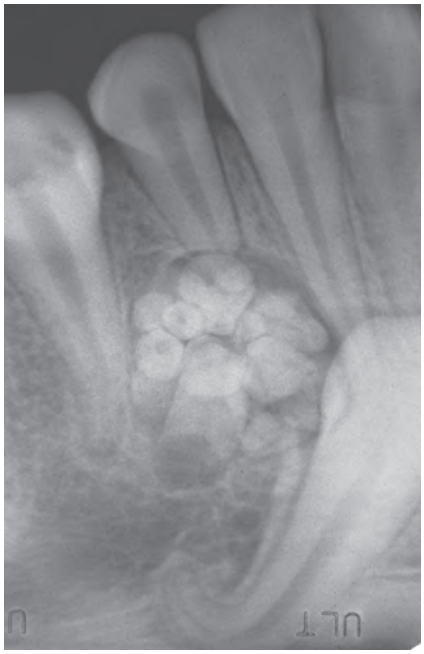
DILACERATION

Dilaceration is an abnormal angulation or bend in the root or, less frequently, the crown of a tooth (Figs. 2.85 and 2.86). A large number of dilacerations present as idiopathic developmental alterations, predominantly in the posterior dentition. In addition, a number of teeth with dilaceration appear to arise after an injury that displaces the calcified portion of the tooth germ, and the remainder of the tooth is formed at an abnormal angle. Injury-related dilaceration more frequently affects the anterior dentition and often creates both a functional and a cosmetic dental problem. Less frequently the bend develops secondary to the presence of an adjacent anatomic structure, cyst, tumor, or odontogenic hamartoma (e.g., odontoma, supernumerary tooth) (Fig. 2.87).

Clinical and Radiographic Features

Dilacerations secondary to trauma usually arise following avulsion or intrusion of the overlying deciduous tooth and primarily affect the maxillary incisors. Dilaceration of the

dentlearn.ir



• **Fig. 2.85 Dilaceration.** Sharp curvature of the root of a maxillary central incisor.

• **Fig. 2.86 Dilaceration.** Maxillary second bicuspid exhibiting mesial inclination of the root. The patient reported no history of injury to this area. (Courtesy of Dr. Lawrence Bean.)

crown is noted more frequently if the trauma occurs prior to the age of three, whereas radicular bends are associated with traumatic events occurring during the later years of tooth development. The maxillary central incisors are the most common teeth to demonstrate crown dilacerations, followed by the mandibular incisors. Impaction of the affected tooth occurs in approximately 50% of these cases.

Regarding dilacerated teeth not associated with trauma, the most commonly affected are mandibular third molars, followed by the maxillary second premolars and mandibular second molars. Although many reviews report a higher frequency of dilacerations in anterior teeth, the molars most likely demonstrate the highest prevalence but are not highlighted because of a lack of associated clinical problems in most instances. Occasionally, involvement of the deciduous teeth is reported, and some have been associated with

• **Fig. 2.87 Dilaceration.** Root angulation of a mandibular cuspid. Development has been altered by the presence of an adjacent compound odontoma. (Courtesy of Dr. Brent Bernard.)

prior trauma secondary to neonatal laryngoscopy and endotracheal intubation. Several publications have mentioned an increased prevalence associated with several syndromes, including Smith-Magenis syndrome, variants of Ehlers-Danlos syndrome, Axenfeld-Rieger syndrome, and congenital ichthyosis.

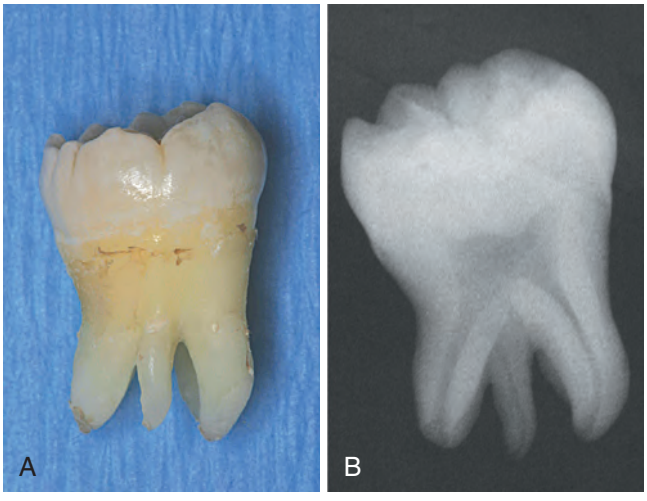
Dilaceration usually is radiographically obvious if the bend occurs in a mesial or distal direction. Roots that bend facially or lingually may be more difficult to detect. Often, the apical portion of these teeth will demonstrate a round increased radiodensity with a central radiolucent dark spot that correlates to the root canal of the bent tooth. The dilacerated portion of the root often may demonstrate a radiolucent halo that represents the associated periodontal ligament. Cone beam computed tomography (CBCT) has been shown to be vastly superior to plain films due to its ability to accurately depict the exact position of the tooth, the extent of root formation, and the degree of dilaceration.

Treatment and Prognosis

The treatment and prognosis vary according to the severity of the deformity. Altered deciduous teeth often demonstrate inappropriate resorption and result in delayed eruption of the permanent teeth. Extraction is indicated when necessary for the normal eruption of the succedaneous teeth. Patients with minor dilaceration of permanent teeth frequently require no therapy. Those teeth that exhibit delayed or abnormal eruption may be exposed and orthodontically moved into position. The possibility that orthodontic movement of severely dilacerated teeth may result in severe external root resorption must be considered during treatment

dentlearn.ir

planning. In some cases with extensive deformation of the affected tooth, perforation of the buccal alveolar ridge by the malpositioned root may occur on repositioning. In such cases, amputation of the root apex with subsequent endodontic therapy may be necessary. Grossly deformed teeth require surgical removal. The extraction of affected teeth may be difficult and result in root fracture on removal. When attempting to perform endodontic procedures, the clinician must use great care to avoid root perforation of teeth with significant dilaceration.



Root dilaceration concentrates stress if the affected tooth is used as an abutment for a dental prosthetic appliance. This increased stress may affect the stability and longevity of the abutment tooth. Splinting of the dilacerated tooth to an adjacent tooth results in a multirooted abutment and overcomes the stress-related problems.

SUPERNUMERARY ROOTS

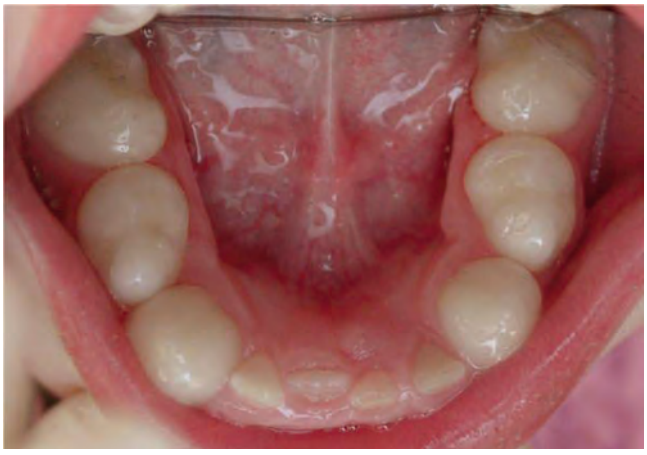
The term **supernumerary roots** refers to the development of an increased number of roots on a tooth compared with that classically described in dental anatomy.

Clinical and Radiographic Features

Any tooth may develop accessory roots, and involvement has been reported in both the deciduous and the permanent dentitions. Data on the frequency of supernumerary roots are sparse, but the prevalence appears to vary significantly among different races. The most frequently affected teeth are the permanent molars (especially third molars) from either arch and mandibular cuspids and premolars (Fig. 2.88). In some instances, the supernumerary root is divergent and seen easily on radiographs; in other cases, the additional root is small, superimposed over other roots, and difficult to ascertain.

• **Fig. 2.88 Supernumerary Root. A,** Gross photograph showing a mandibular molar with a supernumerary root. **B,** Periapical radiograph of the extracted tooth.

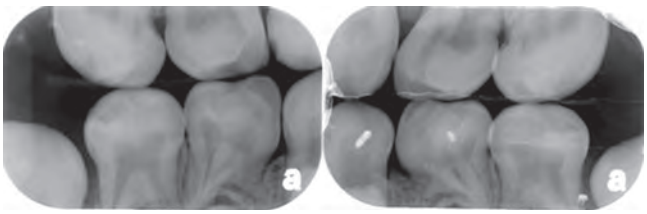
Treatment and Prognosis



No treatment is required for supernumerary roots, but the detection of the accessory root is of critical importance when endodontic therapy or exodontia is undertaken. Extracted teeth always should be examined closely to ensure that all roots have been removed successfully, because accessory roots may not be obvious on the presurgical radiographs. Just as important is the search for accessory canals during endodontic access procedures, because failure to discover these additional openings often results in a lack of resolution of the associated inflammatory process.

GLOBODONTIA

Otodental syndrome is a rare autosomal dominant disorder characterized by a distinctive pattern of dental malformation termed **globodontia** in association with high-frequency sensorineural hearing loss. This condition is thought to be due to haploinsufficiency of *FGF3*, which is localized at chromosome 11q13. Although both globodontia and hearing loss usually are present, variable expressivity is seen, with some family members exhibiting only hearing loss and others revealing globodontia without hearing loss.



Clinical and Radiographic Features

Both the deciduous and permanent dentitions are affected with the cuspids and molars demonstrating dramatically enlarged and bulbous crowns (Figs. 2.89 and 2.90). The normal cusp and groove anatomy of the molars is replaced by numerous developmental grooves that radiate from a central depression onto the facial, lingual, and proximal surfaces, resulting in an occlusal surface that has been described as resembling the *tied end of a sausage.* The canines are distorted similarly, often with three large bulbous projections separated by shallow grooves. The premolars often are missing or reduced in size; when present, they may demonstrate

• **Fig. 2.89 Globodontia.** Dentition demonstrating clinically normal anterior teeth and posterior teeth with enlarged bulbous crowns. Patient had undiagnosed hearing loss that was discovered following identification of otodental syndrome by dentist. (Courtesy of Dr. John Eric Yezerski.)

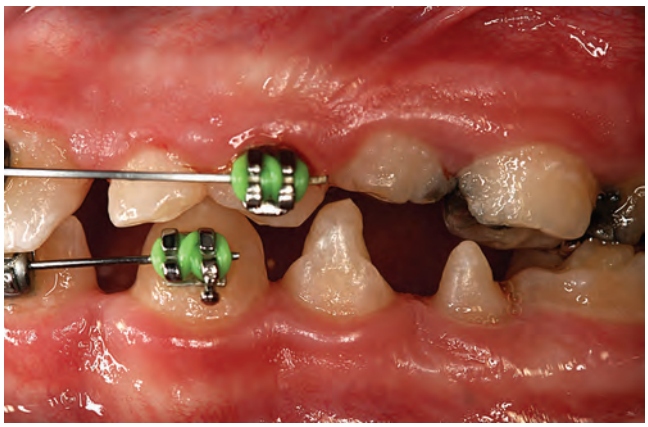
dentlearn.ir

• **Fig. 2.90 Globodontia.** Bite-wing radiographs demonstrating posterior teeth with bulbous crowns and complex pulpal anatomy. (Courtesy of Dr. John Eric Yezerski.)

normal anatomy or appear conical. The incisors are unaffected and exhibit normal size and shape. The globodont roots are short, and the pulp chambers often appear bisected with vertical septa and occasional pulp stones. Focal areas of yellow coronal hypomaturation may occur, especially on the facial surfaces of the canines. In a number of patients, complex odontomas also have been noted. Delayed eruption of both dentitions frequently is seen.

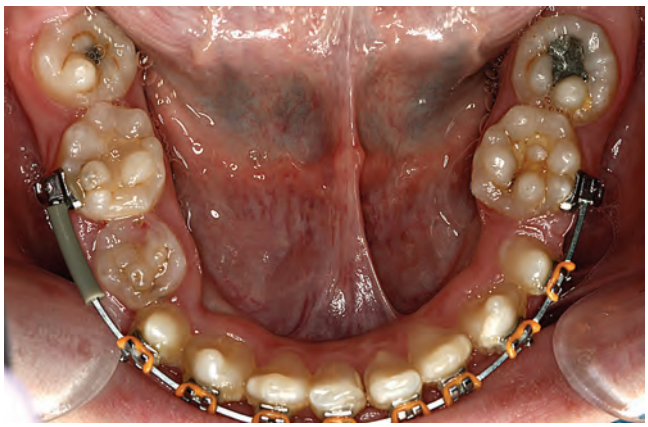
The onset of the hearing loss varies from early childhood to middle age, but it often begins in infancy and progresses to a plateau in the fourth decade. A loss of approximately 65db is noted at all frequencies but is more pronounced at about 1000 Hz. In most patients, the hearing loss usually arises prior to the age of 20 years.

Treatment and Prognosis



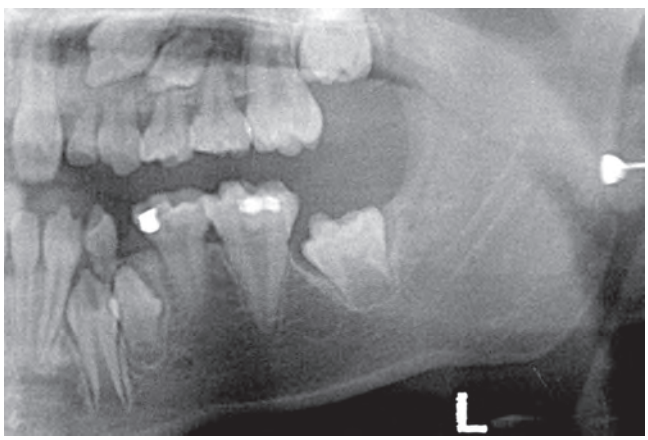
Due to the grossly distorted anatomy, misalignment of the teeth and malocclusion are frequent problems. The bulbous molars have deep fissures that are prone to dental caries, stressing the need for regular professional dental care with preventive procedures such as topical fluorides and dental sealants. If an affected tooth develops dental caries, routine dental restorative treatment can be provided. Endodontic therapy can be very challenging in the molar teeth due to the complexity of the pulpal anatomy. Patients also have a propensity to develop endodontic-periodontic lesions, possibly due to the abnormal coronal and pulpal configuration.

LOBODONTIA



Lobodontia refers to a rare hereditary dental anomaly in which numerous teeth resemble those noted in carnivores. The term is derived from *lobo,* the Spanish word for wolf that arose from the Latin word *lupus.* The abnormality is extremely rare and is inherited as an autosomal dominant trait.

Clinical and Radiographic Features



The most distinctive features are the cuspids and premolars, which demonstrate pointed fang-like tritubercular cusps (Fig. 2.91). The middle of the three lobes of the cuspid crowns are conical with the lateral lobes being dramatically reduced. The premolars demonstrate prominent cone-shaped buccal cusps, often with diminutive lingual cusps.

• **Fig. 2.91 Lobodontia.** Premolar demonstrating pointed fang-like cusps.

• **Fig. 2.92 Lobodontia.** Mandibular molars demonstrating a multitubercular appearance.

• **Fig. 2.93 Lobodontia.** Panoramic radiograph demonstrating pyramidal molars and tritubercular cusps on the premolars and cuspids.

The occlusal anatomy of the molars also is altered significantly and demonstrates a multitubercular appearance (Fig. 2.92). The molar roots are pyramidal with a single fused canal (Fig. 2.93). The incisors often are shovel-shaped with a prominent cingulum or shallow dens invaginatus. Hypodontia is common, most frequently involving the maxillary

dentlearn.ir

second premolars followed by the mandibular second premolars.

Treatment and Prognosis

Thorough radiographic examination is prudent to discover and restore teeth with dens invaginatus prior to devitalization. The abnormal occlusal cusps of the multitubercular molars often cause the same problems that are seen with dens evaginatus with traumatic occlusion, attrition, or fracture predisposing to loss of pulp vitality. Although definitive treatment has not been described, composite reinforcement of the prominent cusps may reduce cuspal damage and allow time for pulpal recession from the coronal protuberances.

◆ DEVELOPMENTAL ALTERATIONS IN THE STRUCTURE OF TEETH

AMELOGENESIS IMPERFECTA

Amelogenesis imperfecta (AI) encompasses a complicated group of conditions that demonstrate developmental alterations in the structure of the enamel in the absence of a systemic disorder or syndrome. Box 2.1 (see page 52) lists several systemic diseases associated with enamel disorders that are not considered isolated amelogenesis imperfecta. Although the definition of amelogenesis imperfecta excludes any association with a syndrome, a number of other dental anomalies are accepted within the spectrum of the disease: pulpal calcification, taurodontism, delayed eruption, gingival overgrowth, open-bite malocclusion, and rarely prognathism.

The formation of enamel is a multistep process, and problems may arise in any one of the steps. In general, the development of enamel can be divided into three major stages:

1. Secretory phase
2. Transition phase
3. Maturation phase

Enamel formation begins with secretion of a protein matrix in which immature hydroxyapatite crystals are deposited. The protein matrix subsequently is degraded and replaced almost completely with inorganic hydroxyapatite. During the secretory phase, the soft protein matrix is deposited. During the transition phase, the matrix deposition achieves the thickness of the final enamel, and the ameloblasts begin to undergo alterations that support the upcoming maturation of the enamel. In the final maturation stage, the protein matrix is degraded into a tissue fluid by proteases as the ameloblasts transport mineral ions into the fluid, leading to the growth of enamel crystals. During this time, the enamel becomes progressively more mineralized until the initial protein matrix is removed almost completely.

The nonsyndromic hereditary defects of the enamel formation are divided into two major patterns: hypoplastic, and hypomineralized. **Hypoplastic amelogenesis imperfecta** is characterized by inadequate deposition of the enamel matrix, which leads to deficient enamel development in the form of surface pits to thinned enamel to complete absence of enamel. **Hypomineralized amelogenesis imperfecta** presents with enamel of normal thickness that is weak and breaks down more rapidly. This pattern can be further subdivided into two presentations: **hypomaturation amelogenesis imperfecta** (characterized by incomplete protein removal resulting in brittle enamel) and **hypocalcified amelogenesis imperfecta** (characterized by insufficient calcium deposition leading to soft enamel that can be removed easily). Use of this classification often is problematic since clinical application of the terminology can be difficult due to mixed phenotypes.

An ideal classification system for amelogenesis imperfecta has not been established yet. Witkop's classification (Table 2.1) remains the most widely accepted and relies on the phenotype (clinical appearance) and the inheritance

TABLE 2.1 Classification of Amelogenesis Imperfecta

Type	Pattern	Specific Features	Inheritance
IA	Hypoplastic	Generalized pitted	Autosomal dominant
IB	Hypoplastic	Localized pitted	Autosomal dominant
IC	Hypoplastic	Localized pitted	Autosomal recessive
ID	Hypoplastic	Diffuse smooth	Autosomal dominant
IE	Hypoplastic	Diffuse smooth	X-linked dominant
IF	Hypoplastic	Diffuse rough	Autosomal dominant
IG	Hypoplastic	Enamel agenesis	Autosomal recessive
IIA	Hypomaturation	Diffuse pigmented	Autosomal recessive
IIB	Hypomaturation	Diffuse	X-linked recessive
IIC	Hypomaturation	Snow-capped	X-linked
IID	Hypomaturation	Snow-capped	Autosomal dominant?
IIIA	Hypocalcified	Diffuse	Autosomal dominant
IIIB	Hypocalcified	Diffuse	Autosomal recessive
IVA	Hypomaturation-hypoplastic	Taurodontism present	Autosomal dominant
IVB	Hypoplastic-hypomaturation	Taurodontism present	Autosomal dominant

dentlearn.ir

pattern. Classification by clinical appearance is problematic, because different phenotypes have been noted within a single affected family. In addition, similar phenotypes may be seen in individuals with very different molecular patterns of disease.

Although the molecular basis underlying many patterns of amelogenesis imperfecta remains poorly defined, the genetics associated with several variations of amelogenesis imperfecta has been clarified. This has led investigators to suggest a future classification system based primarily on the mode of inheritance with secondary discriminators that include the phenotype, molecular genetic basis (site and type of chromosomal mutation, when known), and the biochemical result (protein affected, when known). Although much remains to be discovered, the information necessary for this new classification system is accumulating rapidly, with movement to this new pattern of classification being inevitable.

Whole-genome sequencing (WGS) and whole-exome sequencing (WES) are being replaced by next-generation sequencing (NGS), which has better molecular coverage, a cheaper cost, and greater ease in interpreting the results. NGS has benefitted researchers interested in amelogenesis imperfecta. During the time between the fourth and fifth editions of this text, the number of well-recognized altered genes associated with nonsyndromic AI increased from 7 to 16. Almost certainly, the number will continue to increase as NGS becomes a more standardized tool in research and clinical practice.

Table 2.2 attempts to associate these mutations with their associated phenotypic presentations.

TABLE 2.2 Modified Classification of Amelogenesis Imperfecta

Related Genes	Inheritance	Phenotype
AMELX	X-linked recessive	Heterozygous females: stripes of normal and affected enamel Males: hypomaturation or diffuse smooth hypoplastic
ENAM	Autosomal dominant	Diffuse smooth hypoplastic
ENAM	Autosomal dominant	Localized hypoplastic
ENAM	Autosomal recessive	Homozygotes: Diffuse hypoplastic Heterozygotes: Localized hypoplastic
AMBN	Autosomal recessive	Diffuse hypoplastic
MMP20	Autosomal recessive	Diffuse hypomaturation
KLK4	Autosomal recessive	Diffuse hypomaturation
ITGB6	Autosomal recessive	Hypomineralized/pitted hypoplastic
ITGB6	Autosomal recessive	Diffuse rough hypoplastic

dentlearn.ir

The altered genes may be grouped into those that affect enamel proteins (*AMELX*, *ENAM*, *AMBN*), enamel matrix proteases (*MMP20*, *KLK4*), cell-cell and cell-matrix adhesion (*ITGB6, LAMA3*, *LAMB3*, *COL17A1*, *AMTN*, *FAM83H*), matrix or ion transport (*WDR72*, *SLC24A4*), pH sensing (*GPR68*), crystal nucleation (*C4orf26*), control of gene expression (*FAM20A*, *DLX3*) and genes with unknown function (*ACPT*). In a study over 270 families with AI, just four genes were responsible for over 60% of all cases: *FAM83H*, *FAM20A*, *ENAM*, and *AMELX*.

Several genes deserve additional comment. *LAMA3*, *LAMB3*, and *COL17A1* are associated with autosomal recessive junctional epidermolysis bullosa. Heterozygous carriers sometimes have AI without evidence of any skin alterations, whereas the homozygous individuals would present with skin lesions and not be included in the nonsyndromic patterns of AI. Additionally, different mutations of *FAM20A* have been shown to cause not only AI but also gingival fibromatosis (see page 158) and enamel renal syndrome. Finally, various mutations of *DLX3* can cause nonsyndromic AI or tricho-dento-osseous syndrome (see page 103).

Clinical and Radiographic Features

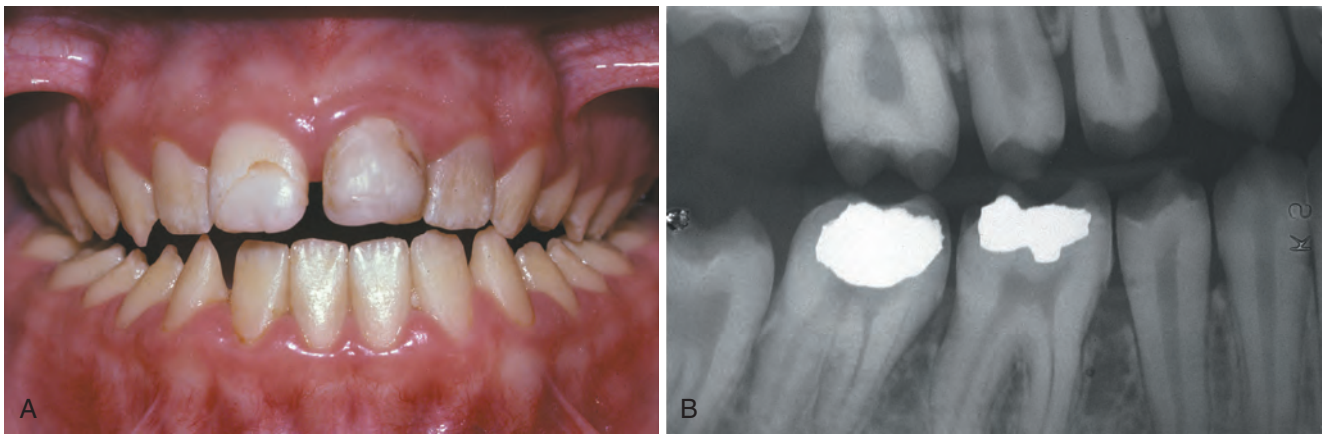
Amelogenesis imperfecta may be inherited as an autosomal dominant, autosomal recessive, or X-linked disorder, with both the deciduous and the permanent dentitions diffusely involved in the vast majority. Due to differing gene pools, the rate of occurrence varies geographically with a prevalence of 1:700 in Sweden and a frequency in the United States of 1:14,000.

Hypoplastic Amelogenesis Imperfecta

In patients with hypoplastic amelogenesis imperfecta, the basic alteration centers on inadequate deposition of enamel matrix. Any matrix present is mineralized appropriately and radiographically contrasts well with the underlying dentin. In the **generalized pattern,** pinpoint-to-pinhead–sized pits are scattered across the surface of the teeth and do not correlate with a pattern of environmental damage (Fig. 2.94). The buccal surfaces of the teeth are affected more severely, and the pits may be arranged in rows or columns. Staining of the pits may occur. Variable expressivity is seen within groups of affected patients. The enamel between the pits is of normal thickness, hardness, and coloration.

In the **localized pattern,** the affected teeth demonstrate horizontal rows of pits, a linear depression, or one large area of hypoplastic enamel. Typically, the altered area is located in the middle third of the buccal surfaces of the teeth. The incisal edge or occlusal surface usually is not affected. Both dentitions or only the primary teeth may be affected. All of the teeth may be altered or only scattered teeth may be affected. When the involvement is not diffuse, the pattern of affected teeth does not correlate with a specific time in development. The autosomal recessive type is more severe and typically demonstrates involvement of all teeth in both dentitions.

In Witkop's phenotypic classification, amelogenesis imperfecta with diffusely reduced enamel thickness was subclassified as *smooth*, *rough,* and *enamel agenesis.* For many researchers, this separation is difficult in various kindreds; therefore, these phenotypic patterns have been merged by many into one category, **generalized thin hypoplastic amelogenesis imperfecta.**



In the **generalized thin variants,** the enamel is extremely thin with teeth that are shaped like crown preparations and demonstrate open contact points. The surface texture varies from smooth with or without shallow grooves to rough with or without scattered pits (Figs. 2.95 and 2.96). The color of the teeth varies from opaque white to yellow to brown. Anterior open bite is not rare. Radiographically, a thin peripheral outline of radiopaque enamel will be noted on many teeth. Often, unerupted teeth exhibiting resorption are seen.

The X-linked patterns of generalized thin amelogenesis imperfecta are a lesson in the lyonization effect. On approximately the sixteenth day of embryonic life in all individuals with two X chromosomes, one member of the pair is

inactivated in each cell. As a result of this event, females are mosaics, with a mixture of cells, some with active maternal X chromosomes and others with active paternal X chromosomes. Usually, the mix is of approximately equal proportions. If one X were to direct the formation of defective enamel and the other X were to form normal enamel, then the teeth would exhibit alternating zones of normal and abnormal enamel. Hemizygous males exhibit diffuse thin enamel in both dentitions. On the other hand, heterozygous females exhibit vertical furrows of thin hypoplastic enamel alternating between bands of normal thickness. The banding often is detectable with dental radiographs.

Hypomaturation and Hypocalcification Variants of Amelogenesis Imperfecta (Hypomineralization Amelogenesis Imperfecta)

Classically, the hypomaturation pattern is associated with enamel that chips and fractures easily but does not demonstrate massive loss upon eruption. In contrast, the hypocalcification pattern has been associated with "cheesy" enamel that is lost rapidly and diffusely except for a residual band in the cervical portion of the teeth. In reality, the distinction is hazy with a spectrum of enamel quality encountered. At the ends of the spectrum, the separation between hypomaturation and hypocalcification can be made easily; however, the center of the spectrum contains numerous patterns that are difficult to classify on a phenotypic basis. For this reason, many investigators prefer the term **hypomineralization amelogenesis imperfecta** for both variants.

Prior to eruption, both forms of hypomineralization AI radiographically demonstrate enamel of normal thickness with a radiodensity that is similar to dentin. In a person with **hypomaturation amelogenesis imperfecta,** the affected teeth are normal in shape but exhibit white opaque enamel that may reveal areas of mottling. Upon eruption, variable degrees of brown discoloration and enamel chipping are seen. The presentation may closely resemble dental fluorosis, making definitive diagnosis difficult in many patients. On

dentlearn.ir

• **Fig. 2.97 Hypomaturation Amelogenesis Imperfecta, X-Linked. A,** Male patient exhibiting diffuse yellow-white dentition. **B,** The patient's mother exhibits vertical bands of white, opaque enamel and translucent enamel. (Courtesy of Dr. Carlos Salinas.)

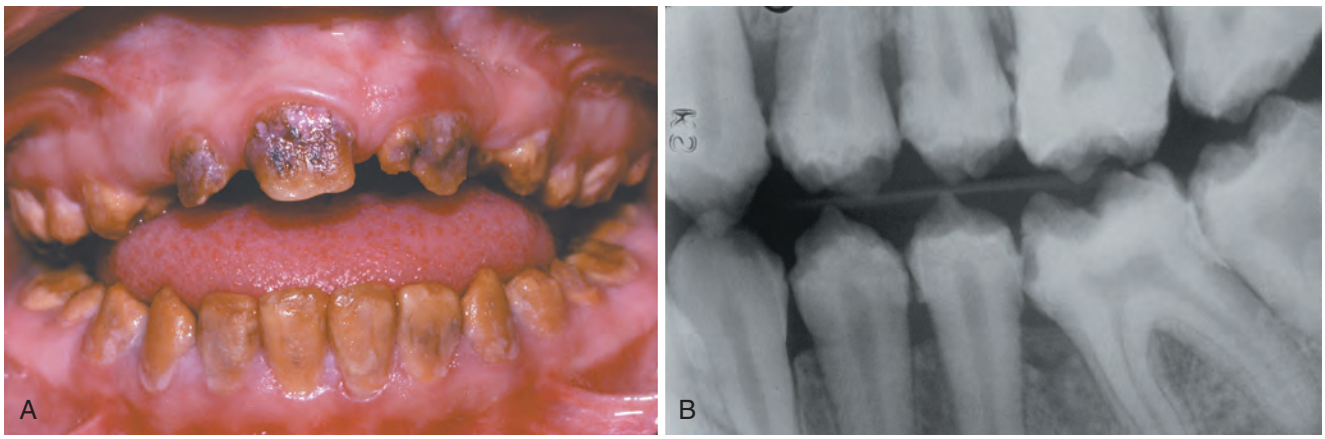
occasion, fluorosis may demonstrate horizontal white banding that corresponds to periods of increased fluoride intake. If present, a chronological distribution also is helpful in interpreting the clinical appearance (such as sparing of the deciduous dentition or premolars and second molars [see Fig. 2.11, page 57]).

In the **pigmented hypomaturation pattern,** the surface enamel is mottled and agar-brown. The enamel often fractures from the underlying dentin and is soft enough to be punctured by a dental explorer. Anterior open bite and unerupted teeth exhibiting resorption are uncommon. Occasionally, the surface enamel may be affected severely and be similar in softness to that of hypocalcified patterns with rapid enamel loss upon eruption. These cases often demonstrate extensive calculus deposition. A combined hypomaturation and hypoplastic phenotype can be seen, but posteruption enamel loss can complicate classification.

The **X-linked hypomaturation pattern** is another lesson in lyonization; however, the lyonization is not as obvious as that seen in the X-linked hypoplastic pattern. Affected males exhibit different patterns in the deciduous and permanent dentitions. The deciduous teeth are opaque white with a translucent mottling, whereas the permanent teeth are opaque yellow and may darken with age (Fig. 2.97A). Heterozygous females exhibit a similar pattern in both dentitions. The teeth demonstrate vertical bands of white opaque enamel and translucent enamel; the bands are random and asymmetric (see Fig. 2.97B). The banding can be seen under regular lighting but is more obvious with transillumination.

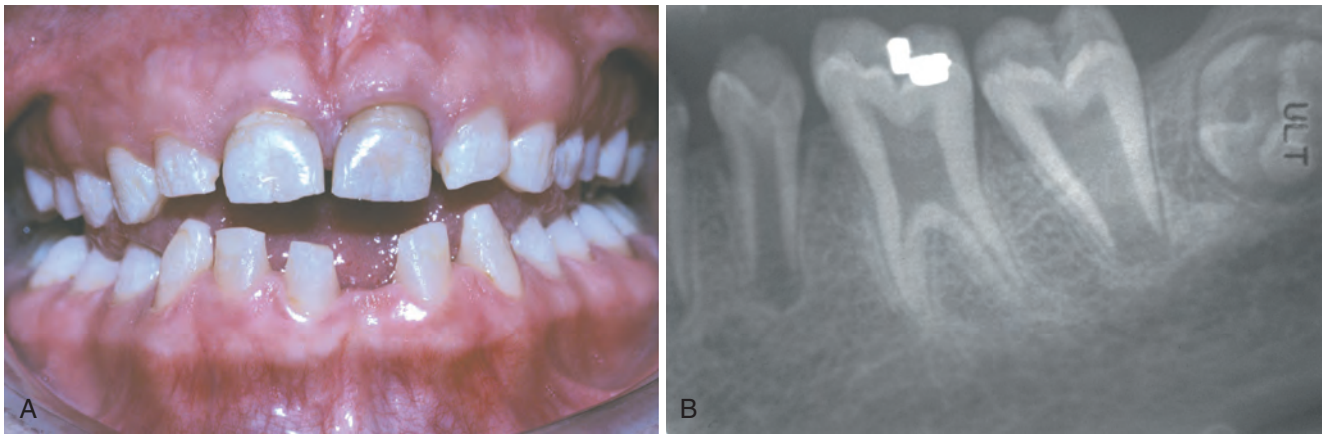
• **Fig. 2.98 Hypomaturation Amelogenesis Imperfecta, Snow-Capped Pattern.** Dentition exhibiting zone of white opaque enamel in the incisal and occlusal one-fourth of the enamel surface. (Courtesy of Dr. Heddie O. Sedano.)

The **snow-capped hypomaturation patterns** exhibit a zone of white opaque enamel on the incisal or occlusal one-quarter to one-third of the crown (Fig. 2.98). The altered areas do not exhibit a distribution that would support an environmental origin, and the surface lacks the iridescent sheen seen with mild fluorosis. The affected teeth often demonstrate an anterior-to-posterior distribution and have been compared with a denture dipped in white paint (only affected anteriors, the anteriors back to the bicuspids, or the anteriors back to the molars). Both the deciduous and the permanent dentitions are affected.



In **hypocalcified amelogenesis imperfecta,** the teeth are appropriately shaped on eruption, but the enamel is very soft and easily lost. On eruption, the enamel is yellow-brown or orange, but it often becomes stained brown to black and exhibits rapid calculus apposition (Fig. 2.99). With years of function much of the coronal enamel is removed, except for the cervical portion that is occasionally calcified better. Unerupted teeth and anterior open bite are not rare.

Amelogenesis Imperfecta with Taurodontism (Hypomaturation/Hypoplastic Amelogenesis Imperfecta)



This type of amelogenesis imperfecta exhibits enamel hypoplasia in combination with hypomaturation. The deciduous and the permanent dentitions are involved diffusely. Historically, two patterns have been recognized that are similar but differentiated by the thickness of the enamel and the overall tooth size. When studying a single kindred, phenotypic variation is seen that would place members of the same family in both divisions; therefore, many believe these divisions should be joined into one phenotype termed merely **amelogenesis imperfecta with taurodontism.**

In the presentation known as the **hypomaturation-hypoplastic pattern,** the predominant defect is one of enamel hypomaturation in which the enamel appears as

dentlearn.ir

• **Fig. 2.99 Hypocalcified Amelogenesis Imperfecta. A,** Dentition exhibiting diffuse yellow-brown discoloration. Note numerous teeth with loss of coronal enamel except for the cervical portion. **B,** Radiograph of the same patient. Note the extensive loss of coronal enamel and the similar density of enamel and dentin.

• **Fig. 2.100 Tricho-Dento-Osseous Syndrome. A,** Dentition exhibiting diffuse enamel hypoplasia and hypomaturation. At birth, the patient exhibited a kinky "steel wool" texture to her hair; with time, the hair straightened. A high index of suspicion was required to arrive at the diagnosis. **B,** Radiograph of the same patient showing significant taurodontism of the first molar and thin enamel, which is similar in density to the dentin.

mottled yellow-white to yellow-brown. Pits are seen frequently on the buccal surfaces of the teeth. Radiographically, the enamel appears similar to dentin in density, and large pulp chambers may be seen in single-rooted teeth in addition to varying degrees of taurodontism.

In the **hypoplastic-hypomaturation pattern,** the predominant defect is one of enamel hypoplasia in which the enamel is thin but also hypomature. Except for the decrease in the thickness of the enamel, this pattern is radiographically similar to the hypomaturation-hypoplastic variant.

A pattern of teeth alteration similar to amelogenesis imperfecta with taurodontism is seen in the systemic disorder, **tricho-dento-osseous syndrome.** This autosomal dominant disorder is mentioned here because the diagnosis may not be readily apparent without a high index of suspicion (Fig. 2.100). In addition to the dental findings, the predominant systemic changes are present variably and include kinky hair, osteosclerosis, and brittle nails. The kinky hair is present at birth but may straighten with age. The osteosclerosis primarily affects the base of the skull and the mastoid process. The mandible often exhibits a shortened ramus and an obtuse angle.

Histopathologic Features

The histopathologic alterations present in amelogenesis imperfecta are not evident in routine preparations. Because decalcification of the teeth is necessary before processing to allow sectioning of paraffin-embedded specimens, all of the enamel is lost. To examine the enamel structure of altered teeth, ground sections of nondecalcified specimens are prepared. The alterations discovered are highly diverse and vary with each clinical type of amelogenesis imperfecta. Detailed descriptions of such alterations were provided by Witkop and Sauk.

dentlearn.ir

Treatment and Prognosis

The clinical implications of amelogenesis imperfecta vary according to the subtype and its severity, but the main problems are aesthetics, dental sensitivity, and loss of vertical dimension. In addition, in some types of amelogenesis imperfecta there is an increased prevalence of caries, anterior open bite, delayed eruption, tooth impaction, or associated gingival inflammation.

Patients with generalized thin enamel hypoplasia demonstrate minimal normal enamel associated with rapid attrition. These variants require full coverage as soon as is practical; if the treatment is delayed, a loss of usable crown length occurs. In the deciduous dentition, stainless steel or composite crowns are appropriate, whereas all-ceramic materials are good choices for the permanent dentition. In young patients without sufficient crown lengths, full dentures (overdentures in some cases) often become the only satisfactory approach until the completion of skeletal growth allows placement of implant-supported prostheses.

The other types of amelogenesis imperfecta demonstrate less rapid tooth loss, and the aesthetic appearance often is the prime consideration. Many less severe cases can be improved by the placement of full crowns or facial veneers on cosmetically objectionable teeth. Problems with bonding restorations to the altered enamel may be overcome by the use of glass ionomer cements with dentinal adhesives.

Generalized delayed eruption and impaction of teeth affected by generalized thin hypoplastic amelogenesis imperfecta has been identified as a component of a very rare condition known as **enamel-renal syndrome** characterized by *FAM20A* mutations, nephrocalcinosis, and sometimes renal failure. The renal changes often are not clinically overt, and mortality associated with renal failure has been reported in affected patients. Such patients should be referred for renal evaluation.

HEREDITARY DISORDERS OF DENTIN

Hereditary disorders of dentin can occur in association with a number of syndromes or arise as an isolated disorder of teeth with no systemic manifestations. Osteogenesis imperfecta is the syndrome most frequently associated with dental manifestations that mimic dentinogenesis imperfecta, but Ehlers-Danlos syndrome, Goldblatt syndrome, and Schimke immuno-osseous dysplasia also have been associated with similar dental changes. In addition, sporadic reports of patients with dentinogenesis imperfecta–like alterations as part of an obviously systemic, but as yet undefined, syndrome have been noted. In addition to a dentinogenesis imperfecta–like phenotype, a variety of other dentin abnormalities have been noted in vitamin-D resistant rickets, vitamin-D dependent rickets, tumoral calcinosis, and calcinosis universalis. The following section concentrates on the nonsyndromic disorders of dentin.

Mature dentin is about 70% mineral, 20% organic matrix, and 10% water. About 85%–90% of the organic matrix is type I collagen, with two genes intimately involved in its production: *COL1A1* and *COL1A2.* The most abundant noncollagenous proteins in dentin are derived from dentin sialophosphoprotein (DSPP) that is cleaved to form three important dentin proteins: dentin sialoprotein (DSP), dentin glycoprotein (DGP), and dentin phosphoprotein (DPP). The primary gene guiding the formation of these proteins is the *DSPP* gene.

Dentinogenesis imperfecta (DGI) is a hereditary developmental disturbance of the dentin in the absence of any systemic disorder and has been shown to be associated with any one of 40 mutations of the *DSPP* gene. Similar dental changes can be seen in conjunction with the systemic hereditary disorder of bone, **osteogenesis imperfecta** (see page 618); but genetic studies have shown that the dental alterations are related to mutations in the *COL1A1* and *COL1A2* genes. Extensive pedigrees of individuals with DSPP-related dentinogenesis imperfecta have been studied, and none have exhibited other changes suggestive of osteogenesis imperfecta. This groundbreaking research has confirmed that osteogenesis imperfecta with opalescent teeth is clearly a separate disease from dentinogenesis imperfecta and should be removed from the classification of dentinogenesis imperfecta.

The classification of hereditary dentin disorders is much less complicated compared to the classification of amelogenesis imperfecta. However, the most widely used systems for classification of hereditary dentin disorders, one by Witkop and the other by Shields, remain widely is use, but in light of current knowledge, appear to be archaic (Table 2.3). Recent advances in genetics have made the Shields nomenclature problematic. The Online Mendelian Inheritance of Man (OMIM) database is the most current classification system for the molecular genetics of human pathoses. In the MIM system, dentinogenesis imperfecta type I as defined by the original Shield's classification (DGI-I) has been removed from the list of DGI and is classified appropriately as *osteogenesis imperfecta.* DGI-II has become DGI-I, whereas DGI-III and the dentin dysplasias (dentin dysplasia type I

TABLE 2.3 Dentinogenesis Imperfecta, Classical Nomenclature

Shields	Clinical Presentation	Witkop
Dentinogenesis imperfecta I	Osteogenesis imperfecta with opalescent teeth	Dentinogenesis imperfecta
Dentinogenesis imperfecta II	Isolated opalescent teeth with pulpal obliteration	Hereditary opalescent teeth
Dentinogenesis imperfecta III	Isolated opalescent teeth with shell teeth	Brandywine isolate

Data from Shields ED: A new classification of heritable human enamel defects and a discussion of dentin defects. In Jorgenson RJ, Paul NW, editor: *Dentition: genetic effects (birth defects original article series)*, no 1, New York, 1983, Alan R Liss, pp. 107–127, vol 19; Witkop CJ Jr.: Amelogenesis imperfecta, dentinogenesis imperfecta and dentin dysplasia revisited: problems in classification, *J Oral Pathol* 17:547–553, 1988.

dentlearn.ir

[DD-I] and dentin dysplasia type II [DD-II]) have retained their previous names. The Shields and OMIM systems currently are contradictory, resulting in confusion with respect to the definition of dentinogenesis imperfecta type I.

Dentinogenesis imperfecta formerly was divided into DGI-II (*hereditary opalescent dentin*) and DGI-III (*Brandywine isolate*). The defining phenotypic feature of the Brandywine isolate was the presence of unusual pulpal enlargement known as *shell teeth* with multiple pulp exposures seen primarily in the deciduous teeth. Current evidence has proven that DGI-III simply represents variable expression of dentinogenesis imperfecta. The original review of the isolate identified only 8% of the kindred with shell teeth. Investigators have documented enlarged pulps in affected individuals whose parents and children have classic dentinogenesis imperfecta. Identical patterns of expression also have been seen in other large kindreds with no connection to the Brandywine isolate. Finally, identical mutations of the *DSPP* gene have been shown to manifest as DGI-II and DGI-III in different families and in different members of the same family. It seems very clear that *dentinogenesis imperfecta type II* and *dentinogenesis imperfecta type III* represent a single disease with variable expressions.

The confusion does not end with DGI-II/III controversy. As mentioned, 40 different mutations of the *DSPP* gene have been discovered in patients of different ethnicities. Of these, 17 mutations affect the DSP region, whereas 23 variants involve the DPP region. No mutation of the DGP region has been discovered. In patients with DGI-II that are associated with mutation of DPP, the posterior region of the gene is altered. Numerous investigators have shown that DD-II arises from modification of the exact same gene but from alteration of the anterior region of the DPP. This clearly indicates that DD-II is allelic to DGI and not a separate disorder. With that understanding, DD-II, DGI-II, and DGI-III appear to represent a spectrum of the same disease, with DD-II being the mild end of the continuum and DGI-III representing the severe end. In a long overdue review of the outdated nomenclature systems, de La Dure-Molla proposed an updated classification system similar to the pattern utilized in the third edition of this text (Table 2.4). In this system, osteogenesis imperfecta with opalescent teeth is removed from the classification of dentinogenesis imperfecta, and the old DD-II, DGI-II, and DGI-III are designated as mild, moderate, and severe forms of DGI.

TABLE 2.4 Modified Classification of Hereditary Disorders Affecting Dentin

DENTIN SIALOPHOSPHOPROTEIN–ASSOCIATED DENTIN DEFECTS

Clinical and Radiographic Features

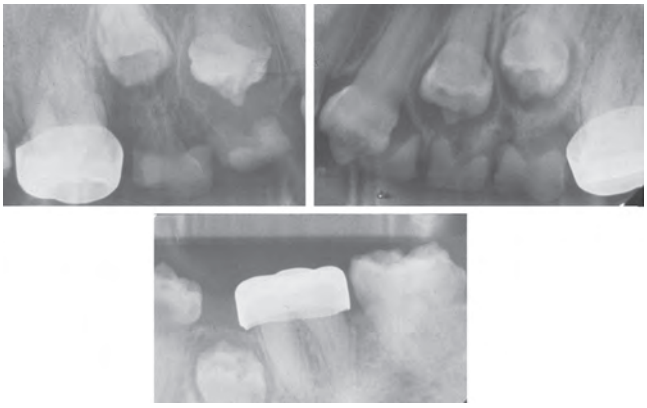
As the nomenclature of DSPP-associated dentin defects evolves, it is expected that the diseases will be listed in the order of phenotypic severity from the mildest to most severe (DD-II, DGI-II, and DGI-III). In spite of this, these disorders are described most efficiently when DGI-II is presented first.

The prevalence of **dentinogenesis imperfecta** (hereditary opalescent dentin, Capdepont's teeth) is not distributed randomly throughout the United States and Europe. Most cases can be traced to whites (people of English or French ancestry) from communities close to the English Channel. The disorder is autosomal dominant and occurs in about 1:8000 whites in the United States. However, the condition is not limited to any race or geographic location.

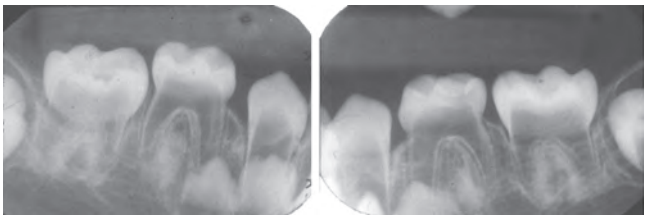
Dentinogenesis imperfecta affects teeth in both dentitions with the severity of the dental alterations varying with the age at which the tooth develops. Deciduous teeth are affected most severely, followed by the permanent incisors and first molars, with the second and third molars being least altered.

The dentitions are discolored, often with a distinctive translucence (Fig. 2.101). The color varies from yellow-brown to light-brown to grayish-blue. Often, the color demonstrates minimal variation within a family but varies significantly among different families. The enamel fractures easily and frequently separates from the underlying defective

dentlearn.ir



• **Fig. 2.102 Dentinogenesis Imperfecta (DGI), Moderate Form.** Dentition exhibiting grayish discoloration with significant enamel loss and attrition.



• **Fig. 2.103 Dentinogenesis Imperfecta (DGI), Moderate Form.** Radiograph of dentition exhibiting bulbous crowns, cervical constriction, and obliterated pulp canals and chambers.

dentin. Once exposed, the dentin often demonstrates significantly accelerated attrition (Fig. 2.102). Radiographically, the teeth have bulbous crowns, cervical constriction, and thin roots. In the **moderate form of DGI**, the pulp chambers and canals initially are very large but demonstrate rapid obliteration upon eruption (Fig. 2.103). Although the pulp appears totally obliterated, a network of interconnected vessels remains and can lead to periapical inflammatory disease when coronal vessels are invaded by bacteria in areas of exposed dentin. The deciduous teeth develop periapical inflammatory disease more often, possibly caused by advanced attrition secondary to thinner enamel.

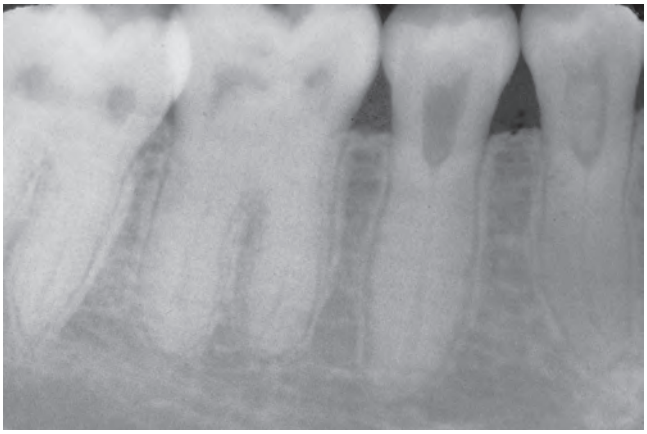
The trait exhibits close to 100% penetrance but variable expressivity. Clinically obvious enamel hypoplasia is noted in some patients (Fig. 2.104). During the initial development of the dentinoenamel junction (DEJ), there is a temporary expression of enamel proteins by odontoblasts and a similar expression of dentin proteins by pre-ameloblasts. Some investigators have suggested that the enamel hypoplasia may be secondary to expression of mutant DSPP protein by pre-ameloblasts during the early formative stage of the DEJ.

• **Fig. 2.104 Dentinogenesis Imperfecta (DGI), Severe Form.** Radiograph of dentition exhibiting bulbous crowns, early obliteration of the pulp, and enamel hypoplasia. (From Levin LS, Leaf SH, Jelmine RJ, et al: Dentinogenesis imperfecta in the Brandywine isolate (DI type III): clinical, radiologic, and scanning electron microscopic studies of the dentition, *Oral Surg Oral Med Oral Pathol* 56:267–274, 1983.)

• **Fig. 2.105 Shell Teeth.** Dentition exhibiting normal thickness enamel, extremely thin dentin, and dramatically enlarged pulps.

Although the pulps usually are obliterated by excess dentin production, the teeth in the **severe form of DGI** (shell teeth) demonstrate significant pulpal enlargement with normal-thickness enamel in association with extremely thin dentin and dramatically enlarged pulps (Fig. 2.105). The thin dentin may involve the entire tooth or be isolated to the root. Shell teeth have been seen most frequently in deciduous teeth in the setting of dentinogenesis imperfecta and the affected teeth often are associated with pulp exposures.

Shell teeth may be unassociated with dentinogenesis imperfecta as an isolated finding in both dentitions with normal tooth shape and coloration, a negative family history, and diffuse involvement. In this unrelated isolated variant, slow but progressive root resorption often occurs.



Several kindreds affected with dentinogenesis imperfecta also have been shown to demonstrate progressive, sensorineural, high-frequency hearing loss. Jaw position has been shown to affect the anatomy of the inner ear, and premature tooth loss has been associated with hearing deficits. At this time, it is unclear if the hearing loss is correlated with the *DSPP* mutation or represents an alteration secondary to the primary gnathic changes. All patients with dentinogenesis imperfecta should be evaluated for hearing loss.

The **mild form of Dentinogenesis imperfecta (dentin dysplasia type II; DD-II; coronal dentin dysplasia)** has dramatically different appearances in the primary and succedaneous dentitions. The primary teeth have a blue-

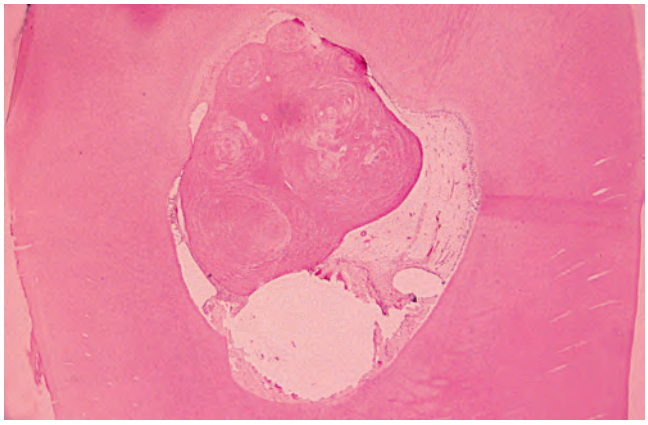
• **Fig. 2.107 Dentinogenesis Imperfecta, Mild Form.** Radiographic appearance of the permanent dentition exhibiting thistle tube–shaped enlargements of the pulp chambers and numerous pulp stones.

to-amber-to-brown translucence, similar to classic dentinogenesis imperfecta (Fig. 2.106). Radiographically, the dental changes include bulbous crowns, cervical constriction, thin roots, and early obliteration of the pulp. The permanent teeth have a normal color clinically; however, radiographically, the pulp chambers exhibit significant enlargement and apical extension. These enlarged pulp chambers have been described as *thistle tube–shaped* or *flame-shaped* (Fig. 2.107). Pulp stones develop in the enlarged pulp chambers.



A similar but unrelated disorder is **pulpal dysplasia.** This process develops in teeth that are normal clinically. Radiographically, both dentitions exhibit thistle tube–shaped pulp chambers and multiple pulp stones.

Histopathologic Features

In dentinogenesis imperfecta, the dentin adjacent to the enamel junction appears similar to normal dentin, but the remainder is distinctly abnormal. Short misshapen tubules

• **Fig. 2.108 Dentinogenesis Imperfecta (DGI).** Coronal dentin exhibiting short misshapen tubules within atypical granular dentin matrix.

• **Fig. 2.109 Dentinogenesis Imperfecta, Mild Form.** Affected permanent tooth exhibiting large pulp stone within the pulp chamber.

course through an atypical granular dentin matrix, which often demonstrates interglobular calcification (Fig. 2.108). Scanty atypical odontoblasts line the pulp surface, and cells can be seen entrapped within the defective dentin. In ground sections the enamel is normal in most patients; however, about one-third of the patients have hypoplastic or hypocalcified defects.

In patients with the mild form of dentinogenesis imperfecta (formerly known as dentin dysplasia type II), the deciduous teeth demonstrate the same pattern noted in the moderate form. However, the permanent teeth exhibit normal enamel and coronal dentin. Adjacent to the pulp, numerous areas of interglobular dentin are seen. The radicular dentin is atubular, amorphous, and hypertrophic. Pulp stones develop in any portion of the chamber (Fig. 2.109).

Treatment and Prognosis

In dentinogenesis imperfecta, the entire dentition is at risk because of numerous problems. The root canals become threadlike and may develop microexposures, resulting in periapical inflammatory lesions. Despite the risk of enamel loss and significant attrition, the teeth often are not good

dentlearn.ir

candidates for full crowns because of cervical fracture. The success of full coverage is best in teeth with crowns and roots that exhibit close to a normal shape and size. Overlay dentures placed on teeth that are covered with fluoride-releasing glass ionomer cement have been used with success in some cases.

The success of therapy varies with the severity of the dental changes in individual patients. In those with extensive attrition, the vertical dimension can be rebuilt by placing nonprecious metal castings with adhesive luting agents on teeth that have received no preparation and are not subject to significant occlusal stress. The newer composites combined with a dentin-bonding agent have been used in areas subject to occlusal wear. When large kindreds have been followed over a long term, many of those affected are candidates for full dentures or implants by 30 years of age in spite of the numerous interventions. Newer materials and techniques may alter this outlook.

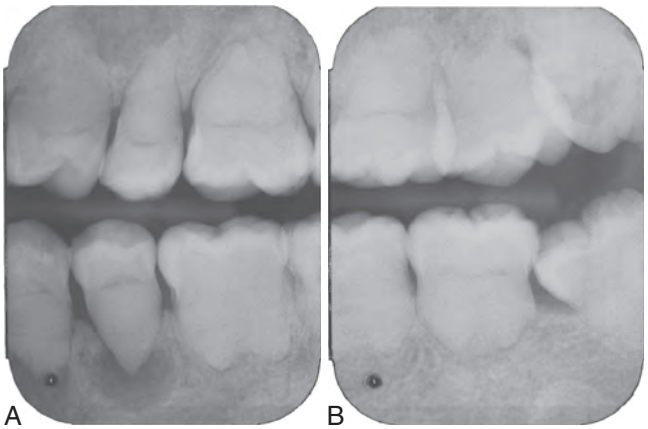
Deciduous teeth in the mild form of dentinogenesis imperfecta ("dentin dysplasia type II") can be approached in a manner similar to that described for the moderate form. Although not frequent, periapical inflammatory lesions have been seen in association with the permanent teeth of some affected patients. Because the pulp canals usually are not obliterated completely, endodontic therapy may be possible.

RADICULAR DENTIN DYSPLASIA (DENTIN DYSPLASIA TYPE I)

Dentin dysplasia was categorized initially in 1939. Historically, two major patterns have been described: type I (radicular dentin dysplasia; DD-I) and type II (coronal dentin dysplasia; DD-II). However, type II has been shown to be a variation of dentinogenesis imperfecta, and the discussion of this condition is included in the previous section. By definition, radicular dentin dysplasia should have no correlation with systemic disease. Systemic diseases reported to be associated with similar dentin changes are listed in Box 2.12.

The genetic changes associated with radicular dentin dysplasia currently are unsettled. Three separate investigations have reported different genes with diverse locations: *SMOC2* on 6q27 (autosomal recessive), *VPS4B* on 18q21.33 (autosomal dominant), and *SSUH2* on 3Q26.1 (autosomal dominant). Two possibilities exist: radicular dentin dysplasia exhibits genetic heterogeneity or several similar but different diseases exist. Subtle differences may be difficult to ascertain in diseases that are rare with so few cases to evaluate. In addition, the small image size in modern publications makes close inspection of these cases most difficult for researchers across the globe to interpret.

• BOX 2.12 Systemic Diseases Correlated With Dentin Dysplasia-Like Alterations



- Calcinosis universalis
- Rheumatoid arthritis and hypervitaminosis D
- Sclerotic bone and skeletal anomalies
- Tumoral calcinosis

Clinical and Radiographic Features

Radicular dentin dysplasia (dentin dysplasia type I; DD-I); has been referred to as **rootless teeth,** because the loss of organization of the root dentin often leads to a shortened root length. Although an autosomal recessive example has been reported, the process typically exhibits an autosomal dominant pattern of inheritance and is one of the rarest forms of human dentin disorders with a prevalence of approximately 1:100,000. The enamel and coronal dentin are normal clinically and well formed (Fig. 2.110), but the radicular dentin loses all organization and subsequently is shortened dramatically (Fig. 2.111). Wide variation in root formation is produced because dentinal disorganization may occur during different stages of tooth development. If the dentin organization is lost early in tooth development,

• Fig. 2.110 Radicular Dentin Dysplasia. Dentition exhibiting attrition but otherwise normal coronal coloration and morphology.

• Fig. 2.111 Radicular Dentin Dysplasia. Posterior dentition exhibiting dramatically shortened roots, absence of pulp canals, and small, crescent-shaped pulp chambers. Note radiolucency at apex of mandibular bicuspid. (Courtesy of Dr. Michael Quinn.)

dentlearn.ir

markedly deficient roots are formed; later disorganization results in minimal root malformation. The variability is most pronounced in permanent teeth and may vary not only from patient to patient but also from tooth to tooth in a single patient. Because of the shortened roots, the initial clinical signs are extreme tooth mobility and premature exfoliation, spontaneously or secondary to minor trauma. Less frequently, delayed eruption is the presenting symptom. The strength of the radicular dentin is reduced, with the teeth being predisposed to fracture during extractions.

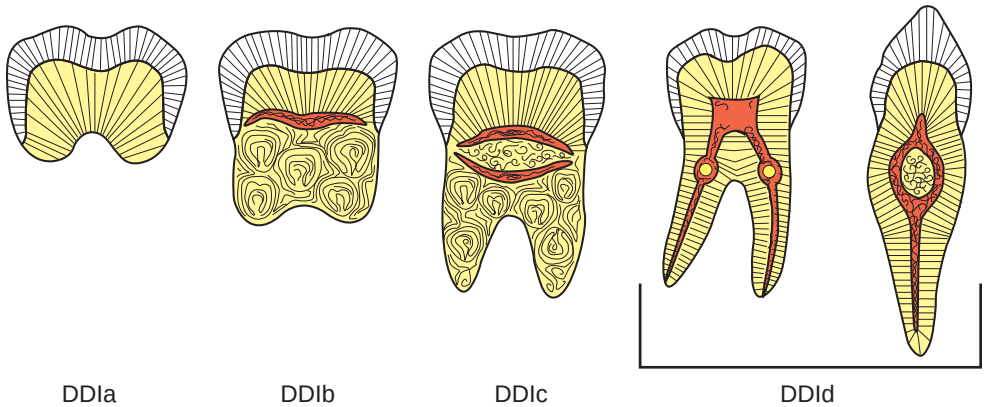
Radiographically, variations in radicular anatomy have been described, and a subclassification of radicular dentin dysplasia has been proposed (Box 2.13; Fig. 2.112). The deciduous teeth often are affected severely, with little or no detectable pulp, and roots that are markedly short or absent (similar to type DDIa). In most patients, the permanent teeth demonstrate short roots with no canals and a small crescent-shaped pulpal remnant parallel of the cementoenamel junction (types DDIb and DDIc). Type DDId is most unusual and should warn the clinician to rule out systemic diseases, such as tumoral calcinosis, that can produce identical changes.

• BOX 2.13 Subclassification of Dentin Dysplasia Type I

- DDIa: No pulp chambers, no root formation, and frequent periapical radiolucencies
- DDIb: A single small horizontally oriented and crescent-shaped pulp, roots only a few millimeters in length, and frequent periapical radiolucencies
- DDIc: Two horizontally oriented and crescent-shaped pulpal remnants surrounding a central island of dentin, significant but shortened root length, and variable periapical radiolucencies
- DDId: Visible pulp chambers and canals, near normal root length, enlarged pulp stones that are located in the coronal portion of the canal and create a localized bulging of the canal and root, constriction of the pulp canal apical to the stone, and few periapical radiolucencies

In general, the teeth without root canals are those that frequently develop periapical radiolucencies without obvious cause (see Fig. 2.111). The radiolucencies represent periapical inflammatory disease and appear secondary to caries or spontaneous coronal exposure of microscopic threads of pulpal remnants present within the defective dentin.

A similar but unrelated disorder is **fibrous dysplasia of dentin.** This autosomal dominant disorder exhibits teeth that are normal clinically. Radiographically the teeth are normal in shape but demonstrate a radiodense product filling the pulp chambers and canals. In contrast to dentinogenesis imperfecta, small foci of radiolucency can be seen in the pulp. Unlike radicular dentin dysplasia, no crescent pulp chambers or decrease in root length is seen. The radiodense intrapulpal material consists of fibrotic dentin.



Histopathologic Features

In patients with radicular dentin dysplasia, the coronal enamel and dentin are normal. Apical to the point of disorganization, the central portion of the root forms whorls of tubular dentin and atypical osteodentin. These whorls exhibit a peripheral layer of normal dentin, giving the root the appearance of a "stream flowing around boulders" (Fig. 2.113).

Treatment and Prognosis

In patients with radicular dentin dysplasia, preventive care is of foremost importance. Perhaps as a result of shortened roots, early loss from periodontitis is frequent. In addition, pulp vascular channels extend close to the dentinoenamel junction; therefore, even shallow occlusal restorations can result in pulpal necrosis. Meticulous oral hygiene must be established and maintained.

If periapical inflammatory lesions develop, the root length guides the therapeutic choice. Conventional endodontic therapy requires mechanical creation of canal paths and has been successful in teeth without extremely short roots. Teeth with short roots demonstrate pulpal ramifications that

• Fig. 2.112 Radicular Dentin Dysplasia. Illustration demonstrating the variability of the radiographic appearance according to the degree of dentin disorganization within the root.

dentlearn.ir

• **Fig. 2.113 Radicular Dentin Dysplasia.** Polarized light view of affected tooth demonstrating a classic "stream flowing around boulders" appearance.

eliminate conventional endodontic treatment as an appropriate therapeutic option. Periapical curettage and retrograde amalgam seals have demonstrated short-term success. In patients with minimal root length, early tooth loss is typical and full dentures or implant-supported prostheses usually become necessary.

REGIONAL ODONTODYSPLASIA (GHOST TEETH)

Regional odontodysplasia is a localized, nonhereditary developmental abnormality of teeth with extensive adverse effects on the formation of enamel, dentin, and pulp. Most cases are idiopathic, but a number have been related to various syndromes, growth abnormalities, neural disorders, and vascular malformations (Box 2.14). A number of causes have been proposed (Box 2.15), but the most popular theory revolves around an alteration in the vascular supply. Several cases have occurred in patients with vascular nevi of the head and neck; in addition, similar changes have been induced in animals by restricting the vascular flow to an area of the jaws.

Clinical and Radiographic Features

Regional odontodysplasia is an uncommon finding that occurs in both dentitions and exhibits no racial predilection and a slight female predominance. A review of the age at the time of diagnosis reveals a bimodal peak that correlates with the normal time of eruption of the deciduous (2–4 years) and permanent (7–11 years) dentitions. Typically, the process affects a focal area of the dentition, with involvement of several contiguous teeth. A maxillary predominance exists with a predilection for the anterior teeth. Occasionally, an unaffected tooth may be intermixed within a row of altered teeth. Ipsilateral involvement of both arches and bilateral changes in the same jaw have been reported. Although rare generalized involvement has been documented, the presence of regional odontodysplasia in more than two quadrants is very uncommon. Involvement of the deciduous dentition typically is followed by similarly affected permanent teeth. In the area of altered teeth, the surrounding bone often exhibits a lower density; in addition, hyperplasia of the soft tissue may be noted overlying affected teeth that are impacted.

Many of the affected teeth fail to erupt. Erupted teeth demonstrate small irregular crowns that are yellow to brown, often with a very rough surface. Caries and associated periapical inflammatory lesions are fairly common. Because of dentinal clefts and very long pulp horns, pulpal necrosis is common (often in the absence of an obvious cause). Radiographically, the altered teeth demonstrate extremely thin enamel and dentin surrounding an enlarged radiolucent pulp, resulting in a pale wispy image of a tooth; hence the term **ghost teeth** (Fig. 2.114). A lack of contrast is seen between the dentin and the enamel, with an indistinct or "fuzzy" appearance of the coronal silhouette. Short roots and open apices may be seen. The enlarged pulps frequently demonstrate one or more prominent pulp stones. The most common presenting signs and symptoms include delayed or

• **Fig. 2.115 Regional Odontodysplasia.** Follicular tissue contains scattered collections of enameloid conglomerates and islands of odontogenic epithelium.

failure of eruption, early exfoliation, abscess formation, malformed teeth, and non-inflammatory gingival enlargement.

Histopathologic Features

In ground sections the thickness of the enamel varies, resulting in an irregular surface. The prism structure of the enamel is irregular or lacking, with a laminated appearance. The dentin contains clefts scattered through a mixture of interglobular dentin and amorphous material. Globular areas of poorly organized tubular dentin and scattered cellular inclusions often are seen. The pulp tissue contains free or attached stones that may exhibit tubules or consist of laminated calcification. The follicular tissue surrounding the crown may be enlarged and typically exhibits focal collections of basophilic enamel-like calcifications called **enameloid conglomerates** (Fig. 2.115). This pattern of calcification is not specific for regional odontodysplasia and has been seen in other processes with disturbed enamel formation, such as amelogenesis imperfecta. Scattered islands of odontogenic epithelium and other patterns of intramural calcification also are seen.

Treatment and Prognosis

Currently no therapeutic consensus exists with respect to management of patients affected by regional odontodysplasia. Careful evaluation of each patient's individual findings is important in order to develop the most appropriate treatment plan. Unerupted teeth should remain untouched, restoring function with a removable partial prosthesis until the skeletal growth period has passed in an effort to prevent atrophy of the alveolar ridge in the affected quadrant. Erupted teeth can be covered with etched-retained restorations or stainless steel crowns until final restorations can be placed after the completion of growth. Because of the fragile nature of the coronal hard tissue and the ease of pulp exposure, tooth preparation is contraindicated. Severely affected and infected teeth often are not salvageable and need to be removed.

Although vitality of the abnormal dentition often is difficult to maintain, such efforts may permit continued dentinal development of teeth affected by regional odontodysplasia. The resultant teeth tend to demonstrate hypoplastic crowns and short roots with more normal appearing canals and well-developed apices.

Following completion of skeletal growth, remaining defective teeth can be removed and replaced with implants. In patients with early loss of severely affected and erupted teeth, significant atrophy of the alveolar ridge can complicate implant placement. In such cases, surgical augmentation of the alveolar process can be used to improve the quality of the site prior to implant placement.

3
Pulpal and Periapical Disease

PULPITIS

Like the brain, the dental pulp is encased in hard tissue that can alter the response to local insults. The surrounding dentin provides rigid mechanical support and protection from the bacteria-rich oral cavity. A focal breach in this barrier can adversely affect the health of the dental pulp. Inflammatory vascular changes increase the pulpal volume, but swelling is restricted due to the surrounding dentinal walls, often triggering pain. Normal pulpal stroma is a resilient gelatin-like material that attempts to localize the increased pressures to the site of damage.

If the inflammatory process is not contained, the dental pulp is uniquely hampered in its response because the only source of vascularity enters through the apical foramen without a collateral blood supply. Upon exposure, the contaminated pulp space acts as a conduit between the oral cavity and the usually sterile alveolar bone. Spread of pulpal infection into bone can lead to serious complications, such as cavernous sinus thrombosis (see page 132), Ludwig angina (see page 132), or systemic sepsis with life-threatening complications. Pulpitis-related pain is an important defense mechanism that can lead to therapeutic intervention prior to serious complications.

Four main types of noxious stimuli are common causes of pulpal inflammation **(pulpitis):**

1. *Mechanical damage:* Mechanical sources of injury include traumatic accidents, iatrogenic damage from dental procedures, attrition, abrasion, and barometric changes.
2. *Thermal injury:* Severe thermal stimuli can be transmitted through large uninsulated metallic restorations or may occur from such dental procedures as cavity preparation, polishing, and exothermic chemical reactions of dental materials.
3. *Chemical irritation:* Chemical-related damage can arise from erosion or from the inappropriate use of acidic dental materials.
4. *Bacterial effects:* Bacteria can damage the pulp through toxins or directly after extension from caries or transportation via the vasculature.

The best classification system for pulpitis is one that guides the appropriate treatment. *Reversible pulpitis* denotes a level of pulpal inflammation in which the tissue is capable of returning to a normal state of health if the noxious stimuli are removed. *Irreversible pulpitis* implies that a higher level of inflammation has developed in which the dental pulp has been damaged beyond the point of recovery. Often, frank invasion by bacteria is the crossover point from reversible to irreversible pulpitis.

Clinical Features

Evaluation of pulpal pain (pulpalgia) includes a combination of the clinical presentation and the response of the tooth to a variety of vitality testing procedures. The predictive value of these tests is sometimes less than optimal. When the procedures demonstrate that the pulp is disease free, the results are highly reliable. However, when a pulp appears to test positively for irreversible pulpitis, histopathologic examination may demonstrate no obvious evidence of pulpal disease. The practitioner should use all available tests, clinical information, and personal judgment in an attempt to arrive at an appropriate diagnosis.

Clinically Normal Pulp

Clinically, a normal pulp exhibits no signs or symptoms that suggest pulpitis. These teeth respond to cold with mild pain that resolves in 1–2 seconds, whereas heat is not associated with pulpal discomfort. Pain to percussion will not be evident, and the radiographic examination of the periradicular bone will be within normal limits.

Reversible Pulpitis

A tooth with **reversible pulpitis** is acutely painful when a stimulus (usually cold or sweet foods, but sometimes heat) is applied, but the discomfort resolves within a few seconds after elimination of the stimulus. Typically, the tooth responds to electric pulp testing at lower levels of current than an appropriate control tooth. Mobility and sensitivity to percussion are absent. A cracked tooth or defective restoration often is present if this pattern of pulpal pain is noted in association with discomfort upon biting. If the pulpitis is allowed to progress, then the duration of the pain on stimulation can become longer and the pulp may become affected irreversibly.

A similar pattern of pulpal pain can occur when exposed dentin receives a thermal, chemical, or physical stimulus. **Dentin sensitivity** should be considered if exposed dentin is present and triggers for reversible pulpitis such as caries, tooth fractures, and defective or newly placed restorations are not present.

dentlearn.ir

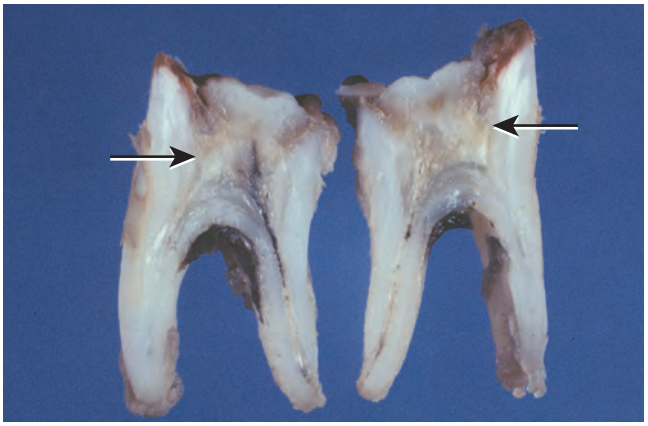
Irreversible Pulpitis

Patients with early **irreversible pulpitis** generally have sharp, severe pain on thermal stimulation, and the pain continues for a longer period of time after the stimulus is removed. Cold is especially uncomfortable, although heat or sweet and acidic foods also can elicit pain. In addition, the pain may be spontaneous or continuous and may be exacerbated when the patient lies down. The tooth responds to electric pulp testing at lower levels of current.

In the early stages of irreversible pulpitis, the pain often can be localized easily to the individual offending tooth; with increasing discomfort, however, the patient may be unable to identify the offending tooth within a quadrant. Although pulpal pain never crosses the midline, it can be referred from arch to arch, making pulp testing of both arches a necessity in difficult cases.

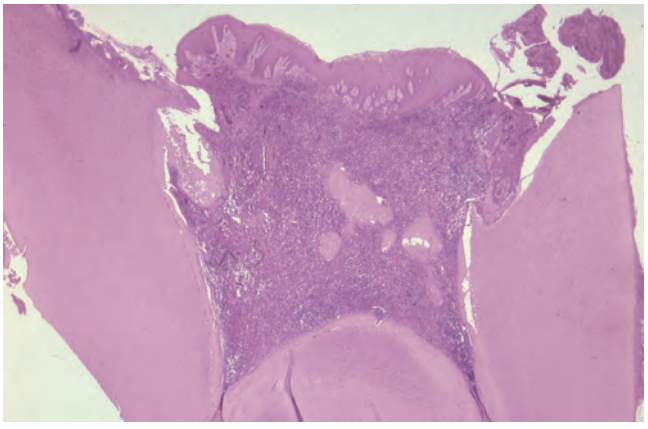
In the later stages of irreversible pulpitis, the pain increases in intensity and is experienced as a throbbing pressure that can keep patients awake at night. At this point, heat increases the pain; however, cold may produce relief. The tooth responds to electric pulp testing at higher levels of current or demonstrates no response. Mobility and sensitivity to percussion usually are absent because significant inflammation has not spread yet to the apical area. If pulpal drainage occurs (e.g., crown fracture, fistula formation), then the symptoms may resolve—only to return if the drainage ceases.

Pulpal Necrosis



Pulpal necrosis should be suspected when the tooth fails to respond to electric or thermal sensitivity testing. Partial pulpal necrosis (pulpal necrobiosis) often occurs and may be isolated to the coronal portion or one canal of a multirooted tooth. Teeth with necrotic pulps present with symptoms that vary from none to acute pain with or without bite sensitivity and hyperocclusion. Diagnosis of pulpal necrosis following tooth trauma often can be problematic due to frequent inaccurate results to electric and thermal pulp tests. These difficulties may arise from the subjective responses required by anxious patients or secondary to nerve damage in pulps with intact blood circulation. Pulse oximetry applied to the injured tooth using a custom stainless steel adapter has shown promise to be a more reliable method for testing pulp vitality over traditional methods.

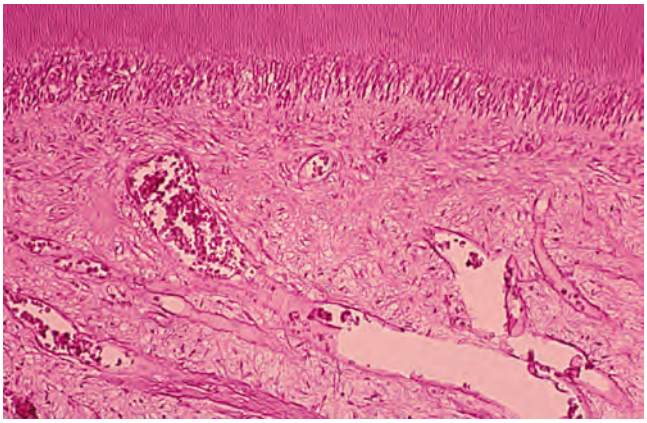
Chronic Hyperplastic Pulpitis



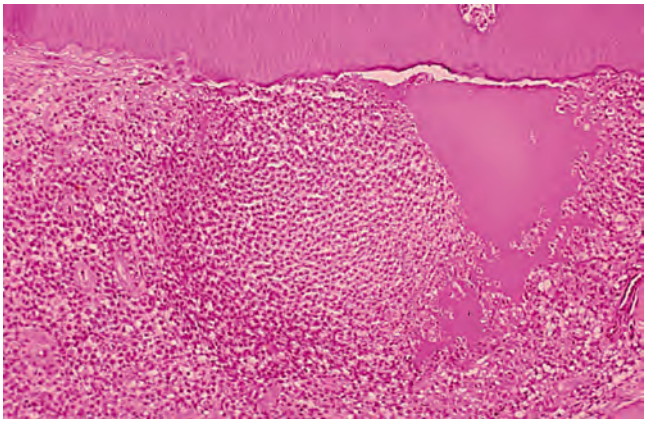
One unique pattern of pulpal inflammation is **chronic hyperplastic pulpitis (pulp polyp).** This condition occurs in children and young adults who have large exposures of the pulp in which the entire dentinal roof often is missing. The most frequently involved teeth are the deciduous or succedaneous molars, which have large pulp chambers in these age groups. Mechanical irritation and bacterial invasion result in a level of chronic inflammation that produces hyperplastic granulation tissue that extrudes from the chamber and often fills the associated dentinal defect (Figs. 3.1–3.3). The apex may be open and reduces the chance of pulpal necrosis secondary to venous compression. The tooth is asymptomatic except for a possible feeling of pressure when it is placed into masticatory function.

• **Fig. 3.1 Chronic Hyperplastic Pulpitis.** Erythematous granulation tissue extruding from the pulp chamber of the mandibular first molar.

• **Fig. 3.2 Chronic Hyperplastic Pulpitis.** Gross photograph demonstrating hyperplastic pulp tissue filling a large coronal carious defect. *Arrows* delineate the previous roof of the pulp chamber.



• **Fig. 3.3 Chronic Hyperplastic Pulpitis.** Same tooth as depicted in Fig. 3.2. Chronically inflamed granulation tissue fills the coronal defect. Note surface stratified squamous epithelium.

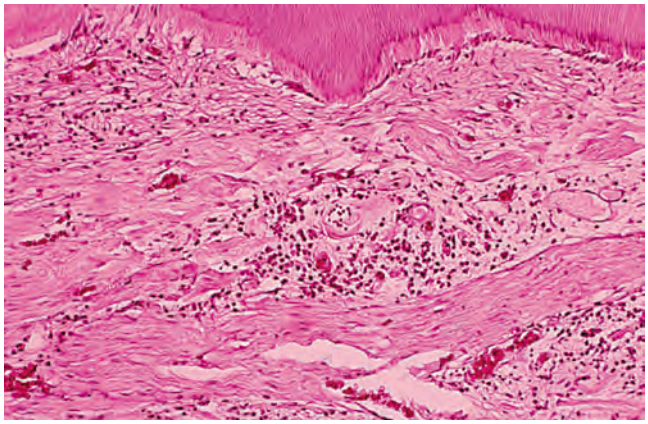


Histopathologic Features

Basically, the histopathology is primarily of academic interest and usually does not affect treatment significantly. Numerous investigations have shown a surprising lack of correlation between histopathologic findings and the clinical symptoms in the majority of pulps examined.

dentlearn.ir

• **Fig. 3.4 Reversible Pulpitis.** Dental pulp exhibiting hyperemia and edema. The adjacent dentin was cut recently during placement of a dental restoration.



• **Fig. 3.5 Irreversible Pulpitis.** Dental pulp exhibiting acute inflammatory infiltrate consisting predominantly of polymorphonuclear leukocytes.

In patients with reversible pulpitis, the pulp usually shows hyperemia, edema, and a few inflammatory cells underlying the area of affected dentinal tubules (Fig. 3.4). Tertiary dentin may be noted in the adjacent dentinal wall, and scattered acute inflammatory cells are found occasionally.

Irreversible pulpitis often demonstrates congestion of the venules that results in focal necrosis. This necrotic zone contains polymorphonuclear leukocytes and histiocytes (Fig. 3.5). The surrounding pulp tissue usually exhibits fibrosis and a mixture of plasma cells, lymphocytes, and histiocytes (Fig. 3.6).

Chronic hyperplastic pulpitis demonstrates a cap of subacutely inflamed granulation tissue that fills the entire space of the original pulp chamber and histopathologically resembles a pyogenic granuloma (see page 525). The surface of the polyp may or may not be covered with stratified squamous epithelium, which migrates from the adjacent gingiva or arises from sloughed epithelium within the oral fluids (see Fig. 3.3). The deeper pulp tissue within the canals typically demonstrates fibrosis and a chronic inflammatory infiltrate. Pulpal calcifications are common in both the radicular and coronal portions. Often the apical portion of the pulp tissue is normal with minimal inflammation or fibrosis.

• **Fig. 3.6 Irreversible Pulpitis.** Same tooth as depicted in Fig. 3.5. The dental pulp exhibits an area of fibrosis and chronic inflammation peripheral to the zone of abscess formation.

Treatment and Prognosis

Reversible pulpitis is treated by removal of the local irritant. On occasion, analgesic medications sometimes are desirable. The prognosis of reversible pulpitis is good if action is taken early enough. The pulp status should be evaluated periodically over the next 3 months to ensure that healing has occurred and the process has not progressed to irreversible pulpitis or necrosis.

Irreversible and chronic hyperplastic pulpitis are treated by extraction of the tooth or by root canal therapy. During pulpectomy of mandibular teeth, profound dental anesthesia may be difficult to attain with an inferior alveolar nerve block. During access opening and instrumentation, patients may report pain despite having numbness of the lower lip and tip of the tongue. Premedication with greater than 400 mg of ibuprofen 30–60 minutes prior to the procedure has been shown to increase the likelihood of successful anesthesia. Similar results also have been obtained with 10 mg of ketorolac or 50 mg of diclofenac.

◆ SECONDARY AND TERTIARY DENTIN

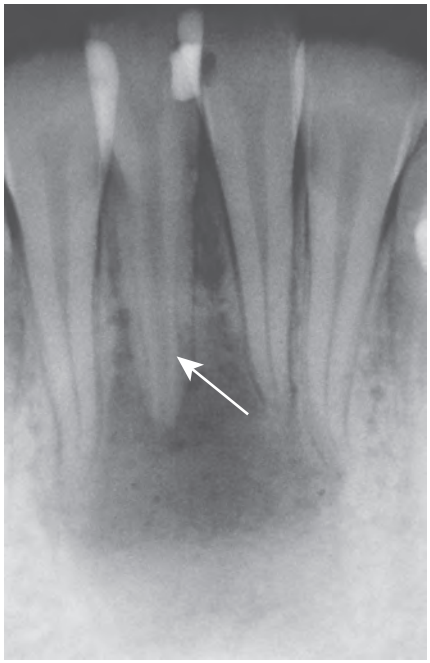
Formation of dentin proceeds throughout life. The dentin formed before completion of the crown is called **primary dentin.** This process is followed by the formation of **secondary dentin.** The same odontoblasts that formed the primary dentin remain functional and produce secondary dentin. With advancing age in functioning teeth, dentin is deposited diffusely along the inner walls and leads to smaller pulp chambers and canals. This type of dentin is termed **physiologic secondary dentin** and exhibits slow and gradual deposition that increases after the age of 35–40 years. Significantly less secondary dentin has been described in impacted teeth, suggesting that functional forces of occlusion promote the deposition. Forensic scientists have suggested that the formation of secondary dentin occurs so consistently that its formation can be used for an estimate of age. Pulp/tooth area ratio, pulp/tooth width-length ratio, and pulpal volume have been performed with cone beam computed tomography

dentlearn.ir

increasing the accuracy and ease of the estimation of the secondary dentin deposition.

Physiologic secondary dentin is more advanced in males and has been associated positively with calcification-related diseases (e.g., arthritis, gout, kidney stones, gall stones, atherosclerosis, and hypertension). Early widespread formation of secondary dentin has been seen in association with **progeria,** a condition characterized by accelerated aging. On occasion, significant traumatic injury can lead to early obliteration of the pulp chamber and canal **(calcific metamorphosis)** in the affected tooth.

Localized new dentin also is laid down in areas of focal injury. This dentin is more haphazardly organized and is termed **tertiary (reactionary, reparative, irregular,** or **irritation) dentin.** This localized dentin formation may occur in response to the following:



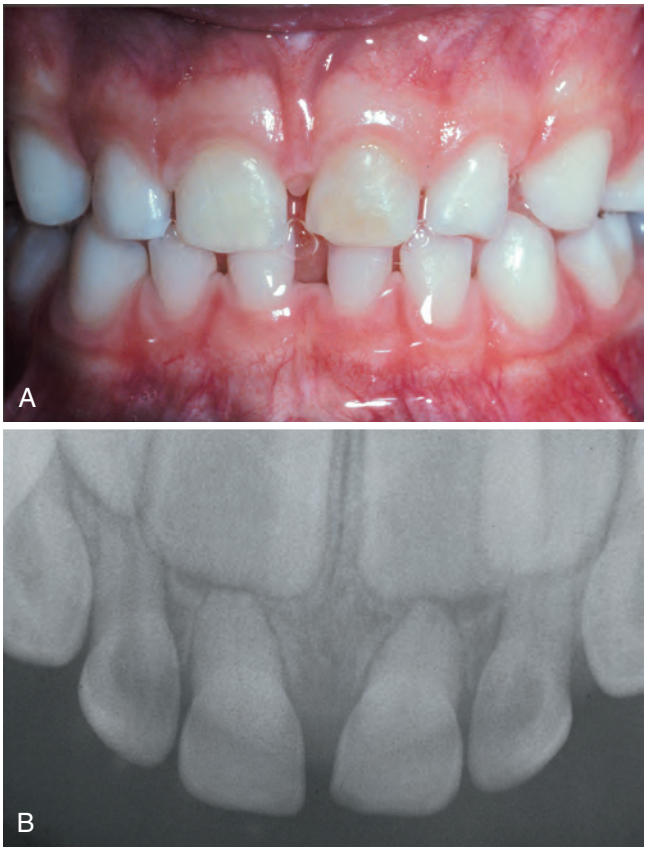
- Attrition
- Fracture
- Erosion
- Abrasion
- Caries
- Periodontal disease
- Mechanical injury from dental procedures
- Irritation from dental materials

Injury of the peripheral odontoblastic processes is all that is required to initiate tertiary dentin formation. If the stimulus is mild to moderate, then the tertiary dentin typically is produced by surviving odontoblasts and is termed *reactionary dentin.* This type of tertiary dentin is more regular in appearance and continuous with the tubules of the primary and secondary dentin. If the stimulus is more severe and leads to the death of the primary odontoblasts, then a new generation of odontoblasts may arise from undifferentiated cells within the pulp and continue to form tertiary dentin that is termed *reparative dentin.* Demineralization of dentin during caries also releases significant amounts of calcium and phosphates. These minerals often diffuse toward the pulp and assist in sclerosis of the tubules as calcium phosphate.

The initial layer of reparative dentin is atubular and known as *interface dentin (fibrodentin).* This thin band may be acellular or exhibit scattered nuclear inclusions. After deposition of the interface dentin, the remainder of the reparative dentin is tubular but not continuous with the primary, secondary, or reactionary dentin. This lack of communication further assists in protecting the pulp from the external stimulus. When the primary odontoblasts die, their dentinal tubules are filled with degenerated odontoblastic processes and are termed *dead tracts.* These tubules usually are sealed off from the pulp by the reparative dentin.

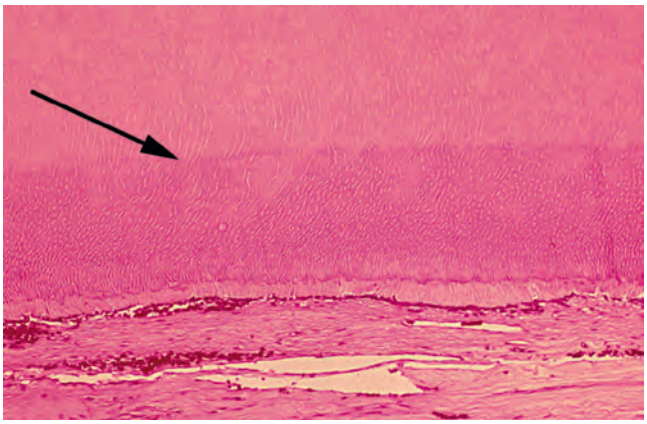
Clinical and Radiographic Features

As noted on periapical radiographs, the deposition of secondary dentin results in diminishing size of pulp chambers and canals. Secondary dentin appears to reduce sensitivity of the affected teeth, susceptibility to dentinal caries, and the trauma of dental procedures. Although production of secondary dentin makes pulp exposure during operative procedures less likely, it also increases the difficulty of locating the pulp chamber and canals during endodontic therapy. On occasion, large inflammatory lesions may involve more than one apex; the size of the canals can be used to help determine the original focus of infection because the canal may be larger in the tooth that became nonvital earlier (Fig. 3.7). Teeth affected by calcific metamorphosis often are discovered clinically by a yellow discoloration of the crown; radiographically, the affected teeth exhibit an accelerated closure of the pulp chamber and canal when compared with adjacent or contralateral teeth (Fig. 3.8). In such cases, the pulpal space may appear to be obliterated completely or reduced dramatically. This alteration usually follows trauma to the tooth and may be seen as early as 3 months after the traumatic episode; however, usually the condition is not detected for about 1 year.



• **Fig. 3.7 Physiologic Secondary Dentin.** Periapical abscess with all four teeth nonresponsive to electric pulp testing. Decreased deposition of physiologic secondary dentin on the right central incisor *(arrow)* delineated the origin of the infection; endodontic treatment of this tooth resolved the lesion.

Histopathologic Features



Physiologic secondary dentin consists of regular tubular dentin that is applied onto the primary dentin. These two layers of dentin can be separated by a line of demarcation, often indicated by a bending of the tubules (Fig. 3.9). With advancing age, as the odontoblasts undergo degenerative changes, the physiologic secondary dentin becomes more irregular with fewer tubules.

The quality and appearance of tertiary dentin depend on the severity of the noxious stimulus that promoted its formation. Tertiary dentin is localized to the pulpal end of the

dentlearn.ir

• **Fig. 3.9 Physiologic Secondary Dentin.** A distinct line of demarcation *(arrow)* separates the primary dentin and physiologic secondary dentin.

odontoblastic processes that were affected (Fig. 3.10). With a mild stimulus, such as abrasion or attrition, reactionary dentin exhibits slow deposition characterized by tubules that are continuous with the secondary dentin and only slightly irregular. With more severe damage (e.g., a rapidly progressing carious lesion), reparative dentin is formed, a process that occurs more rapidly and consists of a thin layer of interface

• **Fig. 3.10 Reparative Secondary Dentin.** Localized deposition of secondary dentin *(bottom)* at the pulpal end of the dentinal tubules affected by the carious process.

dentin on which is deposited irregular dentin with widely scattered, disorganized tubules.

Treatment and Prognosis

In studies of teeth exhibiting calcific metamorphosis, the vast majority of affected teeth never develop clinical or radiographic features suggestive of periapical inflammatory disease; therefore, endodontic therapy should be performed only if periapical pathosis or negative vitality testing is present. Even if a canal space cannot be identified radiographically, conventional root canal therapy usually can locate and negotiate the pulp canal. Because of the dramatically reduced canal space, location of the pulp canal can be difficult, and care must be exercised during access preparation to prevent perforation. If endodontic therapy is unsuccessful, then periapical surgery can be performed in those cases with evidence of periapical inflammatory disease. If vitality testing is positive, then periodic reevaluation appears prudent. To improve dental aesthetics, full coverage is recommended for discolored anterior teeth with large restorations. Otherwise, bleaching often effectively resolves the discoloration.

◆ PULPAL CALCIFICATIONS

Calcifications within the dental pulp are not rare. The prevalence of pulp stones reported in reviews of single cohorts varies widely, but a global meta-analysis of the frequency reported in the international dental literature revealed that 36.5% of all patients develop pulp stones, with approximately 10% of all teeth being affected. Because radiographically detectable pulp stones typically exceed 200 µm in diameter, the prevalence in a histopathologic review would be expected to be much higher. An increased prevalence of pulp stones has been reported in association with a variety of chronic pulpal irritants, such as attrition, abrasion, erosion, caries, periodontitis, dental restorative procedures, orthodontic tooth movement, and tooth injury. Pulp stones are noted more frequently in carious teeth or restored teeth,

dentlearn.ir

suggesting an inflammatory cause. Although many examples remain idiopathic, pulpal calcification also has been associated with aging, fluoride supplementation, hypervitaminosis D, and a few genetic disorders, such as the mild form of dentinogenesis imperfecta (see page 104).

The three types of pulpal calcifications are:

1. Denticles
2. Pulp stones
3. Diffuse linear calcifications

All pulpal calcifications start out as free bodies within the pulp tissue, but many may become attached or embedded in the dentinal walls of the pulp.

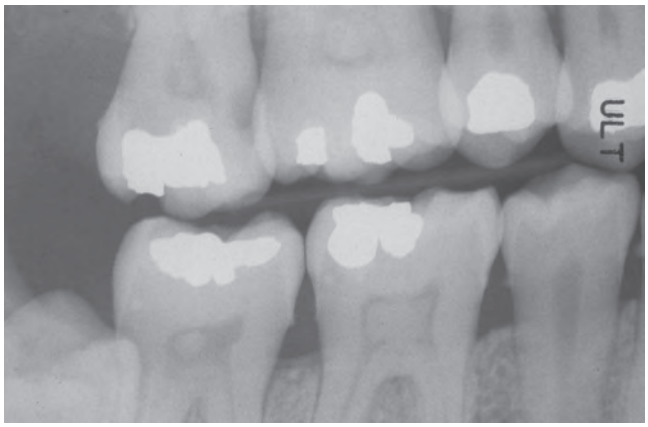
Denticles are believed to form as a result of an epitheliomesenchymal interaction within the developing pulp. Epithelial strands originating from the root sheath, or cervical extensions into the pulp chamber adjacent to furcations, induce odontoblastic differentiation of the surrounding mesenchyme of the dental papilla, forming the core of the denticle. Odontoblasts deposit tubular dentin as they move away from the central epithelium and produce thimble-shaped structures surrounding the epithelium.

Pulp stones are believed to develop around a central nidus of pulp tissue (e.g., collagen fibril, ground substance, necrotic cell remnants). Initial calcification begins around the central nidus and extends outward in a concentric or radial pattern of regular calcified material. Pulp stones are formed within the coronal portions of the pulp and may arise as a part of age-related or local pathologic changes.

Diffuse linear calcifications do not demonstrate the lamellar organization of pulp stones; they exhibit areas of fine, fibrillar, irregular calcification that often parallel the vasculature. These calcifications may be present in the pulp chamber or canals, and the frequency increases with age.

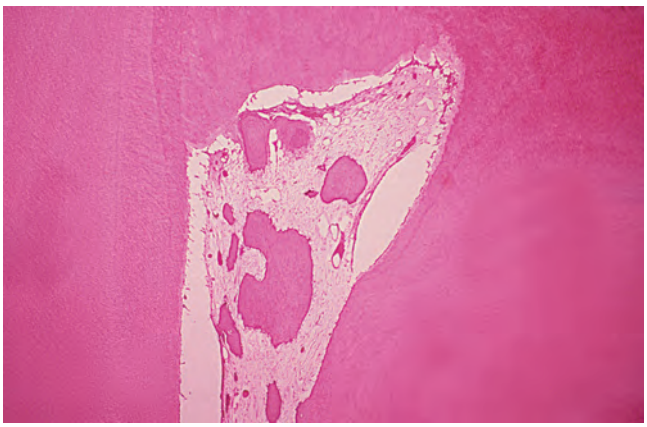
Clinical and Radiographic Features

Denticles and pulp stones can reach sufficient size to be detected on intraoral radiographs as radiopaque enlargements within the pulp chamber or canal (Fig. 3.11). Diffuse calcifications are not detectable radiographically. Radiographically obvious pulp stones are noted most frequently in the molars followed by the premolars; a lower frequency is noted in the incisors. A maxillary and female predominance is noted. Although pulp stones can be seen at any age, there is an increased frequency over the age of 50 years.



Other than rare difficulties during endodontic procedures, pulpal calcifications are typically of little clinical significance. Some investigators associate the calcifications with dental neuralgias, but the high frequency of these lesions in the absence of clinical symptoms argues against this relationship. Others have suggested a relationship between pulpal calcification and carotid artery calcification, which potentially could be a marker for cardiovascular disease. Despite this, studies of the association by multiple groups have not proven a strong correlation. A similar association with kidney stones has been suggested. A systematic review and meta-analysis revealed patients with pulp stones are twice as likely to present with kidney stones. Prominent pulpal calcifications also have been noted in association with certain disease processes, such as the following:

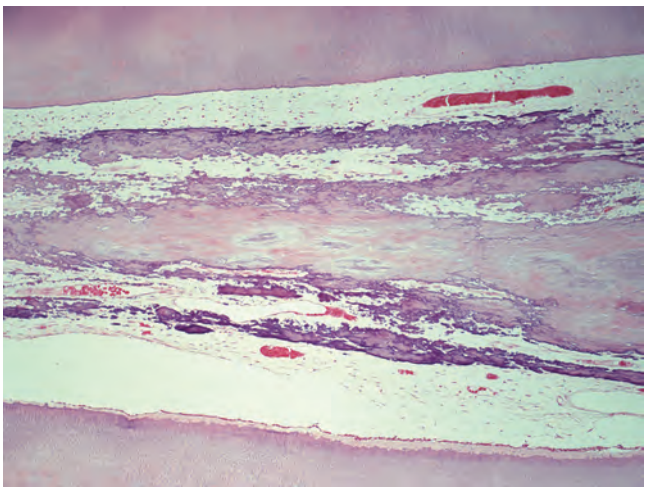
- Radicular dentin dysplasia (Dentin dysplasia type Id) (see page 108)
- Dentinogenesis imperfecta, mild form (see page 104)
- Pulpal dysplasia (see page 107)
- Tumoral calcinosis
- Calcinosis universalis
- Ehlers-Danlos syndrome (see page 760)
- End-stage renal disease



Histopathologic Features

Denticles consist of tubular dentin surrounding a central nest of epithelium. With time, the central epithelium degenerates and the tubules undergo sclerosis, making their detection difficult. Most denticles are attached or embedded. Those that remain free in the pulp occasionally develop outer layers of irregular fibrillar calcification or lamellated layers of calcification similar to those seen in pulp stones.

Pulp stones demonstrate a central amorphous mass of irregular calcification surrounded by concentric lamellar rings of regular calcified material (Fig. 3.12). Occasionally,



• **Fig. 3.11 Pulp Stones.** Multiple teeth demonstrating radiographically obvious calcifications within the pulp chambers.

• **Fig. 3.12 Pulp Stones.** Multiple stones within the pulp chamber.

dentlearn.ir

• **Fig. 3.13 Diffuse Linear Pulpal Calcifications.** Fine, fibrillar calcifications parallel the course of the neurovascular channels within the pulp canal.

a peripheral layer of tubular dentin may be applied by odontoblasts, which arise from the surrounding pulp tissue in response to the presence of the pulp stone. In addition, fibrillar irregular calcified material also may be evident on the periphery of pulp stones.

Diffuse linear calcifications consist entirely of fine, fibrillar, and irregular calcifications that develop in the pulp chambers and canals (Fig. 3.13). This material often is deposited in a linear fashion along the course of a blood vessel or nerve.

Treatment and Prognosis

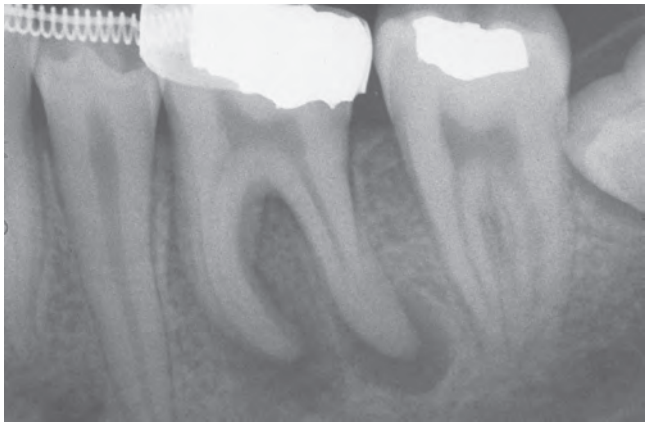
No treatment is required. Most pulpal calcifications are not associated with any significant clinical alterations. In those teeth requiring root canal therapy, cone beam computed tomography has been helpful in discovering those cases in which the stone may obscure or totally block the root canal path.

◆ PERIAPICAL GRANULOMA (CHRONIC APICAL PERIODONTITIS)

The term **periapical granuloma** refers to a mass of chronically or subacutely inflamed granulation tissue at the apex of a nonvital tooth. This commonly used name is not totally accurate because the lesion does not show true granulomatous inflammation microscopically. Although the term **apical periodontitis** may be more appropriate, it may prove confusing to the clinician. Formation of apical inflammatory lesions represents a defensive reaction secondary to the presence of microbial infection in the root canal with spread of related toxic products into the apical zone. Initially, the defense reaction eliminates noxious substances that exit the canals. With time, however, the host reaction becomes less effective with microbial invasion or spread of toxins into the apical area.

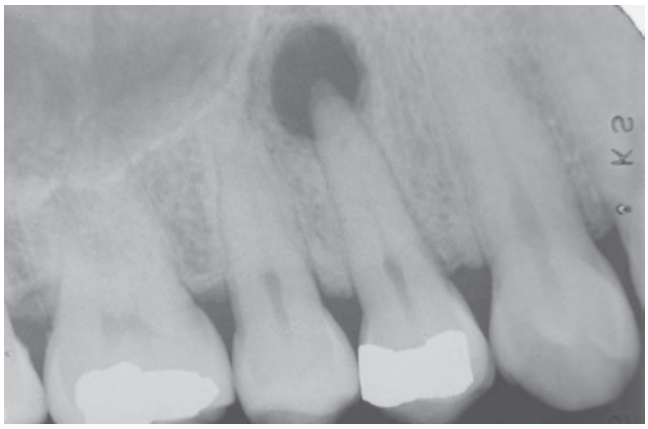
In the early stages of infection, neutrophils predominate and radiographic alterations are not present; this phase of periapical inflammatory disease is termed *acute apical periodontitis.* The involved inflammatory cells are primarily neutrophils and release prostaglandins, which activate osteoclasts to resorb the surrounding bone, leading to a detectable periapical radiolucency. With time, chronic inflammatory cells begin to dominate the host response. Chronic lesions often are asymptomatic and demonstrate little additional change radiographically.

Periapical granulomas may arise after quiescence of a **periapical abscess** or may develop as the initial periapical pathosis. These lesions are not necessarily static. In addition to possible **periapical cyst** formation, a worsening of the pulpal infection can lead to a reappearance of inflammation, redevelopment of symptoms, and possible enlargement of the associated radiolucency. Secondary acute inflammatory changes within a periapical granuloma have been termed a *phoenix abscess,* after the mythical bird that would die, only to arise again from its own ashes. In progressive periapical granulomas, the enlargement often is not continuous but occurs in spurts associated with periodic acute exacerbations.



Clinical and Radiographic Features

The initial phase of periapical inflammatory disease—acute periapical periodontitis—creates a constant dull, throbbing pain. The associated tooth responds negatively to vitality testing or reveals a delayed positive result. Typically, pain on biting or percussion is present, and no obvious radiographic alterations are noted. If the acute inflammatory process evolves into a chronic pattern, then the associated symptoms diminish. In many instances, chronic periapical inflammatory disease is detected without any previous recollection of a prior acute phase.



Most periapical granulomas are asymptomatic, but pain and sensitivity can develop if acute exacerbation occurs. Typically, the involved tooth does not demonstrate mobility or significant sensitivity to percussion. The soft tissue overlying the apex may or may not be tender. The tooth does not respond to thermal or electric pulp tests unless the pulpal necrosis is limited to a single canal in a multirooted tooth.

Most lesions are discovered on routine radiographic examination. The associated radiolucencies are variable, ranging from small, barely perceptible lesions to lucencies exceeding 2 cm in diameter (Figs. 3.14–3.16). Affected teeth typically reveal loss of the apical lamina dura. The lesion may be circumscribed or ill-defined and may or may not demonstrate a surrounding radiopaque rim. Root resorption is not uncommon (Fig. 3.17). Although lesions greater than 200 mm^2 often represent periapical cysts, numerous investigators have been unable to distinguish periapical granulomas from periapical cysts simply on the basis of size and radiographic appearance. Cone-beam computed tomography (CBCT), magnetic resonance imaging (MRI), and high-resolution ultrasound have been reported to distinguish

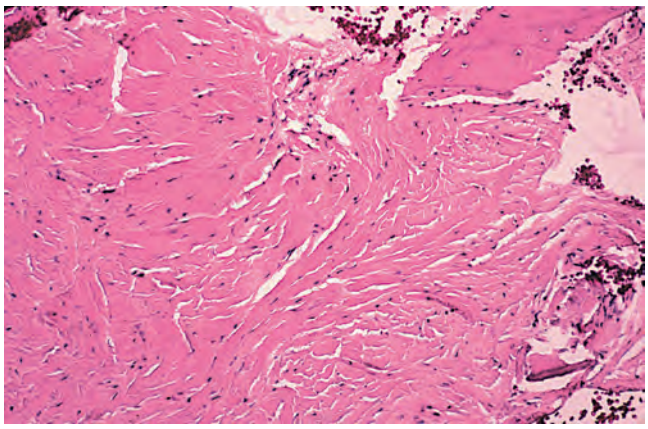
diagnosis solely by imaging. Cyst-like granulomas with luminal fluid but no epithelial lining are identified with some frequency by most oral pathologists. Conversely, relatively solid periapical cysts with an epithelial lining surrounding a small lumen can create a similar pattern to a periapical granuloma. Because periapical inflammatory disease is not static and granulomas can transform into cysts or abscesses (and vice versa) without significant radiographic change, it is not surprising that the radiographic and imaging features are not definitively diagnostic.

Histopathologic Features

Periapical granulomas consist of inflamed granulation tissue surrounded by a fibrous connective tissue wall. The granulation tissue demonstrates a variably dense lymphocytic infiltrate that is intermixed frequently with neutrophils, plasma cells, histiocytes, and, less frequently, mast cells and eosinophils (Fig. 3.18). When numerous plasma cells are present, scattered eosinophilic globules of gamma globulin **(Russell bodies)** may be seen. In addition, clusters of lightly basophilic particles **(pyronine bodies)** also may be present in

dentlearn.ir

association with the plasmacytic infiltrate. Both of these plasma cell products are not specific for the periapical granuloma and may be found within any accumulation of plasma cells. Epithelial rests of Malassez may be identified within the granulation tissue. Collections of cholesterol clefts, with associated multinucleated giant cells and areas of red blood cell extravasation with hemosiderin pigmentation, may be present. Small foci of acute inflammation with focal abscess formation may be seen but do not warrant the diagnosis of periapical abscess.



Treatment and Prognosis

Apical inflammatory lesions result from the presence of microorganisms or their toxic products in the root canal, the apical tissues, or both. Successful treatment depends on the reduction and control of the offending organisms. Because of the anatomic complexity of the root canal systems, some investigators believe absolute eradication of all microorganisms is unlikely; the goal of endodontics is to reduce the microbial load to a level that is insufficient to maintain periapical inflammation. If the tooth can be maintained, then root canal therapy can be performed. Nonrestorable teeth must be extracted, followed by curettage of all apical soft tissue. In symptomatic cases, nonsteroidal anti-inflammatory drugs (NSAIDs) are beneficial; use of systemic antibiotic medications is not recommended unless associated swelling or systemic changes are present.

Teeth treated endodontically should be evaluated at 1- and 2-year intervals (at a minimum) to rule out possible lesional enlargement and to ensure appropriate healing. In addition, many clinicians believe that evaluations at 1, 3, and 6 months are appropriate. Strong emphasis should be placed on the importance of the recall appointments.

Research has shown the most important factor for the successful treatment of periapical inflammatory disease is the quality of the endodontic treatment. In addition, the coronal restoration is critical, and failure can occur in cases with excellent endodontic therapy but poor coronal restoration.

If initial conventional therapy is unsuccessful, endodontic retreatment represents the best approach for minimizing the bacterial contamination and should be considered before periapical surgery. Periapical surgery remains an important tool for resolution of periapical inflammatory disease, but often it is reserved for lesions larger than 2 cm, those associated with teeth that are not appropriate for conventional endodontic therapy, and lesions that fail to respond to endodontic retreatment. Periapical surgery should include thorough curettage of all periradicular soft tissue, amputation of the apical portion of the root, and sealing the foramen of the canal. All soft tissue removed during periapical surgical procedures should be submitted for histopathologic examination. These surgical sites represent areas that have failed to respond to appropriate therapy; as such, histopathologic examination and diagnostic confirmation are mandatory. Although the vast majority of periradicular specimens represent periapical inflammatory disease, large reviews reveal a small but important percentage of other pathoses such as odontogenic keratocysts, fibro-osseous lesions, ameloblastomas, and giant cell granulomas.

• **Fig. 3.19 Periapical Fibrous Scar.** Dense, fibrous connective tissue with vital bone and no significant inflammatory infiltrate.

• **Fig. 3.20 Periapical Fibrous Scar.** Periapical radiolucency of maxilla at the previous site of extraction in which both cortical plates were lost. The site was filled with dense collagenous tissue. (Courtesy of Dr. James Tankersley.)

On occasion, the defect created by periapical inflammatory lesions may fill with dense collagenous tissue rather than normal bone (Fig. 3.19). These **fibrous (periapical) scars** occur most frequently when both the facial and lingual cortical plates have been lost (Fig. 3.20); however, they occasionally arise in areas with intact cortical plates. If during surgery both plates are discovered to be missing, then the patient should be informed of the possibility of scar formation. The development of a periapical scar is not an indication for future surgery.

dentlearn.ir

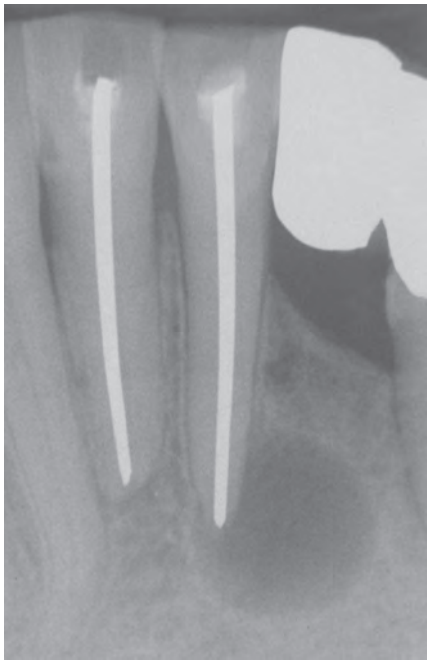
◆ PERIAPICAL CYST (RADICULAR CYST; APICAL PERIODONTAL CYST)

Epithelium at the apex of a nonvital tooth presumably can be stimulated by inflammation to form a true epithelium-lined cyst, or **periapical cyst.** The source of the epithelium is usually a rest of Malassez but also may be traced to crevicular epithelium, sinus lining, or epithelial lining of sinus tracts. Cyst development is common with a wide range of prevalence noted that most likely is related to the stringency of the diagnostic criteria used in a particular study.

When the cyst and root are removed totally, two variations of periapical cyst have been described. **Periapical pocket cysts** are characterized by an incomplete epithelial lining because of extension of the apical portion of the tooth into the cyst lumen. **Periapical true cysts** form a complete epithelium-lined baglike structure that is adjacent to, but separated from, the tooth apex. It is believed that pocket cysts often respond well to conventional endodontic therapy, whereas true cysts require periapical surgery for resolution. Studies have shown an inability to separate a "pocket" cyst from a "true" cyst unless the entire tooth and associated soft tissue are removed *in toto,* which makes the separation most impractical. Because distinguishing between an epithelialized periapical granuloma, a "pocket" cyst, or a "true" cyst has little postsurgical implications, laborious histopathologic examination and subclassification are impractical.

Periapical cysts represent a fibrous connective tissue wall lined by epithelium with a lumen containing fluid and cellular debris. Theoretically, as the epithelium desquamates into the lumen, the protein content is increased. Fluid enters the lumen in an attempt to equalize the osmotic pressure, and slow enlargement occurs. Most periapical cysts grow slowly and do not attain a large size.

On occasion, a similar cyst, best termed a **lateral radicular cyst,** may appear along the lateral aspect of the root. Like the periapical cyst, this lesion also usually arises from rests of Malassez, and the source of inflammation may be periodontal disease or pulpal necrosis with spread through a lateral foramen. Radiographically, these cysts mimic developmental **lateral periodontal cysts** (see page 699). Histopathologically, however, they are consistent with cysts of inflammatory origin.



Periapical inflammatory tissue that is not curetted at the time of tooth removal may give rise to an inflammatory cyst called a **residual periapical cyst.** With time, many of these cysts exhibit an overall reduction in size, and spontaneous resolution can occur from a lack of continued inflammatory stimulus.

Clinical and Radiographic Features

Periapical Cyst

Typically, patients with periapical cysts have no symptoms unless there is an acute inflammatory exacerbation. In addition, if the cyst reaches a large size, then swelling and mild sensitivity may be noted. Movement and mobility of adjacent teeth are possible as the cyst enlarges. The tooth from which the cyst originated does not respond to thermal and electric pulp testing.

The radiographic pattern is identical to that of a periapical granuloma. Cysts may develop even in small periapical radiolucencies, and the radiographic size cannot be used for the definitive diagnosis. A loss of the lamina dura is seen along the adjacent root, and a rounded radiolucency encircles the affected tooth apex (Fig. 3.21). Root resorption is common (Fig. 3.22). With enlargement, the radiolucency often flattens out as it approaches adjacent teeth. Significant growth is possible, and lesions occupying an entire quadrant

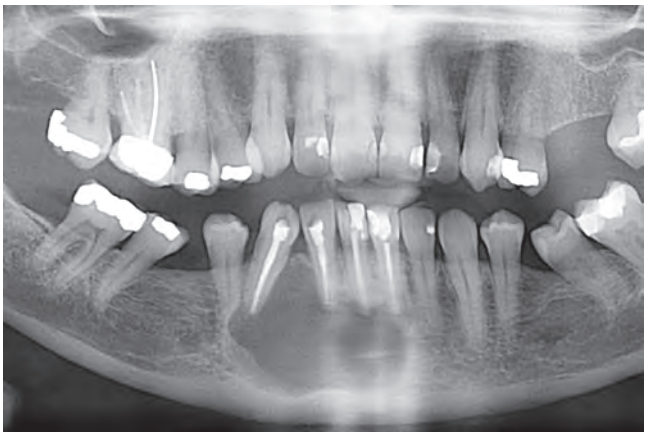
dentlearn.ir

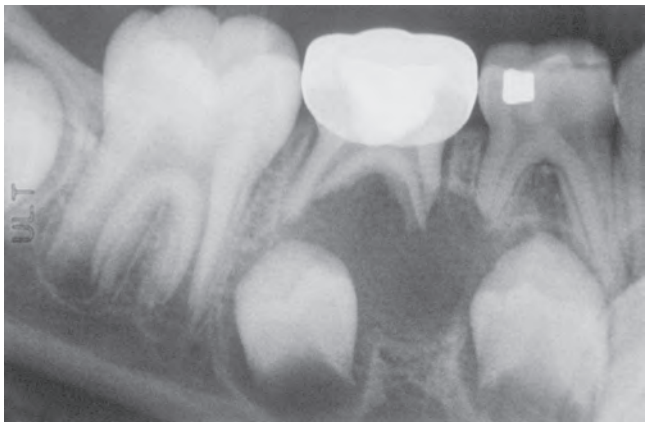
have been noted (Fig. 3.23). Although periapical cysts more frequently achieve greater size than periapical granulomas, neither the size nor the shape of the lesion can be considered a definitive diagnostic criterion. The inability to separate these pathoses on a consistent basis holds true even with newer imaging techniques, such as cone-beam computed tomography (CBCT), magnetic resonance imaging (MRI), and high-resolution ultrasound (see similar discussion in Section "Periapical Granuloma"). Periapical cysts also are known to involve deciduous teeth. These are most frequently associated with molar teeth and appear as a radiolucent zone that surrounds the roots and fills the interradicular space at the bifurcation (Fig. 3.24).

Lateral Radicular Cyst



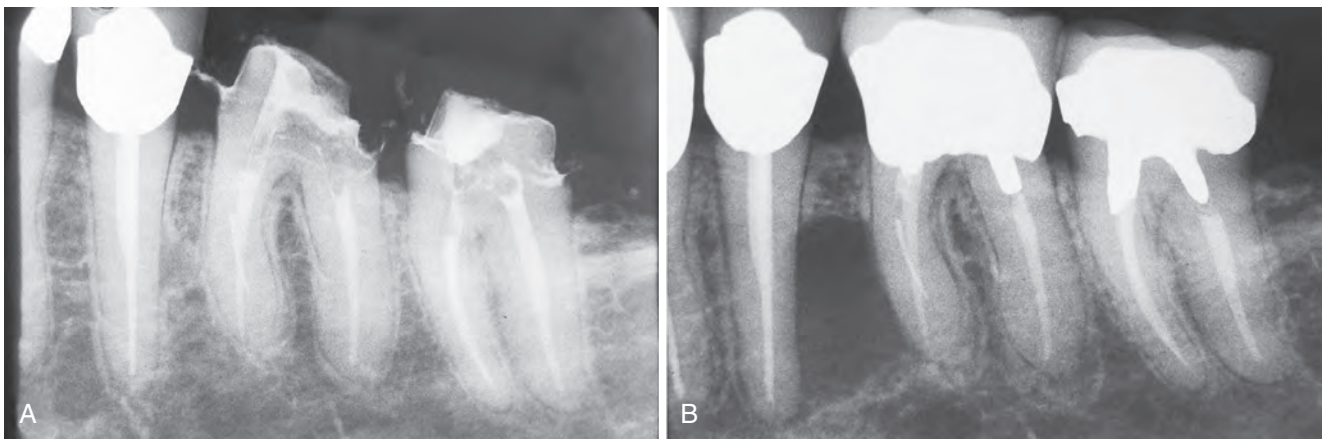
Lateral radicular cysts appear as discrete radiolucencies along the lateral aspect of the root (Fig. 3.25). Loss of lamina dura and an obvious source of inflammation may not be detected without a high index of suspicion. Before surgical exploration of laterally positioned radiolucencies, a thorough evaluation of the periodontal status and vitality of adjacent teeth should be performed. Many examples of the so-called globulomaxillary cyst (see page 27) prove to be of inflammatory origin and represent lateral radicular cysts (Fig. 3.26).

Residual Periapical Cyst



The residual periapical cyst appears as a round-to-oval radiolucency of variable size within the alveolar ridge at the site of a previous tooth extraction (Fig. 3.27). As the cyst ages, degeneration of the cellular contents within the lumen occasionally leads to dystrophic calcification and central luminal radiopacity.

Histopathologic Features



The histopathologic features of all three types of inflammatory cysts are similar. The cyst is lined by stratified squamous epithelium, which may demonstrate exocytosis, spongiosis, or hyperplasia (Fig. 3.28). As seen in dentigerous cysts, scattered mucous cells or areas of ciliated pseudostratified columnar epithelium may be noted in periapical cysts (Fig. 3.29).

• **Fig. 3.30 Periapical Cyst.** Squamous epithelial cyst lining exhibiting numerous irregular and curvilinear Rushton bodies.

Although some maxillary periapical cysts lined by pseudostratified columnar epithelium may have originated from the adjacent sinus lining, the presence of mucous cells or respiratory-like epithelium also can be observed in mandibular cysts. The ability of odontogenic epithelium to demonstrate such specialized differentiation represents an example of *prosoplasia* (forward metaplasia) and highlights the diverse potential of odontogenic epithelium. The cyst lumen may be filled with fluid and cellular debris. On occasion, the lining epithelium may demonstrate linear or arch-shaped calcifications known as *Rushton bodies* (Fig. 3.30). The wall of the cyst consists of dense fibrous connective tissue—often with an

inflammatory infiltrate containing lymphocytes variably intermixed with neutrophils, plasma cells, histiocytes, and (rarely) mast cells and eosinophils. Dystrophic calcification, cholesterol clefts with multinucleated giant cells, red blood cells, and areas of hemosiderin pigmentation may be present in the lumen, wall, or both. Due to the inability of macrophages and giant cells to remove cholesterol, its presence may be partially responsible for failure of healing of cysts in which the original focus of infection was treated appropriately.

Intramural islands of odontogenic epithelium that closely resemble squamous odontogenic tumor (see page 723) rarely have been noted, which could be misdiagnosed as a neoplastic process. Studies have shown these proliferations are not neoplastic and mandate no further treatment beyond the usual standard of care for periapical cysts.

Occasionally, the walls of inflammatory cysts will contain scattered **hyaline bodies (pulse granuloma, giant-cell hyaline angiopathy).** These bodies appear as small circumscribed pools of eosinophilic material that exhibits a corrugated periphery of condensed collagen often surrounded by lymphocytes and multinucleated giant cells (Fig. 3.31). Initially, these foci were thought to be a vascular degenerative process or a foreign body reaction to machinery oil or vegetable matter. Subsequently, these bodies have been shown to represent pools of inflammatory exudate (i.e., extravasated serum) that ultimately undergoes fibrosis and occasionally dystrophic calcification. The multinucleated giant cells are drawn to the site for removal of insoluble hemosiderin granules. Hyaline bodies may be found in any area of chronic intraosseous inflammation, especially periapical inflammatory disease.

Treatment and Prognosis

A periapical cyst is treated in the same manner as a periapical granuloma. When clinical and radiographic features indicate a periapical inflammatory lesion, extraction or conservative nonsurgical endodontic therapy is performed. Although some authors believe that large cystic lesions cannot be resolved with conventional endodontics, experienced clinicians have successfully used nonsurgical root canal therapy for large areas of periapical inflammatory disease that approach 2 cm in diameter. Larger lesions associated with restorable teeth have been treated successfully with conservative endodontic therapy when combined with biopsy and marsupialization, decompression, or fenestration. As with any periapical inflammatory lesion, minimal follow-up at 1 and 2 years is advised strongly.

If the radiolucency fails to resolve, then the lesion often can be managed successfully by nonsurgical endodontic retreatment. As previously mentioned, periapical surgery typically is performed for lesions exceeding 2 cm, those associated with teeth that are not suitable for conventional endodontics, and lesions that fail to respond to endodontic retreatment. Biopsy is indicated to rule out other possible pathologic processes.

Because any number of odontogenic and non-odontogenic cysts and tumors can mimic the appearance of a residual periapical cyst, all of these cysts should be excised surgically. All inflammatory foci in the area of a lateral radicular cyst should be eliminated and the patient observed in a manner similar to that described for the periapical cyst. In some instances, lateral radicular cysts are removed before tooth vitality testing or periodontal evaluation for an adjacent focus of infection. If this diagnosis is made, then a thorough evaluation for an inflammatory source is mandatory.

◆ PERIAPICAL ABSCESS

The accumulation of acute inflammatory cells at the apex of a nonvital tooth is termed a **periapical abscess.** Acute inflammatory lesions with abscess formation may arise as the initial periapical pathosis or from an acute exacerbation of a chronic periapical inflammatory lesion (see discussion of *phoenix abscess,* page 123). Frequently, the source of the infection is obvious. On occasion, however, pulpal death may be trauma related, and the tooth may contain neither a cavity nor a restoration.

In the earliest stage of all forms of periapical inflammatory disease, the periapical periodontal ligament (PDL) fibers may exhibit acute inflammation but no frank abscess formation. This localized alteration, best termed **acute apical periodontitis,** may or may not proceed to abscess formation. Although this process often occurs in association with a nonvital tooth, acute apical periodontitis may be found in vital teeth secondary to trauma, high occlusal contacts, or wedging by a foreign object. The clinical presentation often closely resembles that of a periapical abscess and must be considered in the differential diagnosis.

Clinical and Radiographic Features

Many investigators subdivide periapical abscesses into **acute** and **chronic** types. However, these are misnomers because both types represent acute inflammatory reactions. Periapical

dentlearn.ir

abscesses should be designated as **symptomatic** or **asymptomatic** on the basis of their clinical presentations.

Periapical abscesses become symptomatic as the purulent material accumulates within the alveolus. The initial stages produce tenderness of the affected tooth that often is relieved by direct application of pressure. With progression, the pain becomes more intense, often with extreme sensitivity to percussion, extrusion of the tooth, and swelling of the tissues. The offending tooth does not respond to cold or electric pulp testing. Headache, malaise, fever, and chills may be present.

Radiographically, abscesses may demonstrate a thickening of the apical periodontal ligament, an ill-defined radiolucency, or both; however, often no appreciable alterations can be detected because insufficient time has occurred for significant bone destruction. Phoenix abscesses demonstrate the outline of the original chronic lesion, with or without an associated ill-defined bone loss.

With progression, the abscess spreads along the path of least resistance. The purulence may extend through the medullary spaces away from the apical area, resulting in **osteomyelitis,** or it may perforate the cortex and spread diffusely through the overlying soft tissue (as **cellulitis**). Each of these occurrences is described later in the chapter.

Once an abscess is in soft tissue, it can cause cellulitis or may channelize through the overlying soft tissue. The cortical plate may be perforated in a location that permits entrance into the oral cavity. The purulent material can accumulate in the connective tissue overlying the bone and can create a sessile swelling or perforate through the surface epithelium and drain through an intraoral sinus (Figs. 3.32 and 3.33). At the intraoral opening of a sinus tract, a mass of subacutely inflamed granulation tissue often is found, known as a **parulis** (**gum boil**) (Figs. 3.34 and 3.35). Occasionally, the nonvital tooth associated with the parulis may be difficult to determine, and insertion of a gutta-percha point into the tract can aid in detection of the offending tooth during radiographic examination (Fig. 3.36). Dental abscesses also may channelize through the overlying skin and drain via a **cutaneous sinus** (Fig. 3.37). As would be expected, asymptomatic abscesses associated with a sinus tract demonstrate an associated cortical fenestration. In contrast, symptomatic abscesses without a sinus tract typically will reveal cortical

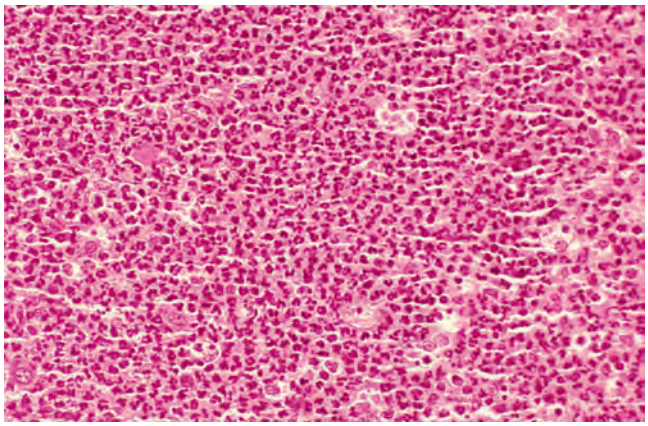
• **Fig. 3.38 Parulis.** Asymptomatic yellow-red nodule of the anterior mandibular alveolar mucosa. The adjacent teeth were asymptomatic and appeared clinically normal.

defects that are absent or smaller in size. When a sinus tract is noted, cone-beam computed tomography can identify the path of drainage through the cortical fenestration to the offending tooth.

Most dental-related abscesses perforate buccally because the bone is thinner on the buccal surface. However, infections associated with maxillary lateral incisors, the palatal roots of maxillary molars, and mandibular second and third molars typically drain through the lingual cortical plate.

If a chronic path of drainage is achieved, a periapical abscess typically becomes asymptomatic because of a lack of accumulation of purulent material within the alveolus. Occasionally, such infections are discovered during a routine oral examination after detection of a parulis or drainage through a large carious defect (Figs. 3.38 and 3.39). If the drainage site becomes blocked, then signs and symptoms of the abscess frequently become evident in a short time. On occasion, periapical infections can spread through the bloodstream and result in systemic symptoms, such as fever, lymphadenopathy, and malaise. The risk of dissemination appears to be less for periapical abscesses that drain freely.



Histopathologic Features

Biopsy specimens from pure abscesses are uncommon because the material is in liquid form. Abscesses consist of a sea of polymorphonuclear leukocytes often intermixed with inflammatory exudate, cellular debris, necrotic material, bacterial colonies, or histiocytes (Fig. 3.40). Phoenix abscesses

dentlearn.ir

• **Fig. 3.39 Periapical Abscess.** Same patient as depicted in Fig. 3.38. Periapical radiolucency associated with the nonvital mandibular lateral incisor.

can maintain a soft tissue component; they present as subacutely inflamed periapical granulomas or cysts intermixed with areas of significant abscess formation. In these cases, the pathologist typically diagnoses the primary lesion but comments about the abscess formation.

Treatment and Prognosis

Treatment of the patient with a periapical abscess consists of drainage and elimination of the focus of infection. Those abscesses associated with a patent sinus tract may be asymptomatic but, nevertheless, should be treated. With localized periapical abscesses, the signs and symptoms typically diminish significantly within 48 hours of initiation of appropriate drainage. When the abscess causes clinical expansion of the bone or soft tissue adjacent to the apex of the affected tooth, incisional drainage of the swelling should be considered because this technique appears to be associated with more rapid resolution of the inflammatory process when compared with drainage through the root canal. If the affected tooth is extruded, then reduction of the occlusion is recommended because chronic occlusal trauma has been shown to delay resolution of the inflammatory process. Unless contraindicated, treatment with NSAIDs usually is appropriate preoperatively, immediately postoperatively, and for subsequent pain control. Use of antibiotic medications for a well-localized and easily drained periapical abscess in a healthy patient is not recommended due to negligible benefits and potential harm associated with use of antibiotics. Antibiotic coverage should be reserved for patients without immediate access to dental care, the medically compromised, and patients with significant cellulitis (see next section) or clinical evidence of dissemination (i.e., fever, lymphadenopathy, malaise). Once the infection has been resolved by extraction or appropriate endodontic therapy, the affected bone typically heals.

Usually, a sinus tract resolves spontaneously after the offending tooth is extracted or endodontically treated. Sinus tracts that persist are thought to contain sufficient infectious material along the fistulous tract to maintain the surface granulation tissue, and surgical removal with curettage of the tract is required for resolution.

◆ CELLULITIS

If an abscess is not able to establish drainage through the surface of the skin or into the oral cavity, it may spread diffusely through fascial planes of the soft tissue. This acute and edematous spread of an acute inflammatory process is termed **cellulitis.** Although cellulitis may occur in otherwise healthy individuals, there is an increased prevalence in patients with variety of medical conditions, such as use of corticosteroid or cytotoxic medications, malignancy, diabetes mellitus, or immunosuppressive disorders including neutropenia, aplastic anemia, and acquired immunodeficiency syndrome (AIDS). Although numerous patterns of cellulitis can be seen from the spread of dental infections, two especially dangerous forms warrant further discussion: (1) **Ludwig angina** and (2) **cavernous sinus thrombosis.**

Ludwig angina, named after the German physician, Friedrich Wilhelm von Ludwig, who described the seriousness of the disorder in 1836, refers to cellulitis of the submandibular region. Angina comes from the Latin word *angere,* which means *to strangle* (an apt term, considering the clinical features described in the following section). In up to 90% of cases, Ludwig angina develops from spread of an acute infection from the lower molar teeth. Other situations associated with this clinical presentation are peritonsillar or parapharyngeal abscesses, tongue piercing, oral lacerations, fractures of the mandible, or submandibular sialadenitis.

The cavernous sinus is a group of thin-walled veins that are located lateral to the sella turcica and medial to the temporal bone. The trochlear and oculomotor nerves and the

dentlearn.ir

maxillary and ophthalmic branches of the trigeminal nerve course through the area. In addition, the internal carotid artery and abducens nerve travel within the sinus. The sinus receives venous drainage from the orbit via the superior and inferior ophthalmic veins. Infection of the sinus can produce a variety of clinical symptoms related to the numerous anatomic structures that course through this site.

The most common cause of cavernous sinus thrombosis is sinusitis, usually from the sphenoid sinus. Less common origins include infections of the middle ear, mastoid, mid-facial region, tonsils, and pharynx. Odontogenic infections are responsible in about 10% of the cases. Cavernous sinus thrombosis can occur via an anterior or posterior pathway. Infection from the maxillary anterior teeth can perforate the facial maxillary bone and spread to the canine space. A septic thrombus develops in the valveless facial veins located in this space, and retrograde propagation occurs from the angular vein to the inferior ophthalmic vein through the inferior orbital fissure into the cavernous sinus. The posterior pathway is followed by infections originating from maxillary premolar or molar teeth, which demonstrate buccal or infratemporal space involvement that may spread via the emissary veins from the pterygoid venous plexus to the inferior petrosal sinus and into the cavernous sinus. Thankfully, cavernous sinus thrombosis is relatively uncommon.

Clinical Features

Ludwig Angina

Ludwig angina is an aggressive and rapidly spreading cellulitis that involves the sublingual, submandibular, and submental spaces bilaterally. Once the infection enters the submandibular space, it may extend to the lateral pharyngeal space and then to the retropharyngeal space. This extension may result in spread to the mediastinum with several serious consequences.

Ludwig angina creates massive swelling of the neck that often extends close to the clavicles (Fig. 3.41). Involvement of the sublingual space results in elevation, posterior enlargement, and protrusion of the tongue **(woody tongue),** which can compromise the airway. In some cases, the elevation of the floor of the mouth creates a mass of tissue that elevates the tongue, creating a bifold appearance that has been termed **double tongue**. Submandibular space spread causes enlargement and tenderness of the neck above the level of the hyoid bone **(bull neck).** Although initially unilateral, spread to the contralateral neck typically occurs. Pain in the neck and floor of mouth may be seen in addition to restricted neck movement, dysphagia, dysphonia, dysarthria, drooling, and sore throat. Involvement of the lateral pharyngeal space can cause respiratory obstruction secondary to laryngeal edema. Tachypnea, dyspnea, tachycardia, stridor, restlessness, and the patient's need to maintain an erect position suggest airway obstruction. Fever, chills, leukocytosis, and an elevated sedimentation rate may be seen. Classically, obvious collections of pus are not present.

• **Fig. 3.41 Ludwig Angina.** Soft tissue swelling of the right submandibular region. (Courtesy of Dr. Brian Blocher.)

Cavernous Sinus Thrombosis

Cavernous sinus thrombosis appears as an edematous periorbital enlargement with involvement of the eyelids and conjunctiva. In cases involving the canine space, swelling also typically is present along the lateral border of the nose and may extend up to the medial aspect of the eye and periorbital area (Fig. 3.42). Protrusion and fixation of the eyeball often are evident, in addition to induration and swelling of the adjacent forehead and nose. Pupil dilation, lacrimation, photophobia, and loss of vision may occur. Pain over the eye and along the distribution of the ophthalmic and maxillary branches of the trigeminal nerve often is present. Proptosis, chemosis, and ptosis are noted in greater than 90% of affected patients. The cavernous sinuses freely communicate via the intercavernous sinus. Although many cases are initially unilateral, without appropriate therapy, the infection may spread to the contralateral side. Cranial magnetic resonance imaging (MRI), which will demonstrate cavernous sinus expansion in the majority of patients, is important to confirm the clinical diagnosis and allow prompt treatment.

Fever, chills, headache, sweating, tachycardia, nausea, and vomiting can occur. With progression, signs of central nervous system (CNS) involvement develop. Meningitis, tachycardia, tachypnea, irregular breathing, stiffening of the neck, and deepening stupor with or without delirium indicate advanced toxemia and meningeal involvement. Occasionally, brain abscesses may result.

dentlearn.ir

Treatment and Prognosis

Ludwig Angina

Treatment of Ludwig angina centers around two major priorities: maintenance of the airway and resolution of the infection. The choice of airway maintenance varies according to the severity of the obstruction. Choices include observation, orotracheal intubation, fiber-optic nasotracheal intubation, and tracheotomy. Orotracheal intubation often is very difficult because of the presence of trismus and swollen soft tissues. On occasion, cricothyroidotomy is performed instead of a tracheostomy because of a perceived lower risk of spreading the infection to the mediastinum.

Resolution of the infection involves elimination of the original focus of infection and intravenous (IV) antibiotic therapy. Penicillin with or without clindamycin or metronidazole frequently is the initial choice with culture and sensitivity testing used to guide final therapy. Although controversial, corticosteroids are prescribed by some clinicians to reduce swelling in order to protect the airway and augment antibiotic penetration.

Limited surgical incision and drainage is appropriate if collections of purulence can be identified. This decision is made best through a combination of physical examination and high-quality imaging. Contrast-enhanced computed tomography appears to be the best modality, but high resolution ultrasound also has been shown to be beneficial. Magnetic resonance imaging is utilized less frequently due to prolonged acquisition time, cost, and interaction with ferromagnetic materials such as implants. Cellulitis without identifiable pockets of purulence is managed medically after resolution of the original focus of infection. Before the use of modern antibiotic medications, the mortality from Ludwig angina often exceeded 50%. Although this rate has been reduced to less than 10%, deaths still occur as the result of complications such as pericarditis, pneumonia, mediastinitis, sepsis, empyema, and respiratory obstruction. The majority of deaths occur in patients over the age of 40 with complicating medical conditions such as diabetes, hypertension, and immunosuppression.

Cavernous Sinus Thrombosis

The therapeutic cornerstones for cavernous sinus thrombosis caused by dental infections are surgical drainage combined with high-dose broad-spectrum antibiotic medications exhibiting a good blood-brain-barrier penetration. The offending tooth should be extracted, and drainage is required if fluctuance is present. Administration of systemic corticosteroid drugs is indicated only in patients who have developed pituitary insufficiency in advanced cases of cavernous sinus thrombosis. Some investigators also prescribe anticoagulant medications to prevent thrombosis and septic emboli; conversely, others believe that thrombosis limits the infection and that the use of anticoagulant drugs may promote hemorrhagic lesions in the orbit and brain.

In older series the mortality rate approached 75%. Even with current medical advances and modern antibiotic medications, the mortality rate remains at approximately 20%–30% with many survivors demonstrating long-term disability such as permanent blindness, double vision, hemiparesis, and sixth cranial nerve palsy.

◆ OSTEOMYELITIS

Osteomyelitis is an acute or chronic inflammatory process in the medullary spaces or cortical surfaces of bone that extends away from the initial site of involvement. The term *osteomyelitis* arose from the ancient Greek words *osteon* (bone) and *muelinos* (marrow) and literally implies infection of the medullary segments of bone. This section describes the classic pattern of osteomyelitis.

The vast majority of osteomyelitis cases are caused by bacterial infections and result in an expanding lytic destruction of the involved bone, with suppuration and sequestra formation. Many believe that this condition is more appropriately termed *suppurative osteomyelitis, bacterial osteomyelitis,* or *secondary osteomyelitis*. This pattern of osseous pathosis is in contrast to an ill-defined group of idiopathic inflammatory disorders of bone that do not respond consistently to antibacterial medications and typically demonstrate ultimate sclerosis of bone without suppuration or sequestra formation. This second pattern of inflammatory bone disease is most

dentlearn.ir

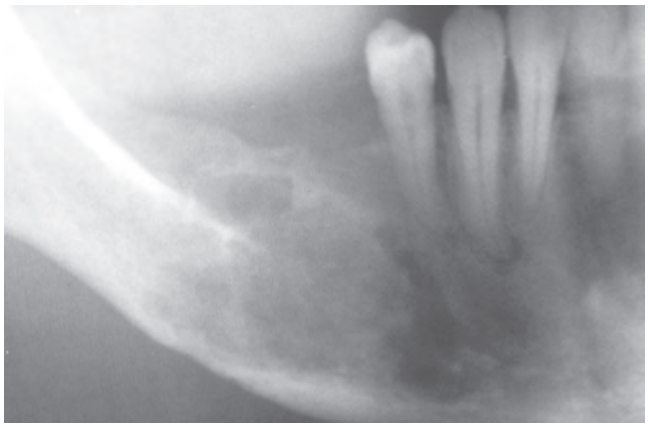
appropriately termed *primary chronic osteomyelitis* but often is included under the term *diffuse sclerosing osteomyelitis*. This disorder and several other patterns of inflammatory bone disease (e.g., focal sclerosing osteomyelitis, proliferative periostitis, and alveolar osteitis) are unique and are covered separately later in the chapter. Osteoradionecrosis is excluded from this discussion because this is primarily a problem of hypoxia, hypocellularity, and hypovascularity in which the presence of bacteria represents a secondary colonization of nonhealing bone rather than a primary bacterial infection (see page 283). In addition, medication-related osteonecrosis represents another unique pattern that is discussed in a later chapter and appears more strongly related to altered bone metabolism (see page 286).

Suppurative osteomyelitis of the jaws is uncommon in developed countries, but it continues to be a source of significant difficulty in developing nations. In Europe and North America, most cases arise after odontogenic infections or traumatic fracture of the jaws. In addition, many cases reported in Africa occur in the presence of necrotizing gingivitis (NG, see page 151) or noma.

Chronic systemic diseases, immunocompromised status, and disorders associated with decreased vascularity of bone appear to predispose people to osteomyelitis. Tobacco use, alcohol abuse, IV drug abuse, diabetes mellitus, exanthematous fevers, malaria, sickle cell anemia, malnutrition, malignancy, collagen vascular diseases, and AIDS have been associated with an increased frequency of osteomyelitis. In addition to radiation, several osseous diseases (e.g., osteopetrosis, dysosteosclerosis, late Paget disease, end-stage cemento-osseous dysplasia) may result in hypovascularized bone that is predisposed to necrosis and inflammation.

Acute suppurative osteomyelitis exists when an acute inflammatory process spreads through the medullary spaces of the bone and insufficient time has passed for the body to react to the presence of the inflammatory infiltrate. **Chronic suppurative osteomyelitis** exists when the defensive response leads to the production of granulation tissue, which subsequently forms dense scar tissue in an attempt to wall off the infected area. The encircled dead space acts as a reservoir for bacteria, and antibiotic medications have great difficulty reaching the site. This pattern begins to evolve about 1 month after the spread of the initial acute infection and results in a smoldering process that is difficult to manage unless the problem is approached aggressively.

Clinical and Radiographic Features



Patients of all ages can be affected by osteomyelitis. There is a strong male predominance, approaching 75% in some reviews. Most cases involve the mandible due to its relatively poor vascular supply and dense cortical bone that is more susceptible to infection when compared to the maxilla. Maxillary disease becomes important primarily in pediatric patients and in cases that arise from NG or noma (in African populations).

Acute Suppurative Osteomyelitis

Patients with acute osteomyelitis have signs and symptoms of an acute inflammatory process that has typically been less than 1 month in duration. Fever, leukocytosis, lymphadenopathy, significant sensitivity, and soft tissue swelling of the affected area may be present. Plain dental or panoramic radiographs may demonstrate an ill-defined radiolucency (Fig. 3.43), occasionally combined with widening of the periodontal ligament, loss of lamina dura, or loss of circumscription of the inferior alveolar canal or mental foramen. Periosteal new bone formation also may be seen in response to subperiosteal spread of the infection. This proliferation is more common in young patients and presents as a single-layered linear radiopaque line separated from the normal cortex by an intervening radiolucent band. Because plain radiographs require loss of up to 50% of bone mineral density to demonstrate an obvious pathosis, such films often may be unremarkable early in the course of infection. Scintigraphy and magnetic resonance imaging (MRI) demonstrate high sensitivity but low specificity. Conventional CT is a better choice due to its good combination of sensitivity and specificity. Being specially designed for imaging the gnathic hard tissues, cone-beam CT represents another excellent alterative with shorter scanning times and lower doses of radiation when compared to conventional CT. On occasion, paresthesia of the lower lip, drainage, or exfoliation of fragments of necrotic bone may be discovered. A fragment of necrotic bone that has separated from the adjacent vital bone is termed a **sequestrum.** Sequestra often exhibit spontaneous exfoliation (Fig. 3.44). On occasion, fragments of necrotic bone may become surrounded by new vital bone, and the dead bone in this situation is known as an **involucrum.**

Chronic Suppurative Osteomyelitis

If acute osteomyelitis is not resolved expeditiously, the entrenchment of **chronic osteomyelitis** occurs, or the process may arise primarily without a previous acute episode. Swelling, pain, sinus formation, purulent discharge, sequestrum formation, tooth loss, or pathologic fracture may occur.

• **Fig. 3.43 Acute Osteomyelitis.** Ill-defined area of radiolucency of the right body of the mandible.

dentlearn.ir

• **Fig. 3.44 Acute Osteomyelitis with Sequestrum.** Radiolucency of the right body of the mandible with central radiopaque mass of necrotic bone. (Courtesy of Dr. Michael Meyrowitz.)

Paresthesia of the lower lip is not uncommon in advanced cases. Patients may experience acute exacerbations or periods of decreased pain associated with chronic smoldering progression (Fig. 3.45).

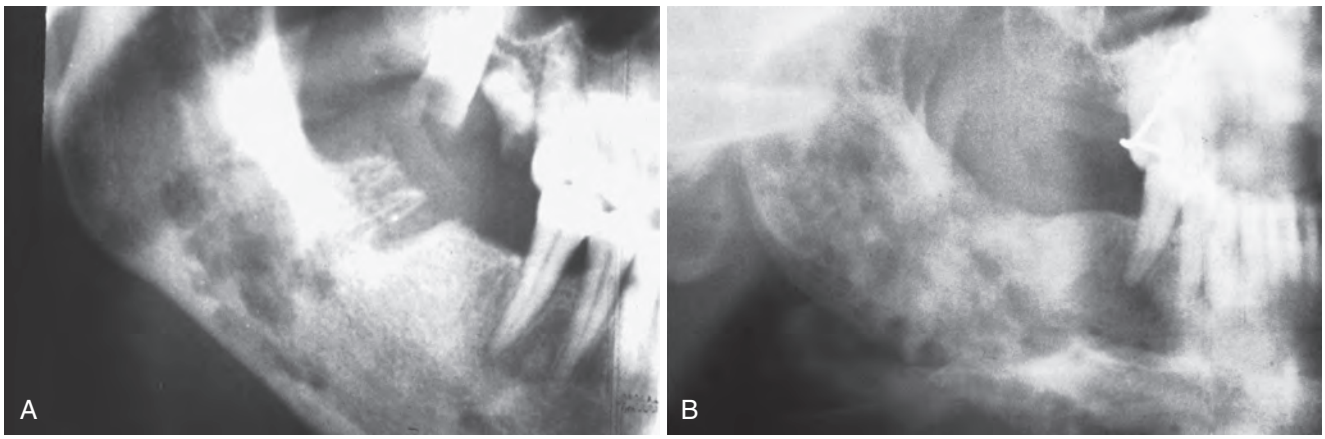
Radiographs reveal a patchy, ragged, and ill-defined radiolucency that may contain central radiopaque sequestra and be intermixed with zones of radiodensity. Less frequently, the infection may be predominantly osteosclerotic or occasionally almost totally osteolytic. The osseous change is continuous and may exhibit spread to the periosteum, often triggering periosteal new bone formation.

Because of an anatomic peculiarity, large portions of each jawbone receive their blood supply through multiple arterial loops originating from a single vessel. Involvement of this single feeder vessel can lead to necrosis of a large portion of the affected bone. Sequestration that has involved an entire quadrant of the jaw has been reported in long-standing cases of chronic osteomyelitis.

Histopathologic Features

Acute Suppurative Osteomyelitis

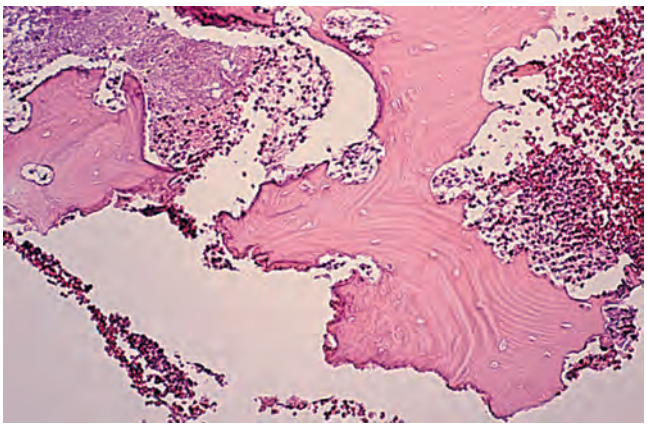
Generation of biopsy material from patients with acute osteomyelitis is not common because of the predominantly liquid content and lack of a soft tissue component. When submitted, the material consists predominantly of necrotic bone. The bone shows a loss of the osteocytes from their lacunae, peripheral resorption, and bacterial colonization (Fig. 3.46). The periphery of the bone and the haversian canals contain necrotic debris and an acute inflammatory infiltrate consisting of polymorphonuclear leukocytes. The submitted material will be diagnosed as a sequestrum unless a good clinicopathologic correlation points to the appropriate diagnosis of acute osteomyelitis.



Chronic Suppurative Osteomyelitis

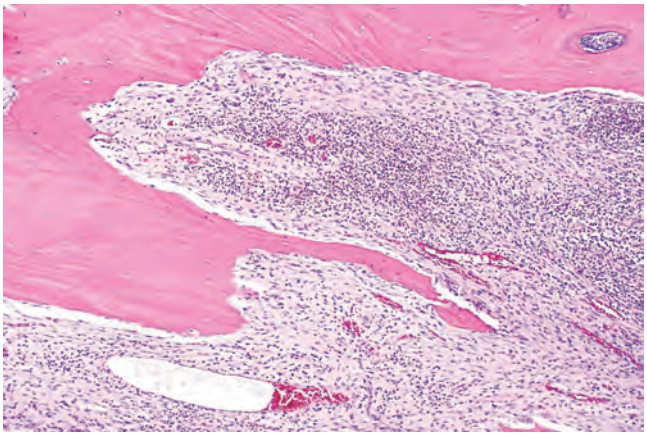
Biopsy material from patients with chronic osteomyelitis demonstrates a significant soft tissue component that consists of chronically or subacutely inflamed fibrous connective tissue filling the intertrabecular areas of the bone (Fig. 3.47). Scattered sequestra and pockets of abscess formation are common.

Treatment and Prognosis



Acute Suppurative Osteomyelitis

Therapy centers around surgical intervention to (1) resolve the source of infection, (2) establish drainage, (3) removal of obviously infected bone, and (4) obtain bacteriologic samples for culture and antibiotic sensitivity testing. While waiting on the bacteriologic evaluation, antibiotics are administered empirically, usually penicillin with metronidazole or clindamycin. Multiple procedures over days to weeks may be required for complete elimination of the infection and reconstruction of the gnathic defect.



• **Fig. 3.45 Chronic Osteomyelitis. A,** Ill-defined area of radiolucency of the right body of the mandible adjacent to a recent extraction site. **B,** After the initial intervention, the patient failed to return for follow-up because of lack of significant pain. An enlarged, ill-defined radiolucency of the right body of the mandible was discovered 2 years after the initial surgery. (Courtesy of Dr. Charles Waldron.)

dentlearn.ir

• **Fig. 3.46 Acute Osteomyelitis.** Nonvital bone exhibits loss of the osteocytes from the lacunae. Peripheral resorption, bacterial colonization, and surrounding inflammatory response also can be seen.

• **Fig. 3.47 Chronic Osteomyelitis.** Subacutely inflamed and reactive fibrous connective tissue filling the intertrabecular spaces with pockets of abscess formation and partially necrotic bone.

Chronic Suppurative Osteomyelitis

Chronic osteomyelitis is difficult to manage medically, presumably because pockets of dead bone and organisms are protected from antibiotic drugs by the surrounding wall of fibrous connective tissue. Surgical intervention is mandatory. The antibiotic medications are similar to those used in the acute form but must be given intravenously in high doses.

The extent of the surgical intervention depends on the spread of the process; removal of all infected material down to good bleeding bone is mandatory in all cases. For small lesions, curettage, removal of necrotic bone, and saucerization are sufficient. In patients with more extensive osteomyelitis, decortication or saucerization often is combined with transplantation of cancellous bone chips. In cases of persisting osteomyelitis, resection of the diseased bone followed by immediate reconstruction with an autologous graft is required. Weakened jawbones must be immobilized.

The goal of surgery is removal of all infected tissue. Persistence of chronic osteomyelitis is typically the result of incomplete removal of diseased tissue. On successful elimination of all infected material, resolution is expected. Adjunctive procedures (e.g., hyperbaric oxygen) are rarely necessary if thorough surgical curettage and sequestrectomy have been accomplished.

Management of persistent cases of chronic osteomyelitis often requires use of more sophisticated techniques. Scintigraphic techniques with technetium-99m (^{99m}Tc)-labeled phosphorus compounds can be used to evaluate the therapeutic response and progress of treatment. Hyperbaric oxygen is recommended primarily for the rare patient who does not respond to standard therapy or for disease arising in hypovascularized bone (e.g., osteoradionecrosis, osteopetrosis, Paget disease, and cemento-osseous dysplasia).

◆ DIFFUSE SCLEROSING OSTEOMYELITIS

Diffuse sclerosing osteomyelitis (DSO) is characterized by more widespread infection associated with varying degrees of gnathic periosteal hyperplasia, sclerosis, and radiolucency. The term DSO should be used only when an obvious infectious process directly is responsible for sclerosis of bone. In these cases, a chronic intraosseous bacterial infection creates a smoldering mass of chronically inflamed granulation tissue that incites sclerosis of the surrounding bone.

Clinical and Radiographic Features

Diffuse sclerosing osteomyelitis is similar to the localized variant (condensing osteitis; see page 141); however, the disorder also is very different. It arises almost exclusively in adulthood, does not exhibit a sex predominance, and primarily occurs in the mandible. An increased radiodensity develops around sites of chronic infection (e.g., periodontitis, pericoronitis, and apical inflammatory disease) in a manner very similar to the increased radiodensity that may be seen surrounding areas of chronic suppurative osteomyelitis. Typically, the altered area is restricted to a single site but may be multifocal or extend to fill an entire quadrant.

The sclerosis centers on the crestal portions of the tooth-bearing alveolar ridge and does not appear to originate in the areas of attachment of the masseter or digastric muscle. The radiodensities do not develop from previously radiolucent fibro-osseous lesions and do not exhibit the predilection for black females, as is found in those patients with florid cemento-osseous dysplasia. Pain and swelling are not typical.

Histopathologic Features

Diffuse sclerosing osteomyelitis demonstrates sclerosis and remodeling of bone. The haversian canals are scattered widely and little marrow tissue can be found. Although the sclerosis occurs adjacent to areas of inflammation, the bone typically is not intermixed with a significant inflammatory soft tissue component. If the adjacent inflammatory process extends into the sclerotic bone, then necrosis often occurs. The necrotic bone separates from the adjacent vital tissue and becomes surrounded by subacutely inflamed granulation tissue. Secondary bacterial colonization often is visible.

dentlearn.ir

Treatment and Prognosis

Diffuse sclerosing osteomyelitis is treated best through resolution of the adjacent foci of chronic infection. After resolution of the infection, the sclerosis remodels in some patients but remains in others. The persistent sclerotic bone is hypovascular, does not exhibit typical remodeling, and is very sensitive to inflammation. The patient and the clinician should work together to avoid future problems with periodontitis or apical inflammatory disease. With long-term alveolar resorption after denture placement, the altered bone does not exhibit typical resorption, and exposure of the bone through the overlying mucosa may occur with secondary osteomyelitis. These secondary lesions can be treated in the same way as a primary acute or chronic suppurative osteomyelitis (see page 136).

◆ CHRONIC NONBACTERIAL OSTEOMYELITIS

Chronic nonbacterial osteomyelitis (primary chronic osteomyelitis) often is confused with, but must be distinguished from, diffuse sclerosing osteomyelitis (DSO) and chronic suppurative osteomyelitis. In contrast to DSO and suppurative osteomyelitis, an association with a bacterial infection is not obvious, and suppuration with sequestration characteristically are absent. A number of causes have been proposed, such as a primary autoimmune disease or an altered immune response to an organism of low virulence, but no single theory has received widespread acceptance. In contrast to suppurative osteomyelitis, cultures are negative in almost all patients and the condition does not respond to long-term antibiotic therapy.

Chronic nonbacterial osteomyelitis (CNO) may be a primary disorder or represent **chronic tendoperiostitis**. Many clinicians believe chronic tendoperiostitis represents a reactive alteration of bone that is initiated and exacerbated by chronic overuse of the masticatory muscles, predominantly the masseter and digastric. In a large series of patients, parafunctional muscle habits (e.g., bruxism, clenching, nail biting, co-contraction, and inability to relax jaw musculature) were known or became evident during follow-up. In neurophysiologic studies, masseter inhibitory reflexes were abnormal in the vast majority of patients studied.

Although CNO may be isolated to the jaw, it could represent one focus of involvement in a patient with more widespread disease, such as **chronic recurrent multifocal osteomyelitis** (**CRMO**), **SAPHO syndrome**, or **sternocostoclavicular hyperostosis** (**SCCH**). Chronic recurrent multifocal osteomyelitis demonstrates involvement of multiple bones and is thought by many to represent a widespread variant of chronic nonbacterial osteomyelitis. SAPHO syndrome is closely related and an acronym for a complex clinical presentation that includes **S**ynovitis, **A**cne, **P**ustulosis, **H**yperostosis, and **O**steitis in which the osseous lesions mirror those of chronic nonbacterial osteomyelitis or CRMO. Sternocostoclavicular hyperostosis most likely represents a subset of CRMO and SAPHO in which the extragnathic bone involvement preferentially affects the sternum, medial end of the clavicle, and upper ribs. All three disorders are associated with an increased prevalence of autoimmune diseases (such as inflammatory bowel disease and seronegative spondyloarthropathies) and skin diseases such as psoriasis, palmoplantar pustulosis, acne fulminans, and acne conglobata. The cause of CRMO and SAPHO is unknown, but they possibly may arise in genetically predisposed individuals with apparent autoimmunity. In rare cases, dermatologic bacteria (most frequently *Propionibacterium acnes*) have been cultured from the osseous lesions, leading researchers to theorize that an abnormal immune response to the microorganism cross-reacts with normal bone or joint structures, leading to the variety of clinical manifestations. Despite this, no widely accepted explanation exists for these lesions.

Clinical and Radiographic Features

Chronic nonbacterial osteomyelitis (CNO) frequently is discovered as an isolated process that typically is localized to the mandible, although patients should be evaluated for extragnathic evidence of SAPHO syndrome or CRMO. The onset of symptoms tends to show two peaks, one in adolescence and the other in adults after the fifth decade of life. A female predominance is noted. Affected patients have recurrent episodes of pain, swelling, local induration, and limited mouth opening that is not associated with any obvious dental infection. Enlargement and tenderness of the overlying soft tissue and masseter muscle often are noted. During periods of disease activity, regional lymphadenopathy and reduced sensation in the distribution of the inferior alveolar nerve may be present. Laboratory testing often with show an elevation of the erythrocyte sedimentation rate and C-reactive protein levels, but the white blood cell count usually is within the normal reference range. Absence of fever, purulence, sequestration, and sinus formation are characteristic. The lack of an obvious association with an odontogenic infection and the nonsuppurative presentation clearly separate this condition from DSO and chronic suppurative osteomyelitis.

In the early stages of CNO, radiographs tend to demonstrate a mixed pattern, with areas of radiolucent osteolysis intermingled with zones of sclerosis (Fig. 3.48). In contrast to the pattern noted in CT images of suppurative osteomyelitis, the osteolytic areas are not continuous and alternate with zones of sclerosis. The affected area of the bone typically is thickened and demonstrates a periosteal proliferation that is more solid than the typical laminated proliferative periostitis of inflammatory origin. Facial asymmetry is not uncommon and often takes years to resolve secondary to slow remodeling. Over time, the affected area becomes predominantly sclerotic, but during subsequent periods of disease activity, new foci of osteolysis and cortical bone destruction appear. These newly affected areas subsequently undergo sclerosis, awaiting the next cycle of disease activity. With disease progression, the clinical symptoms typically diminish,

dentlearn.ir

and the affected bone demonstrates progressive sclerosis and a reduction in the volume. Radiolucent osteolytic areas may remain, but they tend to be relatively small and widely scattered. Overall, the predominant radiographic alteration of primary chronic osteomyelitis is medullary sclerosis, a pattern that is noted invariably in affected patients. Skeletal scintigraphy demonstrates significant uptake in the affected areas and should be performed in all patients in an effort to rule out extragnathic involvement. Alternatively, whole-body coronal magnetic resonance imaging (MRI) with a short tau inversion recovery sequence has proven to be valuable is discovering multifocal skeletal involvement.

• **Fig. 3.48 Chronic Nonbacterial Osteomyelitis**. Sclerosis of the left posterior mandible intermixed with foci of radiolucency and overlying periosteal hyperplasia. No associated odontogenic infection was present. The patient also presented with trimus, tenderness, and soft tissue enlargement. (Courtesy of Dr. Benjamin Noblitt.)

Chronic Tendoperiostitis

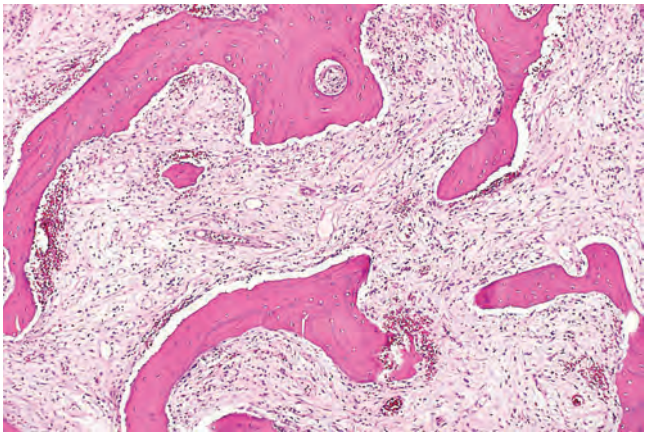
Chronic tendoperiostitis may occur in people of all ages and there is no sex predilection. Recurrent pain, swelling of the cheek, trismus, and limited mouth opening are classic symptoms. Suppuration and an associated infectious cause are not found. Microbiologic cultures are typically negative, with the lesions failing to respond to appropriate antibiotic medications. Uncommon spontaneous resolution with development of radiographic normalcy has been noted.

In most instances, the sclerosis is limited to a single quadrant and centers on the anterior region of the mandibular angle and posterior portion of the mandibular body (i.e., attachment of the masseter muscle). Occasionally, the cuspid and premolar region and the anterior mandible (i.e., attachment of the digastric muscle) may be involved. Relatively radiolucent zones are apparent within the areas of radiodensity. The inferior border of the mandibular body may be affected with significant erosion of the inferior border appearing just anterior to the angle of the mandible (Fig. 3.49). Condylar process deformations are noted in occasional patients and have been suggested secondary to external forces of the masticatory muscles.

CRMO and SAPHO Syndrome

CRMO and SAPHO syndrome appear closely related, and many believe that CRMO represents the pediatric variant of SAPHO. CRMO presents in childhood with pain and swelling of multiple bones, particularly the metaphysis of

• **Fig. 3.49 Chronic Tendoperiostitis**. Diffuse mottled sclerosis of the left side of the mandible with erosion of the inferior border and focal radiolucent notching at the site of the masseter muscle insertion. Coronoid hyperplasia also is present, another sign of the temporomandibular disorder. (Courtesy of Dr. J. P. R. van Merkesteyn.)



dentlearn.ir

long bones, the pelvis, spine, and clavicles. Affected bones typically demonstrate hyperostosis with osteitis that is associated with negative microbiologic cultures and lack of response to antibiotics. Many patients demonstrate concurrent or future neutrophilic skin diseases, such as palmoplantar pustulosis, severe acne, hidradenitis suppurativa, psoriasis, Sweet syndrome, or pyoderma gangrenosum. The dermatologic involvement may be absent, appear after some delay, or be so subtle as to escape detection. In contrast, SAPHO usually is noted in adults, classically affects the axial skeleton (anterior chest wall), and more frequently demonstrates concurrent neutrophilic skin lesions. Gnathic involvement has been reported in both CRMO and SAPHO, mandating full bone scan in any patient with an unexplained chronic nonbacterial osteomyelitis. In contrast to bacterial osteomyelitis, the osteolytic areas are scattered randomly within areas of sclerotic bone. Periosteal new bone formation is common but not related to cortical bone perforation. Investigation of the entire skeleton by bone scintigraphy or magnetic resonance imaging (MRI) classically reveals involvement of multiple sites.

In early gnathic lesions, diffuse osteolytic zones are more prominent than sclerosis, and the affected bone is enlarged because of significant production of periosteal new bone. With time, the bone becomes more sclerotic and decreases in size because of diminished periosteal apposition, while the osteolytic zones become smaller and fewer. External bone resorption and deformity of the mandible are characteristic in older lesions.

Histopathologic Features

Similar histopathologic features of the gnathic lesions are seen in isolated chronic nonbacterial osteomyelitis, SAPHO syndrome, CRMO, SCCH, and chronic tendoperiostitis. The periosteal proliferation reveals parallel and interconnecting thin trabeculae of bone with intervening strips of loose connective tissue. The medullary areas are filled with thin curvilinear trabeculae of cellular woven bone with a hypocellular fibroblastic stroma. These areas easily can be confused with immature fibrous dysplasia (see page 641). In other areas, the curvilinear bone may be lamellar with evidence of significant remodeling and an intermixed chronically inflamed and reactive stroma (Fig. 3.50). The radiolucent foci within the sclerotic bone represent areas of patchy and nodular fibrosis, often demonstrating a chronic inflammatory cellular infiltrate. Also noted with the areas of fibrosis and inflammation are irregular osseous trabeculae with atypical osteoid and significant cellularity that can be worrisome if observed out of context. In the areas of extensive sclerosis, numerous irregular trabeculae of pagetoid bone are present and demonstrate extensive evidence of remodeling with prominent reversal lines, osteoblastic rimming, and focal areas of osteoclastic activity. In obvious contrast to chronic suppurative osteomyelitis, bone necrosis, bacterial colonization, and frank purulence are absent.

• **Fig. 3.50 Chronic Nonbacterial Osteomyelitis.** Curvilinear trabeculae of bone with numerous reversal lines and peripheral resorption intermixed with chronically inflamed and reactive connective tissue.

Treatment and Prognosis

This group of disorders is rare with a limited number of randomized and double-blind studies of the effectiveness of various therapeutic approaches. It can be difficult to ascertain if the clinical responses represent a true therapy-induced alteration or natural waxing and waning of disease activity in these patients.

The first step in patient management is whole body skeletal scintigraphy or MRI to rule out extragnathic bone involvement. If multifocal involvement is noted, the patient should be referred to a rheumatologist for thorough evaluation and systemic therapy. Therapies proven to be effective include nonsteroidal anti-inflammatory medications, corticosteroids, tumor necrosis factor α inhibitors, sulfasalazine, and methotrexate. If the lesions are restricted to bone without dermatologic or GI manifestation, bisphosphonates have proven successful in many patients. In spite of successful management of the majority of patients, recurrences have been noted, often leading to additional therapeutic interventions.

Most treatments directed toward elimination of infection have been proven ineffective. Long-term antibiotic treatment with or without hyperbaric oxygen therapy has not produced consistent long-term success. Surgical decortication has decreased the intensity and frequency of symptoms but has failed to resolve the process totally. Because of inconsistent results from surgical intervention, extensive surgery is contraindicated, especially in young, growing patients.

If the lesions are isolated to the mandible, the patient should be evaluated, and if appropriate, treated for **chronic tendoperiostitis**. The patients should be evaluated for persistent temporomandibular dysfunction symptoms and parafunctional habits. In patients with evidence of tendoperiostitis, nonsteroidal anti-inflammatory medications (etoricoxib or naproxen) combined with conservative therapy directed toward resolution of muscle overuse have resulted in significantly decreased symptoms in most patients and total resolution in a many. The ultimate goal of physical

dentlearn.ir

therapy is to make the patient aware of any parafunctional habits and to discontinue such movements through the following approaches:

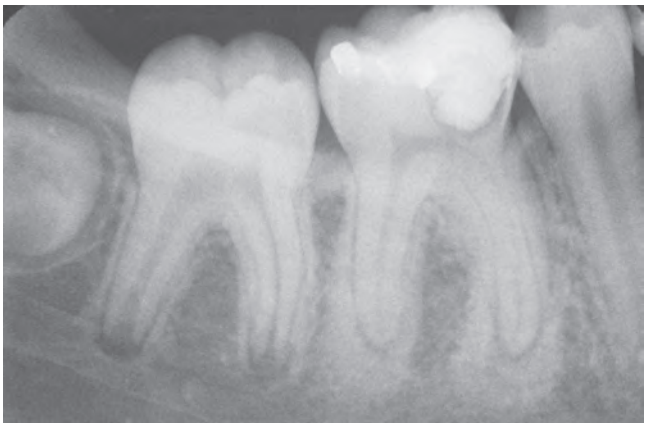
- Muscular relaxation instructions (soft diet, avoidance of parafunctional habits)
- Rotation exercises
- Occlusal splint therapy
- Myofeedback
- Muscle relaxant drugs (e.g., diazepam)

If the patient fails after respond to 6–12 months of conservative therapy or demonstrates no evidence of chronic tendoperiostitis upon evaluation (such as TMJ dysfunction or parafunctional habits), bisphosphonate therapy (pamidronate) of short duration has proven beneficial in both pediatric and adult patients. Limited studies also have revealed a similar benefit to use of denosumab but with more frequent recurrences and the need for more extended therapy. If the antiresorptive medications prove ineffective, the systemic immune modulating medications described for use in patients with multifocal involvement should be considered.

◆ CONDENSING OSTEITIS (FOCAL SCLEROSING OSTEOMYELITIS)

Localized areas of bone sclerosis associated with the apices of teeth with pulpitis (from large carious lesions or deep coronal restorations) or pulpal necrosis are termed **condensing osteitis.** The association with an area of inflammation is critical because these lesions can resemble several other intrabony processes that produce a somewhat similar pattern.

Clinical and Radiographic Features



This secondary sclerosis of bone is seen most frequently in children and young adults but also can occur in older adults. The classic alteration consists of a localized, usually uniform zone of increased radiodensity adjacent to the apex of a tooth that exhibits a thickened periodontal ligament (PDL) space or an apical inflammatory lesion (Fig. 3.51). Clinical expansion should not be present. Most cases occur in the premolar and molar areas of the mandible, and the dental pulp of the involved tooth demonstrates pulpitis or necrosis. The lesion does not exhibit a radiolucent border, as is seen in cases of **focal cemento-osseous dysplasia** (see page 645), although an adjacent radiolucent inflammatory lesion may be present. In addition, the radiopacity is not separated from the apex as would be seen in **idiopathic osteosclerosis** (see page 626).

Treatment and Prognosis

Treatment of the patient with condensing osteitis consists of resolution of the odontogenic focus of infection. After extraction or appropriate endodontic therapy of the involved tooth, approximately 85% of cases of condensing osteitis will regress, either partially or totally. Typically, resolution of the lesion is associated with normalization of the associated periodontal membrane. If the lesion persists and the periodontal membrane remains wide, then reevaluation of the endodontic therapy should be considered. A residual area of condensing osteitis that remains after resolution of the inflammatory focus is termed a *bone scar* (Fig. 3.52). Root resorption has been noted during orthodontics if the sclerotic bone is the path of tooth movement.

◆ OSTEOMYELITIS WITH PROLIFERATIVE PERIOSTITIS (PERIOSTITIS OSSIFICANS, OSSIFYING PERIOSTITIS)

Bone formation within a periosteal reaction is a common finding that occurs in a wide variety of intraosseous pathoses and in all age groups. Causes of periosteal new bone formation include osteomyelitis, trauma, cysts, infantile cortical hyperostosis, fluorosis, avitaminosis C, hypertrophic osteoarthropathy, congenital syphilis, and neoplasms (such as, Ewing sarcoma, Langerhans cell histiocytosis, and osteogenic sarcoma). Of these, osteomyelitis and malignant neoplasms are associated most frequently with formation of bone within a periosteal reaction.

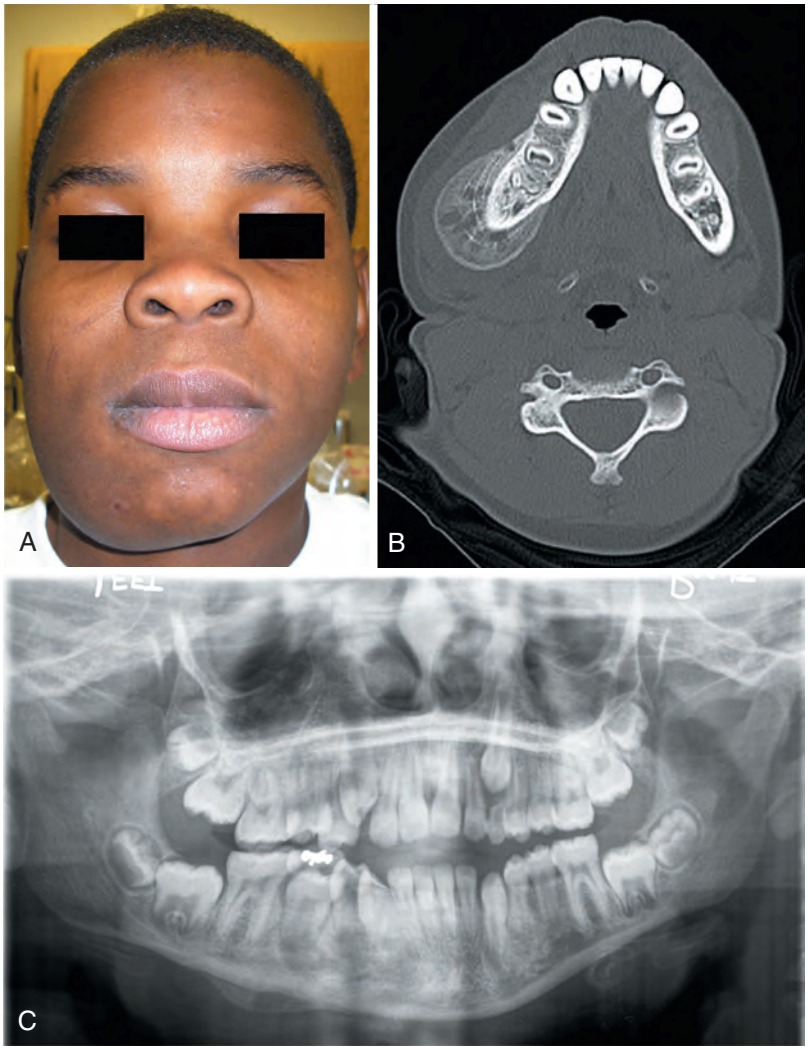
dentlearn.ir



In 1893 a Swiss physician, Carl Garrè, reported in the German literature on patterns of acute osteomyelitis. Since that time, numerous articles have been written that associate Garrè's report with a form of inflammatory periosteal hyperplasia demonstrating an onionskin-like reduplication of the cortical plate. (In these subsequent articles, Garrè's name was misspelled consistently as Garré, with an incorrect accent designation.) However, Garrè did not have any pathologic specimens for microscopic examination, and Roentgen did not discover X-rays until 2 years after Garrè's publication. Nowhere in the original publication is there any mention of periostitis, periosteal duplication, or "onionskinning." Although the term *Garrè osteomyelitis* often is used synonymously for this condition, it is an improper designation that should be disassociated with the entity described in the text that follows.

Clinical and Radiographic Features

Proliferative periostitis represents a periosteal reaction to the presence of inflammation. The affected periosteum forms several rows of reactive vital bone that parallel each other and expand the surface of the altered bone. Affected patients tend to be primarily children and young adults, with a mean age of 13 years. No sex predominance is noted.

As expected, the most frequent cause is dental caries with associated periapical inflammatory disease, although lesions have been reported secondary to periodontal infections, pericoronitis, tooth extractions, fractures, buccal bifurcation cysts, and non-odontogenic infections. Examples adjacent to an unerupted developing tooth also have been documented. Most cases arise in the premolar and molar area of the mandible. The hyperplasia is located most frequently along the lower border of the mandible, but buccal cortical involvement also is common. Isolated lingual cortical enlargement is infrequent. Most cases are unifocal, although multiple quadrants may be affected.

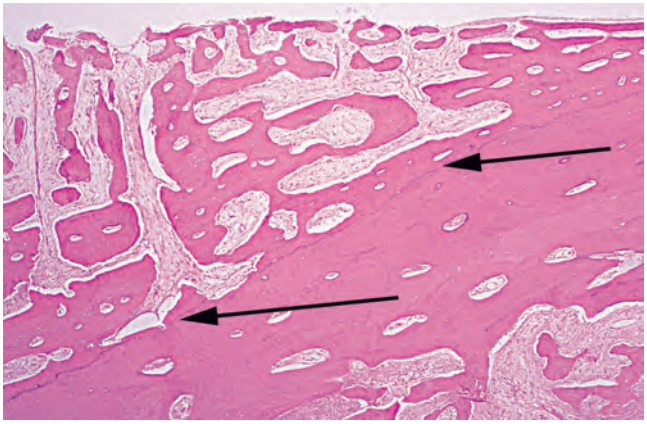
Appropriate radiographs demonstrate radiopaque laminations of bone that roughly parallel each other and the underlying cortical surface (Fig. 3.53). The laminations vary from 1 to 12 in number, and radiolucent separations often are present between the new bone and the original cortex. Less frequently, the new bone formation exhibits consolidation and contains numerous fine bony projections that radiate

• **Fig. 3.53 Proliferative Periostitis. (Courtesy of Drs. Sherif Mekhail and Benjamin Lin.)

dentlearn.ir

perpendicular from the underlying and intact periosteum. Within the new bone, areas of small sequestra or osteolytic radiolucencies may be found.

Because of difficulty in proper angulation and problems related to superimposition of the underlying bone, CT scanning has proved to be consistently superior to conventional radiography in demonstrating proliferative periostitis. On plain films, the alterations are typically seen best on a panoramic or lateral oblique radiograph. If lateral oblique radiographs fail to demonstrate the lesion, then occlusal views and, less frequently, posteroanterior radiographs may be successful.



Histopathologic Features

Usually, biopsy is not required unless the clinical diagnosis is in question. Specimens often reveal parallel rows of highly cellular and reactive woven bone in which the individual trabeculae are frequently oriented perpendicular to the surface. The trabeculae sometimes form an interconnecting meshwork of bone or are scattered more widely, resembling the pattern seen in immature fibrous dysplasia (Fig. 3.54). Between the cellular trabeculae, relatively uninflamed fibrous connective tissue is evident. Sequestra, if included, demonstrate the typical features of bone necrosis (see Osteomyelitis, page 134).

Treatment and Prognosis

Most cases of proliferative periostitis of the jaws are associated with periapical inflammatory lesions, and treatment in these cases (either extraction of the offending tooth or appropriate endodontic therapy) is directed toward eliminating the source of the infection. After the focus of infection has been eliminated and inflammation has resolved, the layers of bone will consolidate in 6–12 months as the overlying muscle action helps to remodel the bone to its original state.

If a unifocal periosteal reaction similar to proliferative periostitis appears in the absence of an obvious source of inflammation, biopsy is recommended because several neoplastic conditions can result in a similar pattern.

• **Fig. 3.54 Proliferative Periostitis.** Interconnecting trabeculae of new bone formation *(top left)* extending from the original cortical surface *(delineated by arrows).*

◆ ALVEOLAR OSTEITIS (DRY SOCKET; FIBRINOLYTIC ALVEOLITIS)

After extraction of a tooth, a blood clot is formed at the site, with eventual organization of the clot by granulation tissue, gradual replacement by coarse fibrillar bone, and, finally, replacement by mature bone. Premature fibrinolysis of the initial clot is thought to be responsible for the clinical condition known as **alveolar osteitis.** Factors deemed to be associated with an increased prevalence include increasing age, oral contraceptive use, tobacco use, preoperative infection, difficult extraction, inexperienced surgeons, surgical flap design (envelope flap rather than modified triangular flap), use of a local anesthetic with vasoconstrictor, and inadequate postoperative irrigation. Of these factors, age, a preoperative infection, and difficulty of extraction have been shown in systematic reviews to be most strongly associated with the development of alveolar osteitis.

Clinical Features

The frequency of alveolar osteitis is higher in the mandible and the posterior areas. After oral contraceptive use is taken into account, there does not appear to be a significant sex predilection. The prevalence is between 1% and 3% of all extractions, but it increases to 25%–30% for impacted mandibular third molars. The frequency appears to be decreased when impacted teeth are removed prophylactically rather than for pericoronitis. The overall prevalence is highest between 20 and 40 years of age (when the majority of teeth are extracted), although the likelihood of developing alveolar osteitis appears greatest for extractions in the 40- to 45-year-old age group.

The affected extraction site is filled initially with a dirty gray clot that is lost and leaves a bare bony socket **(dry socket).** The detection of the bare socket may be hindered by partial retention of the clot or by overlying inflamed tissue that covers the site. The diagnosis is confirmed by probing of the socket, which reveals exposed and extremely sensitive bone. Typically, severe pain, foul odor, and (less frequently) swelling and lymphadenopathy develop 3–4 days after extraction of the tooth. On occasion, the pain radiates from the socket to the ipsilateral ear, temporal region, or eye. Rarely, trismus also may be noted. The signs and symptoms may last from 10 to 40 days.

Treatment and Prognosis

On evaluation of the patient complaining of postextraction pain, a radiograph should be taken of the affected area to rule out the possibility of a retained root tip or a foreign body. All sutures should be removed. The socket is irrigated with warm saline, followed by thorough clinical inspection of the socket for any unexpected pathosis. Curettage of the socket is not recommended, because this typically increases the associated pain. Potent oral analgesics should be prescribed, and the patient should be given a plastic syringe with

dentlearn.ir

instructions to keep the socket clean via home irrigation with a chlorhexidine or saline solution. This irrigation should continue until debris no longer collects within the healing socket (usually 3–4 weeks).

Use of an obtundent and antiseptic dressing, such as iodoform gauze containing eugenol, is controversial. Although the dressing may reduce the symptoms and help keep out food debris, many believe the dressing acts as foreign material and delays healing of the extraction socket. If a dressing is used, then it should be changed every 24 hours for the first 3 days, then every 2–3 days until granulation tissue covers the exposed bone. The dressing should be discontinued as soon as the patient is pain free. After that time, the patient should be given a plastic syringe with instructions for home irrigation.

Many investigators have studied preventive measures for alveolar osteitis including systemic and topical antibiotics, corticosteroids, cessation of smoking the day before and after surgery, copious surgical irrigation, antifibrinolytic agents, platelet-rich fibrin, chlorhexidine gel, and chlorhexidine rinses. Of these interventions, chlorhexidine in any formulation has been shown in multiple systematic reviews to be associated most consistently with a decreased frequency of alveolar osteitis. Chlorhexidine gel placed into the socket appears to be moderately more effective than rinses, with a possibly improved response if covered by a platelet-rich fibrin membrane. Any topical therapy should not be in an ointment form, because such use has resulted in chronic foreign body reactions (e.g., myospherulosis) (see page 315). Some investigators have suggested that debris in the healing socket could disturb wound healing and increase the prevalence of alveolar osteitis. To avoid this problem, gentle irrigation of socket with tap water beginning 48 hours after the surgery has been suggested by some. Finally, failure to follow the surgeon's postextraction instructions also may contribute and stresses the need for quality communication between the clinician and patient.

4
Periodontal Diseases

In this textbook of oral and maxillofacial pathology, the discussion of periodontal diseases is limited appropriately in scope. However, several fine textbooks are available on periodontology and can provide the reader with more information on the background, microbiology, clinical presentations, diagnostic procedures, and current therapies used to treat these diseases.

◆ GINGIVITIS

Gingivitis refers to inflammation limited to the soft tissues that surround the teeth. It does not include the inflammatory processes that may extend into the underlying alveolar ridge, periodontal ligament, or cementum. A similar pattern of inflammation has noted in the mucosa surrounding implants and has been termed **peri-implant mucositis** (see page 167). The primary types of gingivitis are listed in Box 4.1. This part of the text concentrates on the plaque-related types. **Necrotizing gingivitis, medication-influenced gingivitis,** and a specific type of allergic gingivitis **(plasma cell gingivitis)** are presented later in this chapter. Additional forms of allergic gingivitis are discussed in Chapter 9. The gingivitis associated with certain specific infections (e.g., herpes simplex, and human immunodeficiency virus [HIV]) is discussed in Chapters 5 and 7. The gingiva is a frequent site of involvement in several of the dermatologic vesiculoerosive diseases; these are well described in Chapter 16.

The rate, severity, and extent of gingivitis varies according to local and systemic risk factors. The primary local risk factor is the accumulation of plaque, which is related to the level of oral hygiene and anatomical factors such as subgingival restorations and tooth anomalies. Reduced salivary flow also increases the risk for gingivitis due to reduced cleansing of tooth surfaces. Systemic risk factors include metabolic conditions such as hyperglycemia, nutritional factors such as vitamin C deficiency, elevation of sex hormones as seen during puberty and pregnancy, hematologic disorders such as leukemia, and medications that may reduce salivary flow, induce gingival enlargement, or increase sex hormones. The first-generation high-dose oral contraceptives were associated with an increased prevalence of gingivitis, a finding not noted with the newer low-dose formulations. Surprisingly, due to associated vasoconstriction and fibrosis, smoking tends to mask clinical signs of gingivitis such as bleeding upon probing.

Clinical Features

Most cases of gingivitis occur from lack of proper oral hygiene, which leads to the accumulation of dental plaque and calculus; however, many other factors can affect the gingiva's susceptibility to the oral flora. The frequency of gingivitis is high in all age groups, with a prevalence that approaches 95%. Clinically detectable inflammatory changes of the gingiva begin in childhood and increase with age. With similar amounts of dental plaque, the severity of gingivitis is greater in adults than in prepubertal children. Around the time of puberty, there is a period of increased susceptibility to gingivitis **(puberty gingivitis),** with the peak prevalence of involvement occurring between the ages of 9 and 14 years. Between the ages of 11 and 17 years, the frequency declines; then a slow increase is seen until the prevalence approaches 100% in the sixth decade of life.

In most age groups, females demonstrate a lower frequency of gingivitis than do males (although females have periods of increased susceptibility). This may be due more to better oral hygiene in females than to a physiologic difference between the genders. In addition to the years of puberty, females exhibit a greater susceptibility to gingivitis when they are exposed to the high levels of progesterone associated with pregnancy or the older high-dose formulations of oral contraceptives. Several other systemic factors have been shown to increase the frequency of gingivitis and are listed in Box 4.2. In contrast, smoking and use of many antibiotic drugs, corticosteroid medications, and nonsteroidal anti-inflammatory drugs (NSAIDs) have been correlated with a reduced gingival response to plaque. Various local factors that can be related to gingivitis are shown in Box 4.3.

Injury to the gingiva from mastication, oral hygiene techniques, or other habits may result in a breach of the oral mucosa, with secondary infection from the local flora. Most such injuries result in transient areas of erythema. However, if the trauma follows a chronic pattern, then areas of persistently swollen, erythematous gingiva may result. Patients who are mouth breathers or demonstrate incomplete lip closure can display a unique pattern of gingivitis in which the anterior facial gingiva is smooth, swollen, and red (Fig. 4.1).

Susceptibility to plaque-related gingivitis appears to vary within the population, and the individual traits seem to determine the severity of gingivitis, independent of the degree of plaque accumulation. In addition, evidence

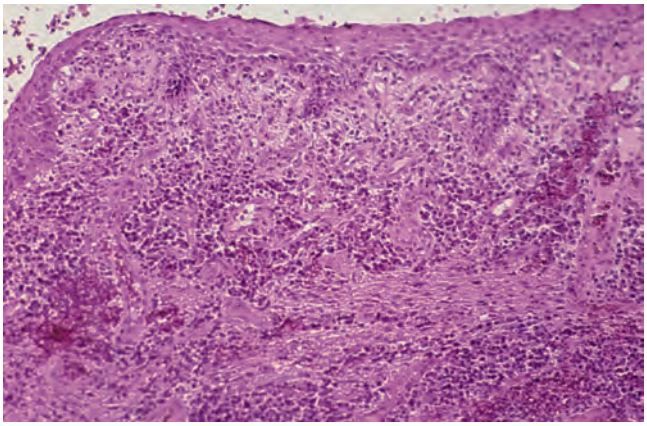
• **Fig. 4.2 Marginal Gingivitis.** Diffuse erythematous alteration of the free gingival margins.

suggests that susceptibility to gingivitis appears linked to susceptibility to future development of periodontitis.

Inflammation of the gingiva may be localized or generalized. If the altered gingiva is associated with less than 30% of the teeth, the process is considered localized, whereas generalized gingivitis demonstrates a wider degree of involvement. The inflammation may be diffuse or confined to the free gingival margins **(marginal gingivitis)** (Fig. 4.2) or the interdental papillae **(papillary gingivitis).** The earliest signs of gingivitis include a loss of stippling plus bleeding on gentle probing. Healthy gingiva is coral pink; with inflammation, the involved gingiva becomes light red. Moderate gingivitis demonstrates glazing, edema, an erythematous enlargement, and bleeding upon probing. Alterations noted in severe gingivitis include an overtly red and edematous appearance with a tendency to bleed easily upon light touching, often with margins that may be blunted, receded, or hyperplastic (Fig. 4.3). When chronic inflammation causes significant enlargement because of edema or fibrosis, the process is termed **chronic hyperplastic gingivitis** (Fig. 4.4). Bleeding

dentlearn.ir



• **Fig. 4.3 Chronic Gingivitis.** Bright-red gingiva is blunted, receded, and hyperplastic secondary to a total lack of oral hygiene. Note the extensive calculus buildup.

• **Fig. 4.5 Hyperplastic Gingivitis with Pyogenic Granuloma.** Diffuse erythematous enlargement of marginal and papillary gingiva with hemorrhagic, tumorlike proliferation (which arose during pregnancy) between the maxillary bicuspid and first molar.

• **Fig. 4.4 Chronic Hyperplastic Gingivitis.** Diffuse erythema and enlargement of marginal and papillary gingiva.

• **Fig. 4.6 Chronic Gingivitis.** Sulcular epithelium with exocytosis overlying connective tissue that contains inflammatory infiltrate consisting of lymphocytes, plasma cells, and polymorphonuclear leukocytes.

occurs easily, and exudate can be seen in the gingival sulcus. A localized tumorlike proliferation of subacutely inflamed granulation tissue, known as a **pyogenic granuloma** (see page 525), can develop on the gingiva of patients with severe gingivitis (Fig. 4.5).

Histopathologic Features

Incipient gingivitis demonstrates a light inflammatory infiltrate consisting of polymorphonuclear leukocytes that accumulate in the connective tissue adjacent to the sulcular epithelium. With progression, the infiltrate becomes more intense and demonstrates a mixture of lymphocytes, plasma cells, and acute inflammatory cells (Fig. 4.6). Areas of fibrosis, hyperemia, edema, and hemorrhage may be present.

Treatment and Prognosis

Although periodontitis always is preceded by gingivitis, most areas of gingivitis remain stable for years, and the number of affected sites that convert to periodontitis is small. Despite this, optimal gingival health should be the goal of all clinicians and their patients. Even when attachment loss is not evident and the alterations appear restricted to the gingival soft tissues, improved oral hygiene practices are recommended to eliminate these areas of persistent inflammation during the early stages of disease.

Treatment of gingivitis consists of elimination (if possible) of any known cause of increased susceptibility and improvement in oral hygiene to decrease the dental plaque responsible for the inflammatory alterations. A further discussion of dental plaque and its relationship to gingival inflammation is presented in the discussion of periodontitis (see page 160). Most self-administered plaque control programs are ineffective unless periodic professional reinforcement of oral hygiene instructions also is provided. Research has shown that few individuals have the physical skills and motivation necessary to obtain and maintain ultimate oral hygiene. An analysis of multiple clinical trials revealed that use of a mechanical toothbrush was

dentlearn.ir

associated with plaque reduction of less than 50%. Although rechargeable rotation/oscillation-powered brushes have demonstrated the ability to remove an increased percentage of plaque, the best toothbrush remains the one that gets into the mouth. The average time individuals spend brushing their teeth is 45–70 seconds daily. To perform this task properly, the teeth should be brushed for 2 minutes twice each day.

Brushing fails to clean the interdental areas and should be supplemented by other cleaning aids, such as specialized wood sticks (not toothpicks), dental floss, or interdental brushes. Research has demonstrated that proper interdental cleansing is correlated directly with decreased caries, gingivitis, and periodontitis, along with an associated increased life span. Although critically important, the percentage of patients who perform daily interdental cleaning is estimated to be as low as 2%. A survey by the American Academy of Periodontology revealed that greater than 35% of respondents would rather complete an unpleasant task, such as file their tax returns or clean their toilets, than floss.

Mechanical removal of dental plaque can be aided by the use of numerous chemical agents, such as mouth rinses with chlorhexidine or essential oils, or dentifrices containing triclosan or stannous fluoride. On occasion, hyperplastic and fibrotic gingiva may have to be recontoured surgically to achieve total resolution of the altered anatomy after improvements in hygiene have been made. If the gingivitis does not resolve after improved plaque control and elimination of obvious contributing factors, then the patient should be evaluated for underlying systemic disorders that could be contributing to the process.

◆ SPONGIOTIC GINGIVAL HYPERPLASIA (SPONGIOTIC GINGIVITIS)

Spongiotic gingival hyperplasia is a clinically and histopathologically distinctive gingival pathosis that was described initially in 2007 as *juvenile spongiotic gingivitis*. Initial reports suggested the lesions were isolated and restricted to children, but it has become obvious that spongiotic gingival hyperplasia may be multifocal and can occur in adults. Although the disorder is idiopathic, many investigators believe the alteration represents an isolated patch of junctional or sulcular epithelium that may become irritated and exteriorized. Others have suggested the proliferation arises from epithelial rests left behind during odontogenesis. The changes do not appear to be plaque-related and fail to respond to improved oral hygiene.

Prior to the initial description, some of these cases were designed as puberty gingivitis, but several features dispute this contention. Numerous examples have been reported in prepubescent children or adults and, in contrast to puberty gingivitis, the lesions do not respond to improved oral hygiene. Additionally, an absence of estrogen and progesterone receptors has been documented in these lesions.

Clinical Features

The most common presentation of spongiotic gingival hyperplasia is a small bright red velvety or papillary alteration that often bleeds easily upon manipulation (Fig. 4.7). Due to the highly vascular appearance, the most common clinical impression is pyogenic granuloma. The facial gingiva overlying the root is affected most frequently, but involvement of the interproximal areas or lingual gingiva also may occur. The lesion typically is sessile, but some examples may be pedunculated with occasional extension into the gingival sulcus (Fig. 4.8). Although the lesion has been diagnosed in adulthood, approximately 90% have been documented during the first two decades of life with a mean age less than 15 years. The alteration demonstrates a strong predilection for the maxillary anterior facial gingiva with almost 80% documented in this region. Early reports suggested a female predominance, but a gender predilection has not been noted in later literature reviews. Although occasional multifocal involvement may be seen, most examples are isolated. The natural history of the lesion is difficult to ascertain due to therapeutic removal, but several examples have been noted for years prior to excision.

• **Fig. 4.7 Spongiotic Gingival Hyperplasia.** Bright red velvety alteration of maxillary facial gingiva in 9-year-old male. (Courtesy of Dr. Tom Ocheltree.)

• **Fig. 4.8 Spongiotic Gingival Hyperplasia.** Red, papillary, and pedunculated lesion with a stalk that extends into the gingival sulcus in a 28-year-old female.

dentlearn.ir

Histopathologic Features

Microscopically, the epithelium is variably hyperplastic and often demonstrates a pebbly to papillary surface. Occasional thinning of the interpapillary plates may be seen. Prominent intercellular edema (spongiosis) and exocytosis by neutrophils are noted consistently. Histopathologically, the epithelium is remarkably similar to junctional or sulcular areas. Upon immunoperoxidase evaluation, the epithelium typically demonstrates diffuse reactivity for CK 8/18 and CK19 with uncommon reactivity for CK1/10 and CK4. In contrast, gingival surface epithelium typically is reactive for CK1/10 and CK4 but without diffuse reactivity to CK8/18 and CK19 (basilar only). These results suggest that spongiotic gingival hyperplasia demonstrates an "*in-between phenotype*" with features that are much closer to junctional epithelium than gingival surface epithelium. In those rare cases that are noted in adults, CK19 can be utilized to confirm the diagnosis. Although many cases are papillary, spongiotic gingival hyperplasia has been shown to be negative for human papillomavirus (HPV) DNA by polymerase chain reaction. The associated stroma reveals vasodilation with congestion and a mixed inflammatory cellular infiltrate.

Treatment and Prognosis

Most of the reported examples have been removed conservatively with a scalpel or laser. Surgical removal from the anterior maxillary facial gingiva with an acceptable aesthetic result can be challenging. Successful elimination with cryotherapy also has been documented with excellent results. One report documented removal by mild cauterization combined with topical corticosteroids, but other cases have revealed an inconsistent response to topical corticosteroids. The reported recurrence rate varies from 6% to 28.6%. Successful elimination by low-energy laser ablation also has been documented in a small number of case reports. Although the lesion may persist for years, the possibility of spontaneous resolution is likely because the process is reported infrequently in adults. It has been suggested that the "*in-between phenotype*" noted in the cytokeratin expression may be junctional epithelium undergoing transition into gingival surface epithelium.

◆ NECROTIZING GINGIVITIS (NECROTIZING ULCERATIVE GINGIVITIS, VINCENT INFECTION; TRENCH MOUTH)

Necrotizing gingivitis (NG) has a distinctive pattern of gingival pathologic changes that have been recognized for hundreds of years. Until recently, the name of this process has been termed *acute necrotizing ulcerative gingivitis* (ANUG); however, several investigators have discontinued the use of acute, because there is no chronic form of the disease. In addition, others prefer the simplified term *necrotizing gingivitis* with discontinuation of "ulcerative," since the ulceration occurs secondary to the necrosis.

In the 1890s, the French physician Jean Hyacinthe Vincent identified a fusiform bacterium, *Bacillus fusiformis* (currently *Fusobacterium nucleatum*), and a spirochete, *Borrelia vincentii,* after microscopic examination of plaque samples from affected sites. Vincent believed that the fusiform bacteria were principally responsible for the condition, and the spirochetes mainly were saprophytic opportunists. The spirochete and fusiform bacterium association remains true today, but more sophisticated techniques have implicated *Fusobacterium nucleatum*, *Prevotella intermedia*, *Porphyromonas gingivalis*, *Treponema* spp., and *Selenomonas* spp. Although the association with bacteria is strong, controversial research has suggested that viruses, such as cytomegalovirus, Epstein-Barr virus, and herpes simplex, may contribute to the onset and progression of the process.

The infection frequently occurs in the presence of psychologic stress. People in military service exhibit an increased frequency of NG; the disorder was so common in the battlefield trenches during World War I that the nickname *trench mouth* became well known.

In addition to stress, other factors have been related to an increased frequency of NG:

- Immunosuppression
- Smoking
- Local trauma
- Poor nutritional status
- Poor oral hygiene
- Inadequate sleep
- Recent illness

Several medications have been reported to cause agranulocytosis, a condition that may clinically present initially as NG. A thorough investigation of all currently utilized medications appears prudent and may lead to discovery of a significant associated immunosuppression. In addition, the immunocompromised status associated with acquired immunodeficiency syndrome (AIDS) (see page 257) or infectious mononucleosis (see page 241) has been related to the development of NG. The list of predisposing factors clearly supports the association between a depressed systemic immunity and the appearance of the disorder.

Clinical Features

NG may occur at any age; however, when encountered in the United States or Europe, it is seen most frequently in young and middle-aged adults. Several publications have reported a higher frequency in whites. The prevalence in the normal population is less than 0.1%; however, in stressed populations (e.g., military recruits), the frequency increases up to 7%. In developing countries, NG typically occurs in very young children suffering from malnutrition.

In a classic case of NG, the interdental papillae are highly inflamed, edematous, and hemorrhagic. Typically, the affected papillae are blunted and demonstrate areas of "punched-out," craterlike necrosis that are covered with a

dentlearn.ir

• **Fig. 4.9 Necrotizing Gingivitis (NG).** Gingiva is friable and hemorrhagic with necrosis of the interdental papillae.

• **Fig. 4.10 Necrotizing Mucositis.** Gingiva exhibits epithelial necrosis that has extended between the adjacent interdental papillae and apically to the alveolar mucosa junction.

gray pseudomembrane (Fig. 4.9). Early cases may be missed easily because the ulceration initially involves only the tip of the interdental papilla. A fetid odor, exquisite pain, spontaneous hemorrhage, and accumulations of necrotic debris usually are noted. Although a bad odor is not always noted, its absence in a patient without predisposing factors should raise concern for other pathoses, such as gonorrhea (see page 184). Occasional ancillary clinical features include lymphadenopathy, fever, and malaise. The process sometimes can lead to a loss of attachment and the development of associated periodontitis **(necrotizing periodontitis)** or spread to adjacent soft tissue **(necrotizing mucositis, necrotizing stomatitis)** (Fig. 4.10). If the necrotizing infection extends through the mucosa to the skin of the face, then it is typically termed *noma* **(cancrum oris)** (see page 191).

Several investigators have suggested that NG, necrotizing periodontitis (NP), and necrotizing stomatitis are one disease process termed **necrotizing gingivostomatitis.** Evidence presented by numerous authors has shown the diseases to be similar clinically, histopathologically, and bacteriologically, with the only differences being underlying systemic factors and anatomic extension of the necrosis.

Histopathologic Features

The histopathologic features of NG are not specific. Typically, affected gingival papillae demonstrate surface ulceration that is covered by a thickened fibrinopurulent membrane. The underlying lamina propria demonstrates an intense acute or mixed inflammatory infiltrate and extensive hyperemia. In nonulcerated affected epithelium, often a loss of the typical surface keratinization occurs. Necrotic material and extensive bacterial colonization often are included in the material submitted for microscopic examination.

Treatment and Prognosis

In contrast to most forms of periodontal disease, NG typically demonstrates quick resolution after removal of the bacterial challenge. Even with conservative therapy, regeneration of the affected gingiva normally is seen. The affected area is treated best with débridement by scaling, curettage, or ultrasonic instrumentation (except when contraindicated, as in HIV-positive patients). Topical or local anesthetic often is required before the clinician can débride the tissues adequately. Frequent rinses with chlorhexidine, warm saltwater, or diluted hydrogen peroxide are beneficial in increasing the therapeutic response. Antibiotic medications (metronidazole and penicillin have been suggested as the drugs of choice) are a useful adjunct, especially in the presence of fever or lymphadenopathy.

Treatment should include instructions on oral hygiene and patient motivation; identification and resolution of any predisposing factors also are advantageous. Supportive therapy (e.g., rest, appropriate fluid intake, and soft nutritious diet) and smoking cessation often improve the clinical response. Follow-up appointments are necessary to reinforce the home care instructions and to rule out a recurrence of the process.

The clinician must be ever vigilant in the search for other clinical signs and symptoms of immunosuppression. Subtle palatal candidiasis or HIV-related oral hairy leukoplakia (see page 253) can be overlooked easily in a patient with NG. Appropriate attention must be directed toward the oral soft tissue examination, especially in patients with infections such as NG that are related to immunosuppression. In addition, a thorough investigation of underlying causes of immunosuppression should be performed on patients whose conditions are resistant to normal therapy.

◆ PLASMA CELL GINGIVITIS (ATYPICAL GINGIVOSTOMATITIS; ALLERGIC GINGIVOSTOMATITIS)

A distinctive pattern of gingival inflammation, **plasma cell gingivitis,** was brought to the attention of health care practitioners during the late 1960s and early 1970s. A rash of cases occurred during that time, and most appear to have

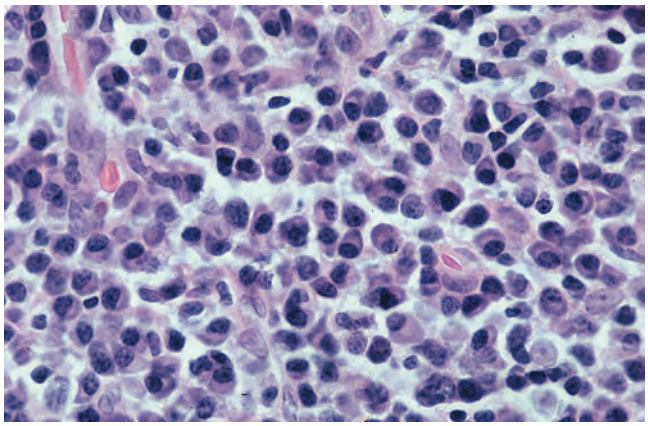
dentlearn.ir

been related to a hypersensitivity to a component of chewing gum. Since that time, the number of cases has dwindled, but similar gingival alterations are reported occasionally.

Although the association with chewing gum has decreased, allergy still is responsible for many reported cases. A brand of herbal toothpaste, a specific type of mint candy, and peppers used for cooking have all been implicated in more recent reports. The list of allergens appears to be variable, and a thorough evaluation often is required to rule out an allergic cause.

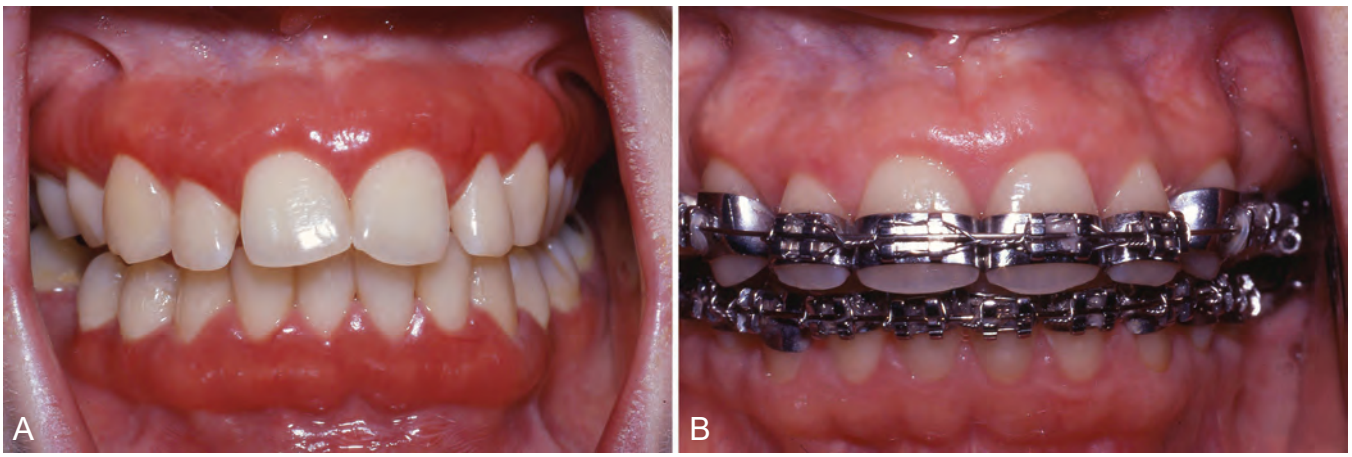
Clinical Features

Patients with plasma cell gingivitis experience a rapid onset of sore mouth, which often is intensified by dentifrices and hot or spicy foods. The entire free and attached gingiva demonstrates a diffuse enlargement with bright erythema and loss of normal stippling (Fig. 4.11). Extension onto the palate can occur, and edentulous areas typically exhibit less intense changes. On occasion, a similar localized gingival and vestibular alteration can occur from topical placement of a material that elicits a similar plasmacytic inflammatory reaction.



Additional sites of involvement may be seen, or the changes may be localized to the gingiva. In the chewing gum–related cases of the early 1970s, involvement of the lips and tongue was typical. The lips were dry, atrophic, occasionally fissured, and angular cheilitis was frequent. Tongue involvement resulted in erythematous enlargement with furrows, mild crenation, and loss of the typical dorsal coating.

More recent reports have described lesions often isolated to the gingiva without the classic lip and tongue involvement seen in the past. A larger percentage of these cases are idiopathic, and occasional extraoral involvement of sites such as the supraglottic region occurs.



Histopathologic Features

The cases of classic plasma cell gingivitis of the 1970s demonstrated psoriasiform hyperplasia and spongiosis of the surface epithelium with intense exocytosis and neutrophilic microabscesses. The underlying lamina propria contains numerous dilated vascular channels and an extremely dense chronic inflammatory infiltrate that is composed predominantly of plasma cells (Fig. 4.12). The more recent cases are similar but often demonstrate less involvement of the surface epithelium and a less dense underlying plasmacytic infiltrate.

Investigation of the clonality of the plasma cell infiltrate may be necessary to rule out the possibility of a monoclonal plasma cell neoplasm. All allergic and idiopathic cases of plasma cell gingivitis demonstrate a polyclonal mixture of plasma cells and a normal profile on plasma immunoelectrophoresis. In addition, the possibility of IgG4-related

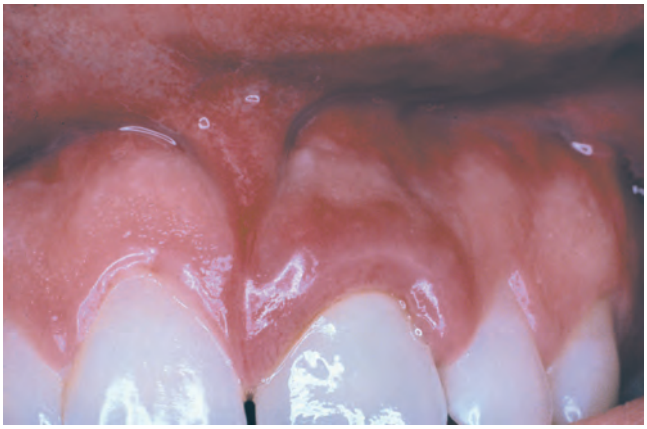
• **Fig. 4.12 Plasma Cell Gingivitis.** High-power photomicrograph exhibiting a dense inflammatory infiltrate consisting predominantly of plasma cells with scattered lymphocytes.

• **Fig. 4.11 Plasma Cell Gingivitis. A,** Diffuse, bright-red enlargement of the free and attached gingiva. **B,** Same patient as depicted in **A** 16 months later after elimination of the inciting allergen. (Courtesy of Dr. Phillip Sheridan).

dentlearn.ir

disease (see page 471) should be considered. In IgG4-related disease, a storiform pattern of sclerosis and scattered eosinophils typically are present along with an IgG4/IgG plasma cell ratio greater than 40%, and elevation of the serum IgG4 level.

It must be remembered that an identical dense infiltrate of plasma cells can be seen in mouth breathing-related gingivitis, plaque-related gingival hyperplasia, and chronic periodontitis. The diagnosis depends on a strong clinical and histopathologic correlation in which the changes are associated with a rapid onset of sore mouth and do not resolve with improved oral hygiene. Reports of this entity that do not fulfill the diagnostic criteria still can be found in the dental and medical literature. Review of the original 1971 publication may be helpful for those contemplating the diagnosis.



Treatment and Prognosis

All patients with plasma cell gingivitis should be instructed to keep a complete dietary history with records of everything taken into the mouth (e.g., foods, dentifrice, mouthwash, tobacco, alcohol, chewing gum, candy, and medications). Possible allergens should be eliminated to discover the underlying cause. If an easy answer is not apparent, then extensive allergy testing and an elimination diet can be undertaken.

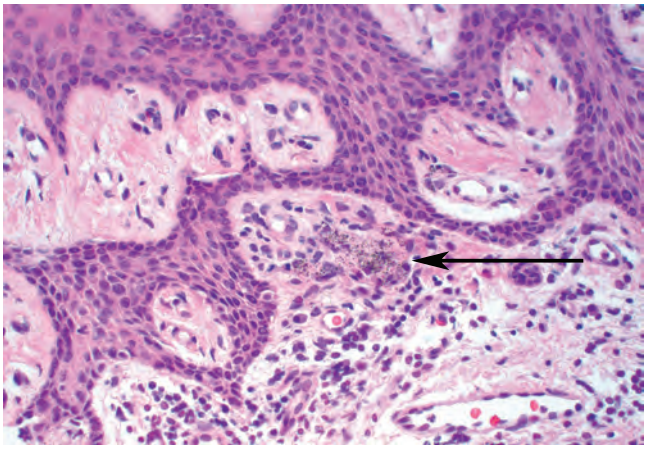
Many patients in whom no underlying cause could be discovered have been treated with topical or systemic immunosuppressive medications with variable results. Dexamethasone rinses, fluocinonide gel, topical triamcinolone, and topical fusidic acid are several of the reported choices. Despite all the evaluations and therapeutic interventions, some patients do not respond to treatment, and no cause for the disease can be identified.

◆ FOREIGN BODY GINGIVITIS

In 1990, Daley and Wysocki described an important pattern of recalcitrant gingivitis that remains surprisingly underrecognized. The alteration represents an inflammatory response to foreign material that has become embedded in the gingival tissues. Energy-dispersive X-ray microanalysis has shown that most of the foreign particles are of dental origin, with abrasives and restorative materials being identified most frequently. These materials appear to be introduced through disrupted gingival or sulcular epithelium during professional hygiene activities, restorative procedures, or during household use of oral hygiene or cosmetic products. The most discovered material is silicon, a major component of toothpaste, polishing paste, pumice, and carborundum disks. When introduced into the gingiva, silicon has been shown to activate fibroblasts, leading to increased levels of inflammatory cytokines. The gingival changes may become evident shortly after the introduction of the material or be delayed for months to years.

• **Fig. 4.13 Foreign Body Gingivitis.** Localized enlarged and erythematous gingiva associated with the maxillary left central incisor. The alterations developed shortly after placement of a porcelain-fused-to-metal (PFM) full crown and were not responsive to conservative local therapy. Biopsy revealed granulomatous inflammation intermixed with foreign material. (Courtesy of Dr. Timothy L. Gutierrez.)

• **Fig. 4.14 Foreign Body Gingivitis.** Red, atrophic mucosa of the left maxillary facial gingiva. The alterations arose following placement of two porcelain-fused-to-metal (PFM) crowns. Biopsy revealed lichenoid mucositis with intermixed fragments of foreign material.



Clinical Features

Foreign body gingivitis presents as focal areas of gingival redness that may demonstrate peripheral radiating striae, intermixed white areas, zones of erosion, or enlargement (Figs. 4.13 and 4.14). Associated discomfort and multifocal involvement are common. The lesions frequently are confused with gingival lichen planus but fail to migrate or develop extra-gingival involvement. More recently, foreign body gingivitis has been associated with discrete gingival leukoplakias that may be verruciform in appearance, occasionally associated with varying degrees of dysplasia, and worrisome for an evolving proliferative verrucous leukoplakia (see page 384) (Fig. 4.15). Although the process may involve any gingival surface, the posterior areas of both arches and the anterior maxillary gingiva are affected most often. There is a female predominance, and most cases present in adulthood with a mean age of approximately 50 years.

dentlearn.ir

• **Fig. 4.15 Leukoplakic Foreign Body Gingivitis.** This clinical presentation exhibits features of both foreign body gingivitis and evolving proliferative verrucous leukoplakia. Biopsy should be extended to the sulcus to enhance the likelihood of including foreign material, if present. Even if foreign material is found, the definitive diagnosis requires a strong clinicopathologic correlation. (Courtesy of Dr. Fred Lucas.)

• **Fig. 4.16 Foreign Body Gingivitis.** Particles of pigmented foreign material *(arrow)* intermixed with lymphocytes and plasma cells.

Histopathologic Features

The histopathologic features are variable but consistently will demonstrate minute opaque grayish-black granules that may be intermixed with translucent crystalline structures (Fig. 4.16). The granules do not tend to polarize, whereas the crystals are highlighted by polarized light. The foreign material is subtle and may be missed without a high index of suspicion. The red variant of foreign body gingivitis tends to exhibit areas of epithelial atrophy often demonstrating degeneration of the basal cell layer, suggestive of gingival lichen planus. The superficial stroma typically reveals a dense lymphocytic band with a deeper patchy inflammatory cellular infiltrate composed predominantly of lymphocytes, plasma cells, and histiocytes. Scattered eosinophils occasionally may be present. The foreign material typically is intermixed within the deeper patchy infiltrate or noted within areas of intermixed granulomatous inflammation. The leukoplakic variant most frequently exhibits hyperorthokeratosis with varying degrees of verruciform hyperplasia or dysplasia. The deeper stroma will demonstrate a similar patchy chronic inflammatory cellular infiltrate with lymphocytes, plasma cells, and histiocytes with or without granulomatous inflammation.

The diagnosis requires a strong clinicopathologic correlation. When foreign material is detected, it is impossible to ascertain if the material is coincidental or causative. In addition, superficial biopsies of foreign body gingivitis can miss the foreign material, because the granules often are deep and adjacent to the gingival sulcus. When presented with a focal lichenoid lesion with foreign material, **lichen planus** (see page 787) must be considered but typically will demonstrate migration and extragingival lesions. When presented with a verruciform leukoplakia with foreign material, the possibility of an evolving **proliferative verrucous leukoplakia** (see page 384) must be considered with appropriate therapy and close follow-up. When significant granulomatous inflammation is present but not intimately associated with the foreign material, the possibility of **orofacial granulomatosis** (see page 330) must be considered.

Treatment and Prognosis

Surgical excision of the affected tissue is the therapy of choice if the process is sufficiently symptomatic or presents as a thickened leukoplakia. In persistently atrophic or erosive areas of foreign body gingivitis, overlaying the damaged area with a graft from a healthy gingival donor site may be a better option than complete excision. Use of topical corticosteroids has produced temporary resolution of sensitivity in some patients, but symptoms typically return upon cessation of therapy. To prevent future introduction of iatrogenic foreign material, clinicians should use care during restorative and oral hygiene procedures that might introduce foreign material into a surgical wound. In addition, dental prophylaxis should be delayed for 2 days after scaling, root planing, and curettage procedures.

◆ DESQUAMATIVE GINGIVITIS

Desquamative gingivitis is a clinical term for gingiva that demonstrates superficial peeling of the epithelium characterized by formation and rupture of mucosal vesicles. The process almost always represents a manifestation of one of several different vesiculoerosive diseases, usually mucous membrane pemphigoid. Some clinicians broaden the definition to include patients with atrophic and erosive gingival lesions without true peeling of the epithelium. In such cases, lichen planus is diagnosed most frequently. Other diagnoses that are made less frequently include linear IgA disease, pemphigus vulgaris, epidermolysis bullosa acquisita, systemic lupus erythematosus (SLE), chronic ulcerative stomatitis, and paraneoplastic pemphigus. The gingival manifestations of these mucosal and dermatologic diseases are described in greater detail in Chapter 16, so further discussion here is not warranted.

dentlearn.ir

◆ DRUG-RELATED GINGIVAL HYPERPLASIA (DRUG-RELATED GINGIVAL OVERGROWTH)

Drug-related gingival hyperplasia refers to an abnormal growth of the gingival tissues secondary to use of a systemic medication. A list of medications reported to be associated with gingival hyperplasia is provided in Box 4.4. Of these medications, a strong association has been noted only with cyclosporine (Fig. 4.17), phenytoin, and nifedipine (Fig. 4.18). In addition to nifedipine, a definitive but much weaker association has been documented with other calcium channel-blocking agents, such as diltiazem, amlodipine, and verapamil. In the remainder of these agents, the prevalence is much lower or the association is weak or anecdotal. Several calcium channel blockers exist that have not been associated with gingival hyperplasia and may represent safer alternatives. As new drugs are developed, the list of offending medications may grow. Cyclosporine is known to be associated with hypertension, often leading to utilization of a calcium channel blocker. When cyclosporine and nifedipine are used concurrently, the severity of the associated hyperplasia often is increased (Fig. 4.19).

Rare reports of gingival hyperplasia associated with use of vemurafenib have been noted. This medication is a targeted BRAF inhibitor utilized in the treatment of metastatic melanoma. It has demonstrated a number of proven cutaneous side effects including keratoacanthoma-like squamous cell carcinoma, keratosis pilaris, acanthopapillomas, and plantar hyperkeratosis. The exact nature of the gingival enlargement

dentlearn.ir

is unclear because none of the patients have had biopsy with histopathologic examination of these oral alterations.

The prevalence of these hyperplasias varies widely; however, as reported in one critical review of the literature, the prevalence related to use of phenytoin is approximately 50%. Cyclosporine and nifedipine each produce significant changes in about 25% of patients treated. Whether there is a relationship between the dose and the risk or severity of the hyperplasia is a controversial issue. Investigators have suggested that susceptibility to cyclosporine gingival hyperplasia is associated with certain histocompatibility antigen (HLA) types, whereas other HLA types appear to protect against hyperplasia. Whether similar correlations exist for the other forms of medication-associated gingival hyperplasia is unknown.

The degree of gingival enlargement appears to be related significantly to the patient's susceptibility and the level of oral hygiene. In observations of patients with excellent oral hygiene, gingival overgrowth (as ascertained by pseudopocket formation) is reduced dramatically or not present. Even with good oral hygiene, however, some degree of gingival enlargement can be discovered in susceptible individuals, although in many cases the changes are difficult to detect. Rigorous oral hygiene often can limit the severity to clinically insignificant levels. Of the medications discussed, cyclosporine appears to be the least responsive to the institution of a rigorous program of oral hygiene; even with this medication, however, the elimination of gingival inflammation results in noticeable clinical improvement. In addition, the degree of drug-associated gingival hyperplasia appears to be markedly higher in smokers.

Clinical Features

Because young patients use phenytoin most often, the gingival hyperplasia it induces is primarily a problem in people younger than age 25. Cases related to the calcium channel blockers occur mainly in middle-aged or older adults. Cyclosporine is used over a broad age range, and this correlates with the age of reported hyperplasia. A greater risk for gingival hyperplasia occurs when the drug is used in children, especially adolescents. No race predilection is present. A male predominance is noted with gingival hyperplasia associated with cyclosporine or calcium channel blockers but not with phenytoin.

After 1–3 months of drug use, the enlargements originate in the interdental papillae and spread across the tooth surfaces (Fig. 4.20). The anterior and facial segments are the most frequently involved areas. In extensive cases, the hyperplastic gingiva can cover a portion (or all) of the crowns of many of the involved teeth (Figs. 4.21 and 4.22). Extension lingually and occlusally can interfere with speech and mastication. Edentulous areas generally are not affected, but significant hyperplasia under poorly maintained dentures and around implants has been noted (Fig. 4.23).

Nongingival soft tissue growths that resemble pyogenic granulomas have been reported in allogeneic bone marrow transplant recipients who are receiving cyclosporine for graft-versus-host disease (GVHD) (Fig. 4.24). It is thought that cyclosporine triggers the proliferations in areas chronically inflamed by GVHD.

In the absence of inflammation, the enlarged gingiva is normal in color and firm, with a surface that may be smooth,

stippled, or granular. With inflammation, the affected gingiva often becomes dark red and edematous, with a surface that is friable, bleeds easily, and occasionally is ulcerated. Pyogenic granuloma-like enlargements occasionally are seen in the presence of heavy inflammation.

Histopathologic Features

Upon histopathologic examination, the overlying surface epithelium may demonstrate elongation of the rete ridges, with long extensions into the underlying stroma. The lamina propria exhibits an increased amount of fibrous connective tissue that demonstrates a normal density of fibroblasts. In patients with secondary inflammation, there is increased vascularity and a chronic inflammatory cellular infiltrate that most frequently consists of lymphocytes and plasma cells. In patients with pyogenic granuloma-like overgrowths, the proliferations often demonstrate an increased vascularity and significant subacute inflammation.

Treatment and Prognosis

Discontinuation of the offending medication by the attending physician often results in cessation, and possibly some regression, of the gingival enlargement; even substitution of one medication for another in the same class may be beneficial. Often the response to medication substitution is not immediate. If the drug use is mandatory, then professional cleaning, frequent reevaluations, and home plaque control are important. Antiplaque agents, such as chlorhexidine, have been beneficial in the prevention of plaque buildup and the associated gingival hyperplasia.

Systemic or topical folic acid has been shown to ameliorate the gingival hyperplasia in some cases. In addition, several authors have documented significant resolution of cyclosporine-related gingival hyperplasia after a short course of metronidazole, azithromycin, or roxithromycin. Azithromycin also may be beneficial in resolving gingival hyperplasia related to nifedipine and phenytoin.

Although gingival hyperplasia is associated with increased probing depths, some investigators do not believe this necessarily leads to exaggerated attachment loss or an increased loss of teeth. Therefore, some clinicians exercise watchful waiting and do not perform invasive therapy without evidence of attachment loss, inappropriate aesthetics, or disruption of speech or mastication. When objectionable alterations are noted and all other interventions fail to achieve significant resolution, eradication of the excess gingival tissues by scalpel or laser remains the treatment of choice. Recurrence is not uncommon, however, especially in patients with inadequate oral hygiene. Due to increased rates of tooth loss in patients with recurrent and persistent drug-related gingival hyperplasia, substitution of the offending medication is the best approach if medically appropriate.

◆ GINGIVAL FIBROMATOSIS (FIBROMATOSIS GINGIVAE; ELEPHANTIASIS GINGIVAE)

Gingival fibromatosis is a slowly progressive gingival enlargement caused by a collagenous overgrowth of the gingival fibrous connective tissue. Despite the name, this disorder bears no relationship to the hypercellular and neoplastic fibromatoses that can occur in soft tissue and bone (see pages 523 and 663). Gingival fibromatosis is a rare condition with an estimated prevalence of 1:750,000.

Gingival fibromatosis may be familial or idiopathic. Other findings sometimes seen in conjunction with gingival fibromatosis include hypertrichosis (Fig. 4.25), generalized aggressive periodontitis, epilepsy, intellectual disability, sensorineural deafness, hypothyroidism, chondrodystrophia, and growth hormone deficiency. The familial variations may occur as an isolated finding or in association with one of several hereditary syndromes. Box 4.5 lists the syndromes that often have been associated with gingival fibromatosis.

dentlearn.ir

• **Fig. 4.25 Hypertrichosis in Association With Gingival Fibromatosis.** Dramatically increased body hair of the back and buttocks in a patient with gingival fibromatosis. (Courtesy of Dr. George Blozis.)

- Costello syndrome
- Cross syndrome
- Infantile systemic hyalinosis
- Jones-Hartsfield syndrome
- Murray-Puretic-Drescher syndrome
- Ramon syndrome
- Rutherford syndrome
- Zimmerman-Laband syndrome

In most cases of isolated gingival fibromatosis, an autosomal dominant pattern of inheritance is seen; however, autosomal recessive examples also have been noted. Incomplete penetrance and variable expressivity are seen. The phenotype of hereditary gingival fibromatosis demonstrates significant genetic heterogeneity with the existence of at least five genes that are responsible for similar patterns of clinical presentation.

Clinical Features

In most instances, the enlargement begins before age 20 and often is correlated with the eruption of the deciduous or permanent teeth (Fig. 4.26). Most investigators believe that the presence of teeth probably is necessary for the condition to occur. Despite this, rare patterns can present in infancy or even at birth. After the process has begun, it can overgrow the associated teeth and even interfere with lip closure. Failure or delay in eruption, or altered position of the erupted teeth, may be evident (Fig. 4.27). In some instances, a tooth

• **Fig. 4.28 Localized Gingival Fibromatosis.** Bilateral and symmetrical fibrotic enlargements of the palatal surfaces of the posterior maxillary alveolar ridges.

• **Fig. 4.29 Gingival Fibromatosis.** Surface stratified squamous epithelium exhibiting long, thin rete ridges and underlying dense, fibrous connective tissue.

may have erupted into a normal position, but the fibrous connective tissue continues to cover the crown and prevent visualization.

The gingival changes may be generalized or localized to one or more quadrants. Either jaw may be involved, but the maxilla is affected more frequently and demonstrates a greater degree of enlargement. Palatal surfaces typically are increased in thickness more than the buccal side. Typically, extension past the alveolar mucosal junction into the mucobuccal fold is not seen, but palatal extensions can cause significant distortion of the contour of the palate and, at times, almost can meet in the midline.

In localized cases, the hyperplasia may involve a group of teeth and remain stable or, later, may extend to other segments of one or both jaws. One distinctive and not uncommon pattern involves the posterior maxillary alveolar ridge. In this pattern, the hyperplastic tissue forms bilaterally symmetrical enlargements that extend posteriorly and palatally from the posterior alveolar ridges (Fig. 4.28). Less commonly, the overgrowth also may be isolated to the facial gingiva of the lower molars.

The gingiva is firm, normal in color, and covered by a surface that is smooth or finely stippled. In older patients, the surface may develop numerous papillary projections. The frenular attachments may appear to divide the gingival tissues of the alveolar ridge into lobules. Associated clinical problems include poor aesthetics, prolonged retention of deciduous teeth, abnormal occlusion, inadequate lip closure, and difficulty in eating and speaking.

Histopathologic Features

The enlargements of gingival fibromatosis consist of dense hypocellular, hypovascular collagenous tissue, which forms numerous interlacing bundles that generally are arranged mostly in a parallel pattern. The surface epithelium often is acanthotic and exhibits long, thin rete ridges that extend deeply into the underlying fibrous connective tissue (Fig. 4.29). Inflammation is absent to mild. On occasion, scattered islands of odontogenic epithelium, foci of dystrophic calcification, or areas of osseous metaplasia may be seen.

Treatment and Prognosis

Mild cases often respond to scaling and root planing followed by close professional follow-up. For more advanced gingival thickening, conservative surgical removal is indicated. The rate of recurrence following excision is reduced if the removal is delayed until full eruption of the permanent dentition. Despite this, local and psychological benefits often exceed the downside of recurrence, warranting earlier removal. Although recurrence is common in dentulous patients, a rigorous program of oral hygiene often slows regrowth. In severe cases, selective extraction of teeth and gingivectomy often are required to achieve a normal gingival morphology.

◆ PERIODONTITIS

Periodontitis refers to an inflammation of the gingival tissues in association with some loss of both the attachment of the periodontal ligament and bony support. With progressive loss of attachment, significant destruction of the periodontal ligament and adjacent alveolar bone can occur. Apical migration of the crevicular epithelium along the root surface results in the formation of periodontal pockets. Loosening and eventual loss of teeth are possible. A patient is deemed to have periodontitis if one of two presentations is noted:

- Interdental clinical attachment loss in two or more nonadjacent teeth
- Buccal or oral clinical attachment loss of $\geq$3 mm with pocketing $>$3 mm at two or more teeth

A national health survey of adults aged 30–79 years conducted from 2009–2014 revealed the prevalence of periodontitis to be 42.2%, with 7.8% being severe. It is assumed that the prevalence is rising since the disease increases with age, the population is living longer, and a greater percentage of the population is retaining their teeth due to a reduction in dental caries.

dentlearn.ir

For more than a century, the presence of the disease has been correlated with the accumulation of dental plaque on the tooth and under the gingiva. Despite this, some patients demonstrate extensive dental plaque but do not develop destructive lesions of the periodontium. Many investigators now believe that periodontitis represents a *microbial-shift disease*. Dramatic differences exist in the content of dental plaque in areas of healthy and diseased periodontium. Healthy sites are colonized primarily by facultative gram-positive organisms, whereas plaque within areas of active periodontitis contains anaerobic and microaerophilic gram-negative flora. Of the more than 500 types of bacteria that may reside in the oral cavity, only a few have been related to periodontitis, and the specific types often correlate with the clinical patterns of periodontitis. Chronic periodontitis is associated strongly with *Treponema denticola*, *Tannerella forsythensis*, and *Porphyromonas gingivalis*. Additional organisms frequently thought to be involved include *Aggregatibacter actinomycetemcomitans* (formerly *Actinobacillus actinomycetemcomitans*), *Prevotella intermedia, Campylobacter rectus*, and *Fusobacterium nucleatum.* Although controversial, some investigators also have suggested that human cytomegalovirus and other herpesviruses could play a contributing role.

The pathogenic organisms exist in an organized community termed a **biofilm.** Bacteria growing in biofilms are relatively protected from normal host defenses and exhibit an increased resistance to locally or systemically administered antibiotic medications. Lipopolysaccharides released from the biofilms are thought to trigger release of catabolic inflammatory mediators that lead to the loss of attachment. Mechanical disruption of this organized bacterial biofilm may be an important factor associated with successful treatment of periodontitis.

The 1999 classification of periodontitis was redefined in 2017 during the World Workshop on the Classification of Periodontal and Peri-implant Diseases and Conditions. The revised classification system identified three different forms of periodontitis:

- Necrotizing periodontitis
- Periodontitis as a direct manifestation of systemic diseases
- Periodontitis

This new classification system combines the old categories of "chronic periodontitis" and "aggressive periodontitis" into a single disease process. Since publication of the 1999 classification, clinicians and educators voiced concerns that the stipulated criteria to separate chronic from aggressive periodontitis were difficult to apply due to substantial overlap. In addition, there was no evidence of a specific pathophysiology that distinguishes the chronic from the aggressive forms of periodontitis. Despite the 2017 reclassification, significant controversy remains. Soon after publication of the findings from the 2017 world workshop, participating members submitted conflicting manuscripts supporting continued separation of chronic periodontitis of adulthood from aggressive periodontitis noted in children and young adults, especially the localized variant.

To stratify the variations within the current category of periodontitis, a staging and grading system was established during the World Workshop. The *staging* is a four-tier system (I–IV) that is meant to define the severity, extent, and complexity of the periodontitis in an individual and primarily utilizes the clinical attachment loss in association with the radiographic presentation and history of tooth loss. The grading is a three-tier system (A–C) that attempts to provide an estimate of the rate of progression, responsiveness to standard therapy, and the potential impact on systemic health. The grading system primarily utilizes the rate of clinical attachment loss over time combined with local factors (amount of biofilm) and grade modifiers such as diabetes and smoking.

Periodontitis associated with systemic disease is not rare, and Box 4.6 lists many of the disorders that may be associated with a premature loss of periodontal attachment. **Necrotizing periodontitis (NP)** represents the loss of attachment that often occurs in association with necrotizing gingivitis (NG) (see page 151). This form has been correlated with aggressive invasion by several spirochetes and *Prevotella intermedia.*

Clinical and Radiographic Features

Periodontitis

With the decline in caries, **periodontitis** has become the primary cause of tooth loss in patients older than 35 years of age. The disorder demonstrates an increased prevalence in males,

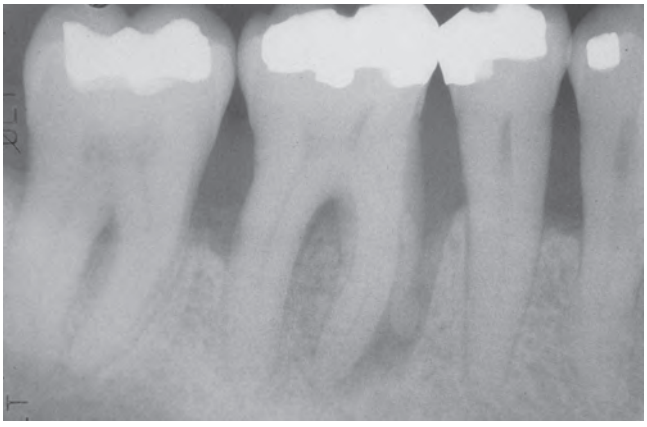
dentlearn.ir

although researchers believe that much of this effect is related to poorer oral hygiene and dental-visit behavior. In addition, an increased prevalence of periodontitis is associated with the following:

- Advancing age
- Smoking
- Diabetes mellitus
- Osteoporosis
- HIV infection
- Lower socioeconomic level

Local factors also may predispose patients to isolated periodontal defects; these include tooth shape and alignment, presence and quality of dental restorations, poor interdental contact, calculus formation, subgingival dental caries, traumatic occlusion, and abnormal alveolar bone or gingival anatomy.



Conversely, it has been suggested that the presence of significant periodontitis may place patients at risk for an increased prevalence or greater severity of certain medical disorders. Although controversial, periodontitis has been associated with an elevated risk for coronary artery disease, stroke, progressive diabetes mellitus, respiratory diseases, and delivery of low–birth weight babies. Although co-occurrence of periodontal disease with these serious medical conditions has been documented, these associations should not be interpreted to insinuate that periodontal disease is causing the medical condition to occur. Most of the supporting evidence arose from observational studies and would be strengthened by well-designed and randomized clinical trials. Since the current scientific evidence of an association between periodontal disease and these medical conditions is weak and without any strong proof of causality, the primary focus when treating periodontal disease should remain preserving the dentition to improve oral health and the quality of life.

In classic periodontitis of adulthood, no abnormalities of the immune system typically are found. Periodontitis begins in youth and early adulthood, takes years to decades to progress, and includes cyclic patterns of exacerbation and remission. The assumption that periodontitis is a disease of aging has been challenged, and most believe the increased periodontal destruction observed in older adults reflects a lifetime of disease accumulation rather than an age-specific disease.

In patients with periodontitis, gingivitis is present and precedes the development of significant periodontal lesions. Although many sites may demonstrate gingivitis and do not progress to attachment loss, lifelong local measures directed against sites of gingivitis represent an effective approach for prevention of chronic periodontitis. As loss of attachment occurs, blunting and apical positioning of the gingival margins typically are present (Fig. 4.30). Periodontal disease is present when a loss of attachment can be demonstrated using a periodontal probe. In the absence of significant gingival hyperplasia, a measurement of pocket depths greater than 3–4 mm indicates destruction of the periodontal ligament and resorption of adjacent alveolar bone; however, clinical attachment loss is the best measurement of accumulated periodontal destruction and represents the diagnostic gold standard. High-quality dental radiographs exhibit a decreased vertical height of the bone surrounding the affected teeth (Fig. 4.31). With advanced bone loss, tooth mobility is present. Although to date there are no confirmed biomarkers for periodontal disease, ongoing research is attempting to analyze saliva for genomic and microbial markers for the early diagnosis of periodontitis.

• **Fig. 4.30 Periodontitis.** Diffuse gingival erythema with blunting and apical positioning of the gingival margins. (Courtesy of Dr. Samuel Jasper.)

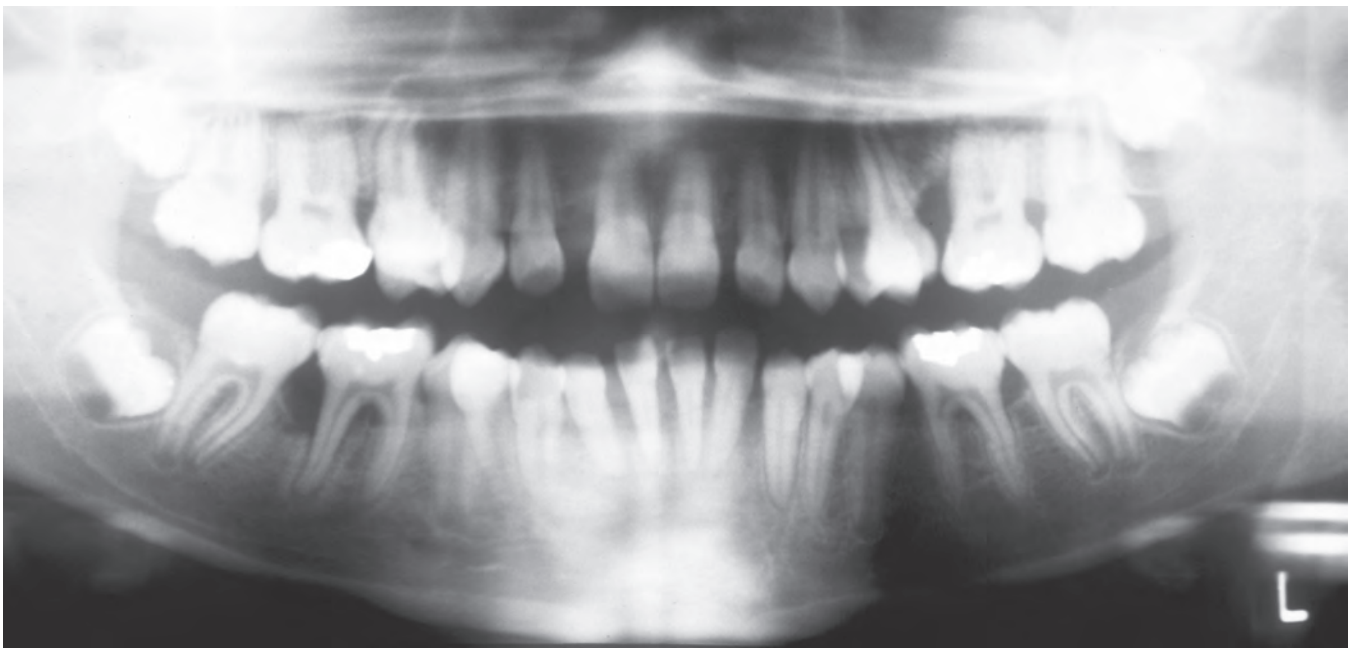
• **Fig. 4.31 Periodontitis.** Generalized horizontal bone loss with an isolated vertical defect involving the mesial root of the first molar.

Although periodontitis is much more frequent in older adults, it also can be a significant problem in children and young adults. In such cases, an investigation for an association with a systemic disease process should be ruled out. Researchers believe that periodontitis arising in early age represents several different pathoses that have been grouped together because of similar clinical presentations. Most patients have a demonstrable neutrophil dysfunction but without systemic manifestations. Although this is a controversial topic, several investigators have suggested that this pattern of periodontitis requires specific bacterial flora and the presence of a selective immune dysfunction that allows

dentlearn.ir

these pathogens to flourish. This unique pattern of immune alteration may explain the failure to defend appropriately against certain periodontal pathogens without exhibiting systemic signs of immunodeficiency. Familial aggregation of patients with this pattern of periodontitis is noted and suggests an underlying genetic foundation. In all likelihood, high stage/grade periodontitis arising in younger patients is genetically heterogeneous, meaning the mutation of any one of several different gene loci can result in the disease.

When presenting in younger patients, the periodontitis may be localized or generalized. The localized variant often begins around 11–13 years of age with a strong familial history and a tendency to demonstrate attachment loss localized to the first molars and incisors. This pattern of periodontal disease demonstrates a 10-fold higher risk in adolescents of African or Middle Eastern descent. The periodontal destruction appears to localize around the first molars and the incisors, possibly because these teeth have been erupted for the longest duration (Fig. 4.32). In numerous clinical studies, minimal supragingival plaque or calculus has been documented; however, this finding is variable. The rate of bone destruction is three to five times faster than that seen in typical periodontitis of adulthood. In the 1999 classification, this pattern of disease was termed *localized aggressive periodontitis*; and many investigators continue to believe that this presentation deserves to be separated from classic chronic periodontitis of adulthood.



In the first molar regions, radiographs reveal vertical bone resorption that often is bilateral and symmetrical. In classic cases, an arc-shaped zone of bone loss extends from the distal aspect of the second bicuspid to the mesial aspect of the second molar. Similar involvement is apparent around the anterior teeth. Tooth migration and mobility are common. If untreated, then the process often continues until the teeth are exfoliated. About one-third of patients affected with localized disease will progress to a more generalized pattern.

Of all the pathogens in dental plaque, *A. actinomycetemcomitans* appears to be predominant in the localized form of periodontitis seen in adolescents. This bacterium is present in disease sites in more than 90% of cases. Its ability to invade gingival tissue has created difficulties in mechanical eradication. Knowledge of its importance to the disease process has led to remarkable advances in therapy.

Generalized periodontitis also can be seen in younger patients but typically demonstrates a wider age range with most patients being between the ages of 12–32. In contrast to many examples of the localized variant, heavy plaque, calculus, and marked gingival inflammation may be present. Compared with the localized variant, more teeth are affected, and the bone loss is not restricted to specific areas of the jaws. In these cases, the pathogens active in the generalized variant are comprised of a wider variety of species, similar to chronic periodontitis seen in older adults.

Necrotizing Periodontitis (Necrotizing Ulcerative Periodontitis)

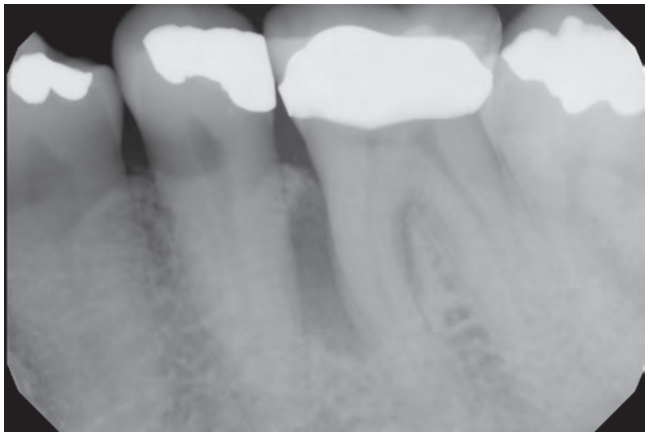
Necrotizing periodontitis (NP) has symptoms similar to NG (see page 151), but it also demonstrates loss of clinical attachment and alveolar bone. This destructive form of periodontitis may arise within a zone of preexisting periodontitis, or it may represent a sequela of a single or multiple episodes of NG. Many believe that NG and NP represent different

• **Fig. 4.32 Periodontitis.** Loss of bone support in the area of the first molars and incisors of both maxillary and mandibular arches in a 14-year-old patient. This pattern of periodontal destruction previously has been termed *localized aggressive periodontitis*.

dentlearn.ir

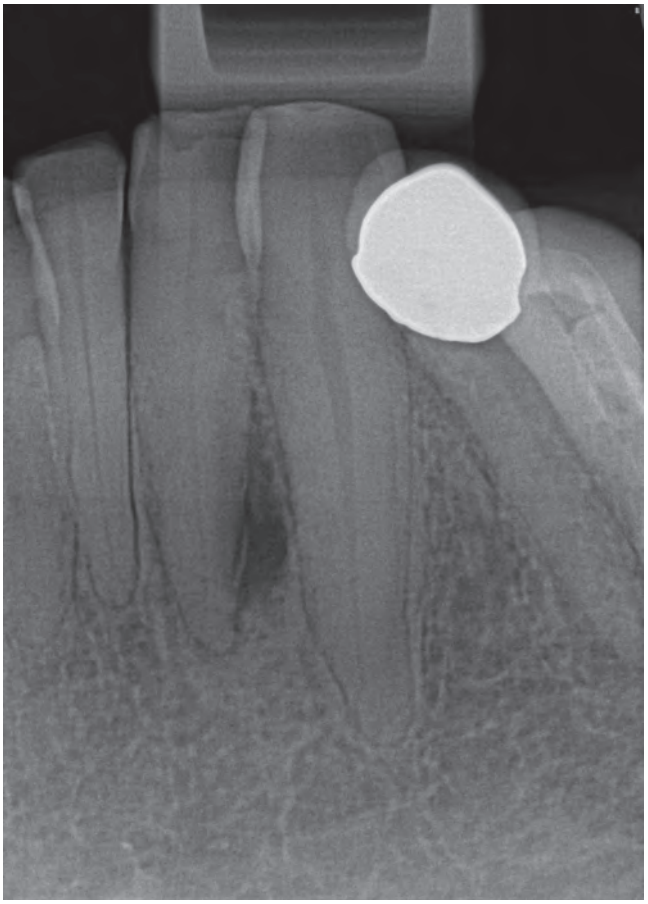
stages of the same infection. Patients affected with this pattern frequently are younger than most patients affected with chronic periodontitis and often demonstrate immunosuppression or malnutrition.

Periodontal Abscess



A **periodontal abscess** (Figs. 4.33 and 4.34) is a localized purulent infection of the gingiva with involvement of the adjacent periodontal attachment and alveolar bone. On occasion, an abscess may be localized to the marginal or interdental gingiva without involvement of the adjacent periodontal ligament or alveolar bone. This lesion is termed a **gingival abscess** and often is secondary to plaque or foreign material that has become entrapped in the gingival sulcus.

A periodontal abscess often arises in a preexisting periodontal lesion and usually is precipitated by alterations in the subgingival flora, host resistance, or both. Factors frequently associated with abscess formation are closure of the entrance into a periodontal pocket, furcation involvement, or diabetes. Many cases arise in patients actively undergoing periodontal therapy, perhaps because of incomplete removal of deep calculus with microbial penetration of the soft tissue surrounding the pocket or premature sealing of the coronal opening to the pocket. Other factors involved less frequently are trauma and anatomic dental anomalies, such as enamel pearls (see page 90) and dens invaginatus (see page 88). Most cases arise in adults; periodontal abscesses in children are rare and most frequently the result of a foreign body that has been introduced into previously healthy periodontal tissues.



On rare occasion, a periodontal abscess may be due a **cemental tear** in which there is a detachment of the cementum from the cementodentinal junction (Fig.4.35). These tears may be secondary to an inherent weakness in the cementum or due to excessive force causing a fracture to develop. Intermittent movement of the fragment during occlusal loading creates a localized inflammatory reaction with development of an associated radiolucency. If the tear is located on the proximal root surface, the inflammatory process may result in a purulent discharge from the periodontal sulcus; while abscesses associated with more apically-positioned lesions could drain through a sinus tract. In most instances, the pulp of the associated tooth remains

dentlearn.ir

• **Fig. 4.36 Periodontal Abscess.** Dark-red and hemorrhagic enlargement of the interdental papilla between the maxillary right lateral incisor and cuspid.

• **Fig. 4.37 Pericoronitis.** Painful erythematous enlargement of the soft tissues overlying the crown of the partially erupted right mandibular third molar.

vital unless the inflammatory lesion has been misdiagnosed, leading to inappropriate root canal therapy.

A periodontal abscess appears as a zone of gingival enlargement along the lateral aspect of a tooth. The involved gingiva may be erythematous and edematous with a slick, red surface, or it may be hemorrhagic with a dark-red coloration (Fig. 4.36). Common symptoms include the following:

- Throbbing pain
- Extreme sensitivity to palpation of the affected gingiva
- Sensitivity, mobility, or extrusion of the adjacent tooth
- Foul taste
- Lymphadenopathy
- Fever, leukocytosis, and malaise (occasionally)

Probing or gentle pressure on the affected gingiva often results in the expression of pus from the sulcus. The abscess may drain through an overlying sinus tract. With drainage, the abscess becomes asymptomatic but can demonstrate acute exacerbations if the mucosa heals over and the pressure builds again. Radiographs often demonstrate bone loss associated with the previous periodontal defect or additional radiolucency secondary to the current acute process. In some cases, the infection can spread into the periapical region and create a combined periodontal-endodontic lesion.

Pericoronitis

Pericoronitis is an inflammatory process that arises within the tissues surrounding the crown of a partially erupted tooth. The inflammatory reaction often arises when food debris and bacteria are present beneath the gingival flap overlying the crown. Other predisposing factors include stress and upper respiratory infections, especially tonsillitis or pharyngitis.

These gingival flaps can exhibit long periods of chronic inflammation without symptoms. If the debris and bacteria become entrapped deep within the gingival flap, then abscess formation develops. Abscess development is seen most frequently in association with the mandibular third molars, and the predominant symptoms are extreme pain in the area, a foul taste, and inability to close the jaws. The pain may radiate to the throat, ear, or floor of the mouth. The affected area is erythematous and edematous, and the patient often has lymphadenopathy, fever, leukocytosis, and malaise (Fig. 4.37). NG-like necrosis may develop in areas of persistent pericoronitis.

Histopathologic Features

When soft tissue from areas of periodontitis is examined microscopically, gingivitis is present and the crevicular epithelium lining the pocket is hyperplastic with extensive exocytosis of acute inflammatory cells. The adjacent connective tissue exhibits an increased vascularity and contains an inflammatory cellular infiltrate consisting predominantly of lymphocytes and plasma cells, but with a variable number of polymorphonuclear leukocytes. Frequently, large colonies of microorganisms, representing plaque and calculus, are noted.

Treatment and Prognosis

Periodontitis

Initial attention must be directed toward elimination of any existing risk factors. Once these influences have been managed, the treatment of periodontitis is directed toward stopping the loss of attachment. The foremost goal of this process is the elimination of the pathogenic bacterial plaque. Scaling, root planing, and curettage can be used to treat early periodontal lesions. In deeper pockets, a surgical flap may be required to gain access to the tooth for necessary débridement. At this time, the underlying bone may be recontoured (if necessary) to aid in the resolution of the periodontal pocket.

In some bony defects, regeneration of the attachment can be attempted through interdental denudation or the placement of autogenous bone grafts, allografts, or alloplastic materials. Often these grafts are used in conjunction with materials, such as polytetrafluoroethylene, to achieve guided tissue regeneration in moderate-to-advanced periodontal defects.

dentlearn.ir

Systemic antibiotics are not warranted except in aggressive, severe, or refractory periodontitis. The organized biofilm is highly resistant to antimicrobials and does not respond to antibiotics administered with no other intervention. Antibiotics can be effective only if administered in association with nonsurgical periodontal therapy that disrupts the biofilm. Although a variety of antibiotics have proven to be effective, amoxicillin combined with metronidazole often is most beneficial.

Several forms of local antibiotic delivery have been developed. The antibiotic drugs are placed directly into sites of refractory periodontitis and consist of gels, ointments, nonresorbable fibers, and resorbable polymers. These antibiotic agents represent an adjunct to scaling and root planing and should be limited to sites that are resistant to conventional therapy alone.

In many cases, the prognosis for periodontitis correlates directly with the patient's desire to maintain oral health. Long-term studies show that periodontal health can be maintained after appropriate periodontal therapy if a program of rigorous oral hygiene and professional care is established. Patients should be encouraged to brush twice daily for at least 2 minutes with a fluoride-containing toothpaste. Rechargeable and oscillating/rotating electric toothbrushes have proven superior to manual or other types of powered toothbrushes. Daily interdental cleansing is important with interdental brushes proven superior to dental floss except in areas of tight contact that prevent utilization of brushes. Use of antiseptic rinses such as sodium hypochlorite, chlorhexidine, essential oils, cetylpyridinium chloride, or povidone-iodine has proven to be a useful adjunct to mechanical plaque removal. Sodium hypochlorite (bleach) has strong antiplaque and anti-inflammatory properties without the staining and reduced effectiveness over time associated with use of chlorhexidine. Twice-weekly rinsing of a 0.25% solution of sodium hypochlorite has been associated with significantly reduced bleeding upon probing along with increased plaque-free tooth surfaces. The rinse also appears to reduce subgingival periodontopathic bacteria in periodontal pockets as deep as 7–9 mm.

Bacterial morphotypes return to pretreatment levels 42 days after professional prophylaxis, but pathogenic complexes capable of inducing attachment loss require approximately 3 months to be reestablished functionally. In patients with less-than-optimal oral hygiene or with isolated defects that cannot be self-cleaned, further loss of attachment can be prevented if professional scaling and root planing are performed at 3-month intervals.

In younger patients, scaling and root planning alone do not stop progression of the periodontitis. Defects in leukocyte function, in addition to the invasive capabilities of the involved pathogenic organisms, mandate the use of antibiotics in combination with mechanical removal of subgingival plaque and inflamed periodontal tissues. Although tetracycline, amoxicillin and clavulanate potassium, minocycline, and erythromycin can be used in selected patients, the combination of high-dose (500 mg three times per day) amoxicillin and metronidazole has been shown to be most effective in controlling the involved periodontal pathogens, especially *A. actinomycetemcomitans*. The effectiveness of the antibiotics appears to be improved if initiated immediately after scaling and root planing. Continued therapy often is predicated on microbiologic testing to ensure selection of the most appropriate antimicrobial agent. Use of local antiseptic agents, such as sodium hypochlorite, chlorhexidine, or povidone-iodine has proven beneficial. Patients with active disease may be at increased risk for adverse peri-implant gingival infection.

A reevaluation with professional prophylaxis is performed once a month for 6 months and then every 3 months thereafter. Specimens for anaerobic cultures are obtained at each 3-month recall. Patients with refractory disease or significant colonization by pathogenic organisms receive additional courses of appropriate antibiotics. Long-term follow-up is mandatory because of the possibility of reinfection or incomplete elimination of the organisms. The presence of deep residual pockets is associated with disease progression. In such circumstances, periodontal surgery often is performed to eliminate these defects. This intervention is directed at any pocket consistently deeper than 5 mm and typically is performed after 2–6 months of nonsurgical therapy.

Necrotizing Periodontitis

Once any underlying influence (e.g., immunosuppression, malnutrition) has been resolved, NP often responds well to irrigation, débridement of the necrotic areas, effective oral hygiene measures, and administration of systemic antibiotic medications. Failure to respond to standard therapy mandates a thorough physical evaluation to rule out the possibility of an underlying disease.

Periodontal Abscess

A gingival or periodontal abscess is treated by drainage through the sulcus or by an incision through the overlying mucosa. Thorough cleansing of the area with removal of all foreign material, plaque, and calculus should be performed. Penicillin or other antibiotic drugs are prescribed when a fever is present. Analgesic agents are prescribed, and the patient receives a soft diet, is told to use warm salt-water rinses, and is instructed to return each day until the symptoms have resolved. After the acute phase has passed, the patient is treated for any underlying chronic pathologic periodontal condition.

Treatment of periodontal abscesses due to cemental tears involves complete removal of the fragment with the associated inflammatory tissue. If the tear is located along the coronal third of the root, the fragment often can be removed via nonsurgical scaling and root planing, while deeper lesions require a surgical periodontal approach.

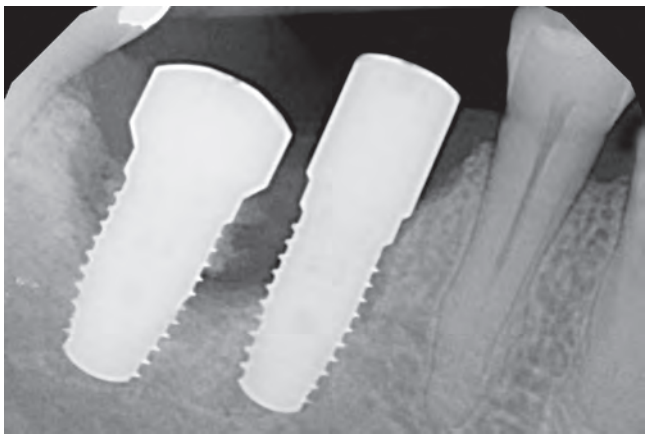
Pericoronitis

Acute pericoronitis is treated with gentle antiseptic lavage under the gingival flap to remove gross food debris and bacteria. Systemic antibiotic agents are used if a fever or general

dentlearn.ir

symptoms are noted. The patient is instructed to use warm saltwater rinses and to return in 24 hours. Once the acute phase has subsided, the tooth can be extracted if long-term maintenance is contraindicated. If tooth retention is desirable, then the overlying gingival flap is removed surgically, which is followed by elimination of all food debris and bacterial colonies by thorough curettage.

◆ PERI-IMPLANT DISEASES



Brånemark's landmark work with osseointegration of titanium implants in the late 1950s has led to a revolution in dentistry with an estimated 12 million implants installed annually throughout the world. Despite a 10-year implant survival of 95%, biological complications related to local development of bacterial biofilms are noted and are very similar to gingivitis and periodontitis of the natural dentition. **Peri-implant mucositis** refers to inflammation of the soft tissues surrounding an implant without loss of associated bone, whereas **peri-implantitis** demonstrates inflammation of the soft tissues with loss of supporting bone. The reported prevalence of peri-implantitis is approximately 20% of all implant-treated patients and 10% of all implants. This frequency translates to development of peri-implantitis in over 1 million implants annually.

In contrast to natural dentition, the attachment of dental implants is much more fragile due to the lack of a periodontal ligament and normal junctional epithelium. Once established, peri-implantitis exhibits a more accelerated pattern of disease progression when compared to periodontitis. Strong risk factors include poor oral hygiene, no regular professional maintenance care, and a history or presence of periodontitis. Other possible negative influences include smoking, diabetes, implant design that prevents ease of cleansing, and cement remnants adjacent to the implant.

Clinical and Radiographic Features

Peri-implant mucositis is inflammation of the soft tissues surrounding a dental implant without additional bone loss after the initial remodeling that occurs during healing of the surgical placement. Healthy peri-implant soft tissues are fragile and often will demonstrate local dot-like bleeding upon gentle probing, but the mucosa will not demonstrate other evidence of inflammation. In contrast, peri-implant mucositis will demonstrate local swelling, redness, and shininess with or without sensitivity. Profuse (linear or drop-like) bleeding with or without purulence will be noted upon gentle probing. An increased probing depth without bone loss often is seen due to the soft tissue swelling.

Peri-implantitis will present with features of peri-implant mucositis combined with the presence of bone loss (Fig. 4.38). Although some degree of nonpathologic bone loss can be seen during the first year of function, any additional loss greater than 2 mm represents peri-implantitis. Increasing pockets depths also will be noted.

• **Fig. 4.38 Peri-implantitis.** Pathologic circumferential bone loss associated with mandibular implant. (Courtesy of Dr. Scott Price.)

Treatment and Prognosis

The treatment of the peri-implant diseases is very similar to that utilized for gingivitis and periodontitis. Peri-implant mucositis therapy should concentrate on improved patient oral hygiene and professionally administered plaque control with repeated oral hygiene instructions and close follow-up. Thorough removal of plaque with manual or electric toothbrushes and interdental cleansing with devices such as floss or interdental brushes must be stressed and may be supplemented with antiseptic agents such as chlorhexidine.

Treatment of peri-implantitis mirrors that of peri-implant mucositis but also includes thorough professional debridement often combined with antiseptics or locally delivered antibiotics. When the bone loss is severe, surgical intervention is necessary to debride and decontaminate the infected sites with hand instruments, ultrasonic tips, or lasers. Extensive intervention should be undertaken only if there is strong evidence the implant can remain functional and be maintainable. Patients at high risk for failure include those who are committed to smoking, have poor oral hygiene, a history of high stage/grade periodontitis, or evidence of rapidly progressing bone loss with mobility.

◆ PAPILLON-LEFÈVRE SYNDROME

In 1924, Papillon and Lefèvre initially described the syndrome that bears their names. This autosomal recessive disorder predominantly demonstrates oral and dermatologic manifestations; similar dermatologic changes can be seen in the absence of oral findings **(Unna-Thost syndrome, Howell-Evans syndrome, Vohwinkel syndrome, Gamborg Nielsen syndrome,** and **mal de Meleda).** Because of the autosomal recessive inheritance pattern, the parents typically are not affected; consanguinity is noted in approximately one-third of cases.

Genetic studies of patients with Papillon-Lefèvre syndrome have mapped the major gene locus to chromosome 11q14-q21 and revealed mutation and loss of function of the *cathepsin C* gene. This gene is important in the structural

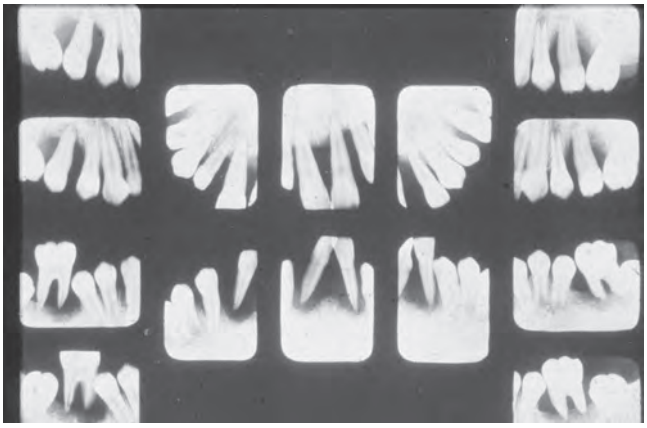
dentlearn.ir

growth and development of the skin and is critical for appropriate immune response of myeloid and lymphoid cells. Researchers believe that the loss of appropriate function of the *cathepsin C* gene results in an altered immune response to infection. In addition, the altered gene may affect the integrity of the junctional epithelium surrounding the tooth.

A closely related disease, **Haim-Munk syndrome,** also exhibits palmoplantar keratosis, progressive periodontal disease, recurrent skin infections, and several skeletal malformations. In this syndrome, the skin manifestations are more severe, and the periodontal disease is milder. Studies have demonstrated that Haim-Munk syndrome and many examples of prepubertal periodontitis also exhibit mutation of the *cathepsin C* gene and represent allelic variants of the mutated gene responsible for Papillon-Lefèvre syndrome.

Clinical and Radiographic Features

Papillon-Lefèvre syndrome exhibits a prevalence of one to four per million people in the population, and carriers are thought to be present in two to four per thousand persons. In most cases, the dermatologic manifestations become clinically evident in the first 3 years of life. Diffuse transgredient (first occurs on the palms and soles and then spreads to the dorsa of the hands and feet) palmar-plantar keratosis develops, with occasional reports of diffuse follicular hyperkeratosis, nail dystrophy, hyperhidrosis, and keratosis on the elbows and knees (Fig. 4.39). Other less common sites of involvement include the legs, thighs, dorsal surface of the fingers and toes, and (rarely) the trunk. Although the appearance of the dermatologic manifestations is variable, the lesions typically present as white, light-yellow, brown, or red plaques and patches that develop crusts, cracks, or deep fissures.



• **Fig. 4.39 Papillon-Lefèvre Syndrome.** Plantar keratosis of the foot.

The oral manifestations consist of dramatically advanced periodontitis that is seen in both the deciduous and the permanent dentitions. Upon eruption of the deciduous teeth, diffuse hemorrhagic and hyperplastic gingivitis develops in association with rapid loss of periodontal attachment (Fig. 4.40). The extensive loss of osseous support often results in teeth that radiographically appear to be floating in soft tissue (Fig. 4.41). At 4–5 years of age, all primary teeth typically have been lost or extracted. Once edentulous, the gingiva returns to a normal state of health until eruption of the permanent dentition restarts the cycle of rapidly progressive periodontal disease. By age 15, all the permanent teeth have been lost in most affected individuals. Although other pathogenic bacteria have been isolated from sites of active disease, *A. actinomycetemcomitans* has been related directly to the periodontal destruction.

In addition to the dermatologic and oral manifestations, numerous investigators have documented less frequent findings. Impaired somatic development and ectopic calcifications of the falx cerebri and choroid plexus have been reported, in addition to an increased susceptibility to

• **Fig. 4.40 Papillon-Lefèvre Syndrome.** Generalized erythematous gingivitis.

• **Fig. 4.41 Papillon-Lefèvre Syndrome.** Multifocal sites of bone loss in all four quadrants. (From Giansanti JS, Hrabak RP, Waldron CA: Palmoplantar hyperkeratosis and concomitant periodontal destruction [Papillon-Lefèvre syndrome], *Oral Surg Oral Med Oral Pathol* 36:40, 1973.)

dentlearn.ir

infections beyond the oral cavity. Pyoderma, furunculosis, pneumonia, hepatic abscesses, cerebral abscesses, and other infections have been documented.

Sporadic cases of a Papillon-Lefèvre syndrome-like clinical phenotype has been reported. To confirm the diagnosis of Papillon-Lefèvre syndrome, gene sequencing usually is performed. It has been noted that active cathepsin C is excreted in the urine of normal individuals but is absent from those affected with Papillon-Lefèvre syndrome, making urinalysis a simple and inexpensive method for diagnostic confirmation.

Histopathologic Features

Once again, the histopathologic features of Papillon-Lefèvre syndrome are like those seen in chronic periodontitis and are not specific. Submitted tissue often contains hyperplastic crevicular epithelium with exocytosis. The underlying connective tissue exhibits increased vascularity and a mixed inflammatory cellular infiltrate consisting predominantly of plasma cells intermixed with polymorphonuclear leukocytes, lymphocytes, and histiocytes. Initially, histopathologic examination is recommended to rule out other pathologic causes of the periodontal destruction.

Treatment and Prognosis

Skin lesions in these patients have been treated most successfully using systemic retinoids, such as etretinate, acitretin, and isotretinoin. This approach has resulted in remarkable improvement with complete clearance in most patients. Surprisingly, a few authors have reported improvement of the associated periodontal disease during periods of retinoid use, but others have disputed this claim. Possible adverse reactions caused by retinoid administration include angular cheilitis, dry lips, hair loss, arthralgia, tendinous and ligamentous calcifications, and teratogenicity. To avoid these drug-related adverse reactions, patients with mild dermatologic manifestations often are treated with topical lubricants, keratolytic agents (salicylic or lactic acid), corticosteroids, or antibiotics.

Attempts at resolution of the periodontal disease often have been frustrating. Despite extensive periodontal therapy and antibiotic agents, in many patients, the disease progresses until all teeth are lost. However, several investigators have reported a cessation of attachment loss, and two different treatment approaches have been used.

Despite the use of numerous antibiotic medications, several reports document a difficulty in resolution of the infection associated with teeth that already exhibit attachment loss. Some clinicians recommend extraction of all deciduous teeth to eliminate the periodontal pathogens and reduce the risk of transmitting these organisms to the permanent dentition. Following eruption of the permanent teeth, antibiotics are utilized to prevent redevelopment of periodontitis.

The second approach revolves around a direct attack against *A. actinomycetemcomitans.* Therapy with high-dose amoxicillin and metronidazole has proven effective when combined with extraction of severely affected teeth, high patient compliance, and strong supportive periodontal therapy. In clinical studies, the progression of attachment loss of the erupted dentition and the periodontal destruction of the teeth that erupt after the initiation of therapy were slowed dramatically. Rigorous oral hygiene, chlorhexidine mouth rinses, frequent professional prophylaxis, and periodic appropriate antibiotic therapy are necessary for long-term maintenance.

5 Bacterial Infections

IMPETIGO

Impetigo is a superficial infection of the skin that is caused by *Staphylococcus aureus, Streptococcus pyogenes* (group A, β-hemolytic), or both. Two main patterns are seen. Seventy percent of the cases are **nonbullous impetigo** with *S. aureus* being most responsible in the industrialized world whereas *S. pyogenes* is predominant in developing nations. **Bullous impetigo** is less common and predominantly caused by *S. aureus.* The term *impetigo* is derived from a Latin word meaning "attack" because of its common presentation as a scabbing eruption. Intact epithelium normally is protective against infection; therefore, many cases arise in damaged skin, such as preexisting dermatitis, cuts, abrasions, or insect bites. Secondary involvement of an area of dermatitis has been termed **impetiginized dermatitis.** An increased prevalence is associated with debilitating systemic conditions, such as human immunodeficiency virus (HIV) infection, type 2 diabetes mellitus, or dialysis.

Clinical Features

Although impetigo may occur at any age, the infection is seen predominantly during childhood and represents the most common bacterial skin infection between the ages of 2 and 5. **Nonbullous impetigo (impetigo contagiosa)** is the more prevalent pattern and usually involves the face, the extremities, or trunk. The facial lesions usually develop around the nose and mouth. In many patients with facial involvement, the pathogenic bacteria are harbored in the nose and spread onto the skin into previously damaged sites, such as scratches or abrasions. Often, facial lesions will have a linear pattern that corresponds to previous fingernail scratches. The peak occurrence is during the summer or early fall in hot, moist climates. Impetigo is contagious and easily spread in crowded or unsanitary living conditions.

Nonbullous impetigo initially appears as red macules or papules, with the subsequent development of fragile vesicles. These vesicles quickly rupture and become covered with a thick, amber crust (Fig. 5.1). The crusts are adherent and have been described as honey-colored or like "cornflakes glued to the surface." Some cases may be confused with exfoliative cheilitis (see page 294) or recurrent herpes simplex (see page 231). Pruritus is common and scratching often causes the lesions to spread (Fig. 5.2). Lymphangitis, cellulitis, fever, anorexia, and malaise are uncommon, although leukocytosis occurs in about half of affected patients.

In an infrequent pattern of impetigo termed **ecthyma,** the central area of the crust becomes necrotic and forms a deep indurated ulceration. This lesion heals slowly and often is associated with a permanent scar.

Due to its strong association with *S. aureus*, **bullous impetigo** also has been termed **staphylococcal impetigo.** The lesions frequent the trunk and intertriginous areas (axilla, neck, groin); involvement of the buttocks and extremities is less common. *Blistering dactylitis* is a localized pattern of bullous impetigo that typically involves the distal portion of a finger or more rarely a toe. Infants and newborns are infected most commonly, but the disease also may occur in children and adults. The lesions are characterized by superficial vesicles that rapidly enlarge to form larger flaccid bullae. Initially, the bullae are filled with clear serous fluid, but the contents of the bullae quickly become more turbid and eventually purulent. Although the bullae may remain intact, they usually rupture and develop a thin brown crust that some describe as "lacquer." Weakness, fever, lymphadenopathy, and diarrhea may be seen. Although uncommon, spread of the infection can result in cellulitis, osteomyelitis, septic arthritis, and pneumonia. Associated scarlet fever, rheumatic heart disease, and poststreptococcal glomerulonephritis also have been noted.

Diagnosis

A strong presumptive diagnosis normally can be made from the clinical presentation. When the diagnosis is not obvious clinically or the infection fails to respond to standard therapy within 7 days, the definitive diagnosis requires isolation of *S. aureus* or *S. pyogenes* from cultures of the skin lesions and testing the isolate for antibiotic sensitivity.

Treatment and Prognosis

For patients with nonbullous impetigo involving only a small area with few lesions, topical mupirocin or fusidic acid (available in Canada and Europe, not in the United States) has been shown to be effective. Increasing reports of resistance to these medications are appearing, especially in infections associated with methicillin-resistant *S. aureus* (MRSA). In such cases, utilization of topical retapamulin or ozenoxacin has been proven effective in many patients. Removal of the crusts with a clean cloth soaked in warm soapy water is recommended before application of topical therapy, rather than placing the medication on inert,

dentlearn.ir

• **Fig. 5.1 Impetigo.** Amber crusts of the skin and vermilion border of the lips.

• **Fig. 5.2 Impetigo.** Scaly and amber-colored crusts of the perioral skin.

dried, exfoliating skin. For bullous or more extensive lesions, topical antibiotic drugs often are insufficient; the treatment of choice is a 1-week course of a systemic oral antibiotic. The best antibiotic is one that is effective against both *S. pyogenes* and penicillin-resistant *S. aureus*. Cephalexin, dicloxacillin, flucloxacillin, and amoxicillin-clavulanic acid represent good current choices. In communities frequented with MRSA, therapy with agents such as trimethoprim/sulfamethoxazole, clindamycin, tetracycline, or fluoroquinolones is recommended. For severe cases in which MRSA has been isolated, linezolid or vancomycin are most effective. Inappropriate diagnosis and treatment with topical corticosteroids may reduce the inflammatory host response to the bacterial infection and temporarily improve the appearance, but the causative organism will not be eliminated, allowing the infection to persist, or spread.

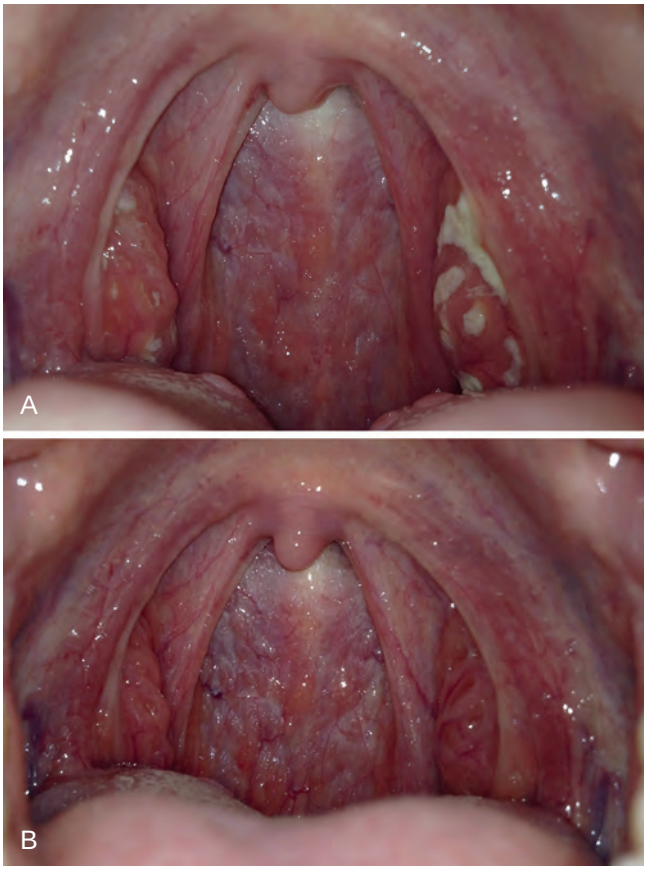
◆ ERYSIPELAS

Erysipelas is a superficial cellulitis of the skin that involves the dermis and the upper subcutaneous tissue. Although most cases are nonculturable, the infection most commonly is associated with β-hemolytic streptococci. Other organisms, such as *Staphylococcus aureus,* have been isolated from the lesions, but it is unclear if these bacteria are causative or a contaminant. The infection rapidly spreads through the lymphatic channels, which become filled with fibrin, leukocytes, and streptococci. Although also associated with ergotism, the term *Saint Anthony's fire* has been used to describe erysipelas. Because the French House of St. Anthony, an 11th-century hospital, had fiery red walls like the color of erysipelas, the term *Saint Anthony's fire* was used to describe this disease. Today, with most cases noted in the lower legs, classical facial erysipelas often is a forgotten diagnosis. At times, the appropriate diagnosis has been delayed because of confusion with facial cellulitis from dental infections.

Clinical Features

Erysipelas tends to occur primarily in young and older adult patients or in those who are debilitated, diabetic, immunosuppressed, obese, or alcoholic. Patients who have areas of chronic lymphedema or large surgical scars (such as, postmastectomy or saphenous venectomy) also are susceptible to this disease. The infection may occur anywhere on the skin, especially in areas of previous trauma. Over 80% of the cases are noted in the lower legs, but involvement of the face, arm, and upper thigh is not rare. In facial erysipelas, an increased prevalence is noted in the winter and spring months, whereas summer is the peak period of involvement of the lower extremities.

When lesions occur on the face, they normally appear on the cheeks, eyelids, and bridge of the nose, at times producing a butterfly-shaped lesion that may resemble lupus erythematosus (see page 798). If the eyelids are involved, then they may become edematous and shut, thereby resembling angioedema (see page 348). The affected area is painful, bright red, well-circumscribed, swollen, indurated, and warm to the touch (Fig. 5.3). Often the affected skin will demonstrate a surface texture that resembles an orange peel *(peau d'orange).* Intermixed bullous or hemorrhagic lesions may be seen and often require more intensive antibiotic therapy. High fever and lymphadenopathy often are present. Lymphangitis, leukocytosis, nausea, and vomiting occur infrequently. Diagnostic confirmation is difficult because cultures usually are not beneficial.



Treatment and Prognosis

The treatment of choice is penicillin. Alternative antibiotic drugs include macrolides (such as, erythromycin), cephalosporins (such as, cephalexin), and fluoroquinolones (such as, ciprofloxacin). On initiation of therapy, the area of skin involvement often enlarges, probably secondary to the release of toxins from the dying streptococci. A rapid resolution is noted within 48 hours. Without appropriate therapy, possible complications include abscess formation, gangrene, necrotizing fasciitis, toxic shock syndrome with possible multiple organ failure, thrombophlebitis, acute glomerulonephritis, septicemia, endocarditis, and death. Recurrences may develop in the same area, most likely in a previous zone

of damaged lymphatics or untreated athlete's foot. With repeated recurrences, permanent and disfiguring enlargements may result. In cases with multiple recurrences, prophylaxis with oral penicillin has been used.

◆ STREPTOCOCCAL TONSILLITIS AND PHARYNGITIS

Tonsillitis and **pharyngitis** are extremely common and may be caused by many different organisms. The most common causes are group A β-hemolytic streptococci, adenoviruses, enteroviruses, influenza, parainfluenza, and Epstein-Barr virus. Although a virus causes the majority of pharyngitis cases, infection with *S. pyogenes* (group A β-hemolytic streptococci) is responsible for 20%–30% of acute pharyngitis cases in children and 5%–15% of cases in adults. Spread is typically by person-to-person contact through respiratory droplets or oral secretions, with a short incubation period of 2–5 days.

Clinical Features

Although the infection can occur at any age, the greatest prevalence occurs in children 5–15 years old, with most cases in temperate climates arising in the winter or early spring. The signs and symptoms of **tonsillitis** and **pharyngitis** vary from mild to intense. Common findings include sudden onset of sore throat, temperature of 101–104°F, dysphagia, tonsillar hyperplasia, redness of the oropharynx and tonsils, palatal petechiae, cervical lymphadenopathy, and a yellowish tonsillar exudate that may be patchy or confluent (Fig. 5.4). Other occasional findings include a "beefy" red and swollen uvula, excoriated nares, and a scarlatiniform rash (see next topic). Conjunctivitis, coryza (rhinorrhea), cough, hoarseness, discrete ulcerative lesions, anterior stomatitis, absence of fever, a viral exanthem, and diarrhea typically are associated with the viral infections and normally are not present in streptococcal pharyngotonsillitis.

Diagnosis

Although the vast majority of pharyngitis cases are caused by a viral infection, reviews have shown that approximately 60% of patients with sore throats receive antibiotic therapy. To minimize overuse, antibiotics should not be prescribed without confirmation of bacterial infection. Except for very rare infections, such as *Corynebacterium diphtheriae* (see page 177) and *Neisseria gonorrhoeae* (see page 184), antibiotics are of no benefit for acute pharyngitis unless related to group A streptococci.

Current clinical guidelines in the United States recommend use of a rapid antigen detection kit (RADT). A positive

dentlearn.ir

result in patients with clinical evidence of pharyngitis supports antibiotic therapy. Due to the low sensitivity of RADT, bacterial culture is recommended upon a negative RADT in pediatric patients, resulting in a 1–5 day delay. In 2015, the FDA approved the first in-office nucleic acid amplification test (NAAT) that negates the need for a two-step algorithm and provides an answer within 15–25 minutes.

Although NAAT can significantly reduce the diagnostic delay in patients with pharyngitis, it does not resolve the diagnostic dilemma completely. Estimates suggest that approximately 20% of asymptomatic school-aged children are carriers of group A streptococci during the winter and spring seasons. When presenting with a viral pharyngitis, the carriers could demonstrate a false positive result to the NAAT tests. The gold standard for separating carriers from true streptococcal pharyngitis requires two serologic samples (titers of antistreptolysin and anti-DNase B) taken 2–4 weeks apart. Due to this extensive delay and associated cost, such extensive evaluation is not a part of standard clinical practice.

Treatment and Prognosis

Streptococcal pharyngitis usually is self-limited and resolves spontaneously within 3–4 days after onset of symptoms. The primary goals of therapy are to shorten the duration of symptoms, prevent the spread of infection, and prevent several rare complications. Possible suppurative complications include peritonsillar abscess, retropharyngeal abscess, cervical lymphadenitis, bacteremia (with resultant fever, nausea, and vomiting), necrotizing fasciitis, and toxic shock syndrome. Nonsuppurative complications also are seen and include acute rheumatic fever, rheumatic heart disease, and poststreptococcal glomerulonephritis. Initiation of appropriate therapy within the first 9 days after development of the pharyngitis prevents rheumatic fever. Patients are considered noncontagious 24 hours after initiation of appropriate antibiotic therapy.

The oral antibiotic of choice for group A streptococci is either penicillin V or amoxicillin. Common choices for patients allergic to penicillin are the first-generation cephalosporins such as cephalexin. Acetaminophen or ibuprofen can be utilized for moderate-to-severe pain, with ibuprofen being shown to be the superior of the two. Topical anesthetics such as lidocaine or benzocaine can be used for throat pain in older children and adolescents but should be avoided in younger children.

◆ SCARLET FEVER (SCARLATINA)

Scarlet fever is a systemic infection produced by specific strains of *S. pyogenes*, (group A, β-hemolytic streptococci). The disease begins as a streptococcal tonsillitis with pharyngitis in which the organisms elaborate an erythrogenic toxin that attacks the blood vessels and produces the characteristic skin rash. The condition occurs in susceptible patients who do not have antitoxin antibodies. The incubation period ranges from 1 to 7 days, and the significant clinical findings include fever, enanthem, and exanthem.

Scarlet fever was once a common cause of childhood death, but it nearly disappeared during the 20th century. Despite this, major outbreaks have occurred during the last decade, predominantly in the United Kingdom and eastern Asia. Between 2014 and 2016, the United Kingdom experienced its highest level of scarlet fever in 50 years. Although the subject of significant research, the cause for the resurgence remains unclear.

Clinical Features

Scarlet fever is most common in children from the ages of 3 to 12 years. The enanthem of the oral mucosa involves the tonsils, pharynx, soft palate, and tongue (see discussion of streptococcal pharyngotonsillitis in previous section). The tonsils, soft palate, and pharynx become erythematous and edematous, and the tonsillar crypts may be filled with a yellowish exudate. In severe cases, the exudates may become confluent and can resemble diphtheria (see page 177).

Scattered petechiae may be seen on the soft palate in up to 10% of affected patients. During the first 2 days, the dorsal surface of the tongue demonstrates a white coating through which only the fungiform papillae can be seen; this has been called **white strawberry tongue** (Fig. 5.5). By the fourth or fifth day, **red strawberry tongue** develops when the white coating desquamates to reveal an erythematous dorsal surface with hyperplastic fungiform papillae. These tongue findings are nonspecific and have been seen in multisystem inflammatory syndrome of COVID-19 (see page 265) and Kawasaki disease.

Classically, in untreated cases, fever develops abruptly around the second day. The patient's temperature peaks at approximately 103°F and returns to normal within 6 days. Abdominal pain, headache, malaise, nausea, and vomiting frequently are present. The exanthematous rash develops within the first 2 days and becomes widespread within 24 hours. The classic rash of scarlet fever is distinctive and often is described as a "sunburn with goose pimples." Pinhead punctate areas that are normal in color project through

• **Fig. 5.5 Scarlet Fever.** Dorsal surface of the tongue exhibiting white coating in association with numerous enlarged and erythematous fungiform papillae (white strawberry tongue).

dentlearn.ir

the erythema, giving the skin of the trunk and extremities a sandpaper texture. In heavily pigmented individuals, the rash may be more difficult to visualize, but the sandpaper texture remains palpable. The chest and stomach usually are involved initially with eventual spread to other parts of the body. The rash is more intense in areas of pressure and skin folds. Often, transverse red streaks, known as **Pastia lines,** occur in the skin folds secondary to the capillary fragility in these zones of stress. Frequently, the facial cheeks will appear flushed, and circumoral pallor will be noted.

The rash usually clears within 1 week, and then a period of desquamation of the skin occurs. This scaling begins on the face at the end of the first week and spreads to the rest of the skin by the third week, with the extremities being the last affected. The desquamation of the face produces small flakes; the skin of the trunk comes off in thicker, larger flakes. This period of desquamation may last from 3 to 8 weeks.

Diagnosis

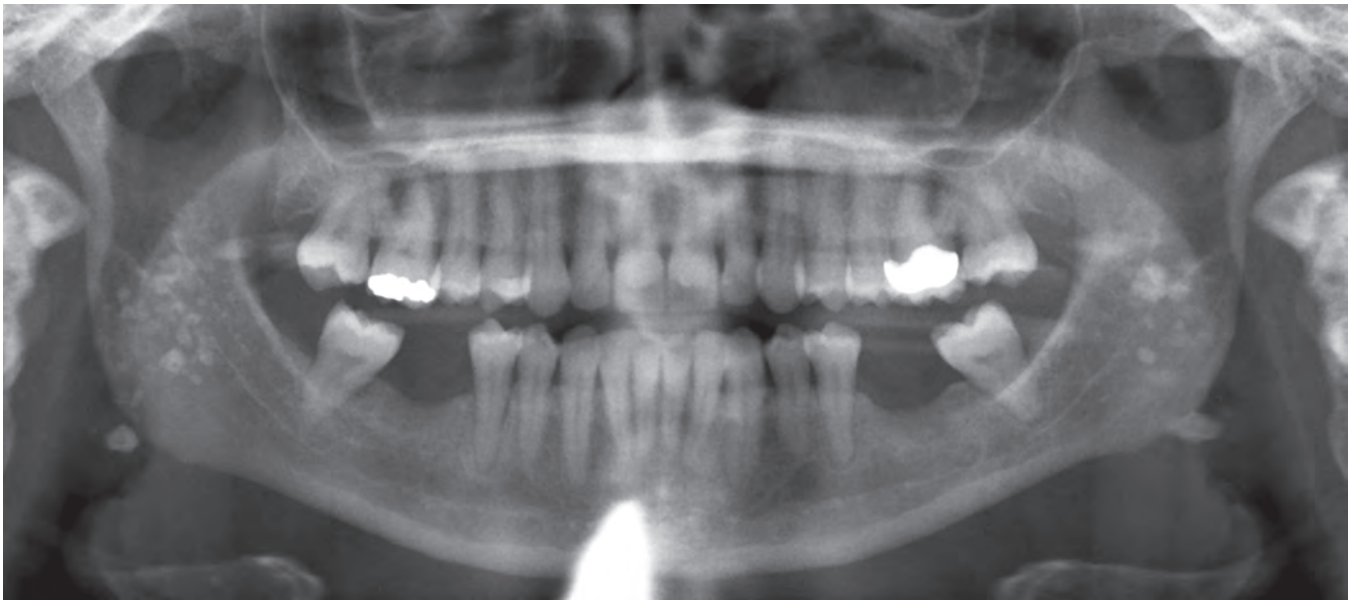
As described in greater detail in the previous discussion of streptococcal pharyngotonsillitis, the diagnosis is made by use of a rapid antigen detection kit (RADT), which is followed by throat culture in patients whose RADT is negative. Alternatively, the single-step nucleic acid amplification test (NAAT) is replacing RADT in many clinics.

Treatment and Prognosis

Treatment of scarlet fever and the associated streptococcal pharyngitis is necessary to prevent the possibility of complications, such as peritonsillar or retropharyngeal abscess, sinusitis, or pneumonia. Late complications are rare and include otitis media, acute rheumatic fever, glomerulonephritis, arthralgia, meningitis, and hepatitis. The oral antibiotic of choice for group A streptococci is either penicillin V or amoxicillin. Other choices for penicillin-allergic patients are, the first-generation cephalosporins (such as, cefadroxil or cephalexin). Ibuprofen can be used to reduce the fever and relieve the associated discomfort. The fever and symptoms show dramatic improvement within 48 hours after the initiation of treatment. With appropriate therapy, the prognosis is excellent.

◆ TONSILLAR PLUGS AND TONSILLOLITHIASIS

Anatomically, Waldeyer's ring includes the palatine, lingual, pharyngeal and Eustachian tube tonsils. The tonsils demonstrate numerous deep, twisted, and epithelial-lined invaginations. The invaginations, which are termed *tonsillar crypts*, function to increase the surface area for interaction between the immune cells within the lymphoid tissue and the oral environment. These convoluted crypts commonly are filled with desquamated keratin showing secondary bacterial colonization. The contents of the invaginations often become compacted and form a mass of foul-smelling material known as a **tonsillar plug.** Occasionally, the condensed necrotic debris and bacteria undergo dystrophic calcification and form a **tonsillolith (tonsillar concretion).** These structures have been shown to contain a living biofilm of densely packed bacteria demonstrating a diversity of rods, cocci, and filamentous organisms embedded within an extracellular matrix.



Clinical and Radiographic Features

Tonsillar plugs and tonsilloliths are seen rather frequently. Reviews of panoramic radiographs reveal a prevalence of tonsilloliths within the palatine tonsils that ranges from 7.2% to 13.4%, with computed tomography demonstrating a much higher frequency of discovery (16% to 46.1%). Although more poorly recognized, concretions within the tonsillar tissue in the base of the tongue also are not rare with a reported frequency of 1.5% on panoramic radiographs and 4.8% on computed tomography. Affected palatine tonsils may demonstrate one or more enlarged crypts filled with yellow debris that varies in consistency from soft to friable to fully calcified. In contrast to acute tonsillitis, the surrounding tonsillar tissue is not acutely painful, dramatically inflamed, or significantly edematous. Tonsilloliths can develop over a wide age range, from childhood to old age, with a mean patient age in the early 40s. Although a male predominance has been reported, other studies have not noted a gender predilection. These calcifications vary from small clinically insignificant lesions to massive calcifications more than 14 cm in length. Tonsilloliths may be single or multiple, and bilateral cases are not rare.

Although many palatine tonsillar plugs and tonsilloliths are asymptomatic, they can promote recurrent tonsillar infections and may lead to pain, abscess formation, ulceration, dysphagia, chronic sore throat, irritable cough, or otalgia. Halitosis is a common complaint and not surprising because several of the bacteria within the associated biofilm are known to produce hydrogen sulfide and methyl mercaptan, both of which are associated strongly with oral malodor. Occasionally, patients report a dull ache or a sensation of a foreign object in the throat that is relieved on removal of the tonsillar plug. In patients with large stones, clinical examination often reveals a hard, yellow submucosal mass of the affected tonsil. In older adult patients, large tonsilloliths can be aspirated and produce significant pulmonary complications. Dyspnea, esophageal perforation, and mediastinitis have been reported in association with large tonsilloliths. When symptomatic, lingual tonsilloliths are reported to be associated with local discomfort, anterior neck pain, or sensation of a foreign body.

Most frequently, palatine tonsilloliths are discovered on panoramic radiographs as radiopaque objects superimposed on the midportion of the mandibular ramus (Fig. 5.6). In other cases, small radiopacities may be seen posterior or inferior to the angle of the mandible. Most lingual tonsilloliths

dentlearn.ir

• **Fig. 5.6 Tonsilloliths.** Cluster of radiopacities noted bilaterally in the midportion of the ascending ramus. (Courtesy of Dr. Kim Nichols.)

are noted along the margin of the soft tissue shadow of the base of the tongue, primarily inferior and posteroinferior to the mandible on panoramic radiographs. When compared to palatine tonsilloliths, lingual concretions tend to be smaller in size and fewer in number.

Diagnosis

A strong presumptive diagnosis can be made through a combination of the clinical and radiographic features. After detection on a panoramic radiograph, if further diagnostic confirmation of tonsilloliths is deemed necessary, then their presence can be confirmed with computed tomography (CT), magnetic resonance imaging (MRI), or the demonstration of the calculi on removal of the affected tonsil.

Treatment and Prognosis

Tonsilloliths discovered incidentally during evaluation of a panoramic radiograph often are not treated unless associated with significant tonsillar hyperplasia or clinical symptoms. Affected individuals occasionally try to remove tonsillar plugs with instruments, such as straws, toothpicks, and dental instruments. Such therapy has the potential to damage the surrounding tonsillar tissue and should be discouraged. Patients should be educated to attempt removal by gargling warm salt water or using pulsating jets of water.

Superficial calculi can be enucleated or curetted; deeper symptomatic tonsilloliths require local excision. Redevelopment of removed concretions is common. Laser or coblation cryptolysis has been utilized successfully to reduce the extent of the tonsillar invaginations and stop the redevelopment of the concretions. If evidence of associated chronic tonsillitis is seen, then tonsillectomy provides definitive therapy.

◆ DIPHTHERIA

Diphtheria is a life-threatening infection most commonly produced by *Corynebacterium diphtheriae*. *C. ulcerans* and *C. pseudotuberculosis* are less common causes and usually discovered in individuals exhibiting contact with farm animals or dairy products. The name of the disease derives from the Greek word *diphthera* which translates to "leather hide" in reference to the tenacious pseudomembrane that is typical on the soft palate and pharynx of affected patients. The disease initially was described in 1826, and *C. diphtheriae* (also termed *Klebs-Löffler bacillus*) was discovered by Klebs in 1883 and isolated in pure culture by Löffler in 1884. Humans are the sole reservoir, and the infection is acquired through contact with an infected person or carrier usually through respiratory droplets.

The bacterium produces a lethal exotoxin that causes tissue necrosis, thereby providing nutrients for further growth and leading to peripheral spread. The exotoxin interferes with cellular protein synthesis. In addition to the death of affected cells, involvement of Schwann cells can lead to demyelination of peripheral nerves with significant associated neuropathies. The first effective antitoxin was discovered by the German physician, Emil von Behring, who was awarded the first Nobel Prize in medicine for this work. The antitoxin has been available since 1913, and immunization has been widespread in North America since 1922. The vaccination is an antitoxin that protects against toxin-related tissue damage but does not prevent infection by the bacteria.

Widespread vaccination led to a dramatically decreased prevalence of the infection until the 1990s when collapse of the Soviet Union produced inconsistent vaccination and localized outbreaks. The process finally was controlled by administration of vaccine to all children, adolescents, and

dentlearn.ir

adults (regardless of immunization histories). In addition, the disease remains endemic in areas of the globe such as south and southeast Asia and Africa where vaccination rates are less than 80%.

In addition to these pockets of disease, infections may occur in people who are immunosuppressed or who have failed to receive booster injections as required. Isolated outbreaks still are reported in the urban poor and Native American populations of North America. Overall, diphtheria currently is rare in the United States with only six reported cases between 2000 and 2015.

Clinical Features

The signs and symptoms of diphtheria arise 1–5 days after exposure to the organism. The initial systemic symptoms, which include low-grade fever, headache, malaise, anorexia, sore throat, and vomiting, arise gradually and may be mild. Although skin wounds may be involved, the infection predominantly affects mucosal surfaces and may produce exudates of the nasal, tonsillar, pharyngeal, laryngotracheal, or conjunctival areas. Urethritis from toxigenic *C. diphtheriae* has been noted secondary to orogenital contact. Involvement of the nasal cavity often is accompanied with prolonged mucoid or hemorrhagic discharge. The oropharyngeal exudate begins on one or both tonsils as a patchy, yellow-white, thin film that thickens to form an adherent gray covering. With time, the membrane may develop patches of green or black necrosis. The superficial epithelium is an integral portion of this exudate, and attempts at removal are difficult and may result in bleeding. The covering may continue to involve the entire soft palate, uvula, larynx, or trachea, resulting in stridor and respiratory difficulties. Palatal perforation can occur but is very uncommon. Rarely, the lesions have been isolated to the oral cavity.

The severity of the infection correlates with the spread of the membrane. Local obstruction of the airway can be lethal and historically was one of the most common causes of death, leading to the diphtheria nickname of "*strangling angel*." Involvement of the tonsils leads to significant cervical lymphadenopathy, which often is associated with an edematous neck enlargement known as *bull neck.* Toxin-related paralysis may affect oculomotor, facial, pharyngeal, diaphragmatic, and intercostal muscles. The soft palatal paralysis can lead to nasal regurgitation during swallowing. Oral or nasal involvement has been reported to spread to the adjacent skin of the face and lips.

Cutaneous diphtheria can occur anywhere on the body and is characterized by chronic skin ulcers that frequently are associated with infected insect bites and may harbor other pathogens, such as *S. aureus* or *S. pyogenes.* These skin lesions can arise even in vaccinated patients and typically are not associated with systemic toxic manifestations. When contracted by travelers from developed nations, the diagnosis often is delayed because of the nonspecific clinical presentation and a low index of suspicion. The cutaneous lesions represent an important reservoir of infection and can lead to more typical and lethal diphtheria in unprotected contacts.

Although bacteremia is rare, circulating toxin can result in systemic complications, such as myocarditis, neuropathy, thrombocytopenia, proteinuria, and renal failure. Myocarditis and neurologic difficulties are seen most frequently and usually are discovered in patients with severe nasopharyngeal diphtheria. Myocarditis may present as progressive weakness and dyspnea or lead to acute congestive heart failure. The neuropathy associated with diphtheria usually is biphasic. Initially, lower cranial neuropathies arise a few weeks after the pharyngeal infections and often present with dysphonia, dysphagia, palatal paralysis, and numbness of the face, tongue, and gingiva. Subsequently, polyneuropathy of the extremities becomes evident as the cranial neuropathies begin to fade. A significant number of patients become quadriplegic at the nadir. A peripheral polyneuritis resembling Guillain-Barré syndrome also may occur.

Diagnosis

Although the clinical presentation can be distinctive in severe cases, laboratory confirmation should be sought in all instances. Although culture remains the diagnostic gold standard, a polymerase chain reaction (PCR) analysis has become available and has reduced the time required to confirm the diagnosis. Except during an epidemic, the diagnosis can be difficult due to the rarity of the infection and the inexperience of many physicians with the disease.

Treatment and Prognosis

Treatment of the patient with diphtheria should be initiated at the time of the clinical diagnosis and should not be delayed until the results of the culture are received. Antitoxin should be administered in combination with antibiotics to prevent further toxin production, to stop the local infection, and to prevent transmission. Erythromycin, procaine penicillin, or intravenous (IV) penicillin may be used. Most patients are no longer infectious after 4 days of antibiotic therapy, but some may retain vital organisms. The patient is not considered to be cured until three consecutive negative culture specimens are obtained.

Because the antitoxin neutralizes only circulating toxin that is not bound to tissue, prompt administration is critical. This factor stresses the need for maintaining local stocks that have not reached their expiration date. Patients demonstrate improved outcomes if the antitoxin is administered within 48 hours of the first pharyngeal symptoms.

Before the development of the antitoxin, the mortality rate approached 50%, usually from cardiac or neurologic complications. Although the outcome is unpredictable, the current mortality rate is less than 5%, with most patients demonstrating a total or near-complete recovery with only mild residual deficits. Development of myocarditis is an important predictor of mortality.

dentlearn.ir

Deaths still occur in the United States because of delays in therapy secondary to lack of suspicion. With worldwide travel and visitors from across the globe, prevention is paramount. Even in those vaccinated as children, it must be remembered that a booster inoculation is required every 10 years. Currently, the inoculation in adults has been combined into the *Tdap vaccine* that includes tetanus, diphtheria, and pertussis.

◆ SYPHILIS (LUES)

Syphilis is a worldwide chronic infection produced by *Treponema pallidum*. The organism is extremely vulnerable to drying; therefore, the primary modes of transmission are sexual contact or from mother to fetus. Humans are the only proven natural host for syphilis.

After the advent of penicillin therapy in the 1940s, the prevalence of syphilis slowly decreased for many years but often demonstrated peaks and troughs associated with sexual activity during that era. A peak occurred during the "sexual revolution" of the 1960s, but fear of acquired immunodeficiency syndrome (AIDS) in 2000 led to the fewest reported cases of primary and secondary syphilis since reporting began in 1941. As more effective therapy for AIDS has been developed, sexual activity has changed once again with an increasing prevalence of sexually transmitted diseases being reported, primarily because of increases among men who have sex with men (MSM). Congenital syphilis followed a similar trend and reached a low in 2012 only to increase by 38% over the next 2 years. This rapid increase in congenital syphilis was related directly to a 22% increase in syphilis noted in women during the same time period. Oral sex is thought to have played an increasingly important contribution to the recent surge in the number of sexually transmitted diseases, as many falsely believed that unprotected oral sex was a safe or no-risk sexual practice, representing a good replacement for other higher-risk behaviors. During the recent wave, it is estimated there are more than 12 million new syphilitic infections annually in the world.

In patients with syphilis, the infection undergoes a characteristic evolution that classically proceeds through three stages. A syphilitic patient is highly infectious only during the first two stages, but pregnant women also may transmit the infection to the fetus during the latent stage. Maternal transmission during the first two stages of infection almost always results in miscarriage, stillbirth, or an infant with congenital malformations. The longer the mother has had the infection, the less the chance of fetal infection. Infection of the fetus may occur at any time during pregnancy, but the stigmata do not begin to develop until after the fourth month of gestation. The clinical changes secondary to the fetal infection are known as **congenital syphilis.** Oral syphilitic lesions are uncommon but may occur in any stage. Due to the rarity of oral lesions and the nonspecific microscopic pattern, appropriate histopathologic diagnosis easily can be missed by pathologists inexperienced with the pathosis.

Clinical Features

Primary Syphilis

Primary syphilis is characterized by the **chancre** that develops at the site of inoculation, becoming clinically evident 3–90 days after the initial exposure. Most chancres are solitary and begin as papular lesions that develop a central ulceration. Approximately 85% arise in the genital areas, whereas 10% are anal, 4% are oral, and the remaining 1% affect other extragenital locations.

Intraoral lesions of primary syphilis are documented infrequently, because the symptoms associated with this stage tend to resolve within a few days with many patients not seeking therapy. The oral lesions are seen most commonly on the lip, but other sites include the buccal mucosa, tongue, palate, gingiva, and tonsils (Fig. 5.7). The upper lip is affected more frequently in males, whereas lower lip involvement is predominant in females. Some believe this selective labial distribution may reflect the surfaces most actively involved during fellatio and cunnilingus. The oral lesion appears as a painless, clean-based ulceration or, rarely, as a vascular proliferation resembling a pyogenic granuloma. Regional lymphadenopathy, which may be bilateral, is seen in most patients. At this time, the organism is spreading systemically through the lymphatic channels, setting the stage for future progression. If untreated, then the initial lesion heals within 3–8 weeks.

Secondary Syphilis

The next stage is known as *secondary* (disseminated) *syphilis* and is discovered clinically 4–10 weeks after the initial infection. The lesions of secondary syphilis may arise before the primary lesion has resolved completely. During secondary syphilis, systemic symptoms often arise. The most common are painless lymphadenopathy, sore throat, malaise, headache, weight loss, fever, and musculoskeletal pain. A consistent sign is a diffuse, painless, maculopapular cutaneous rash,

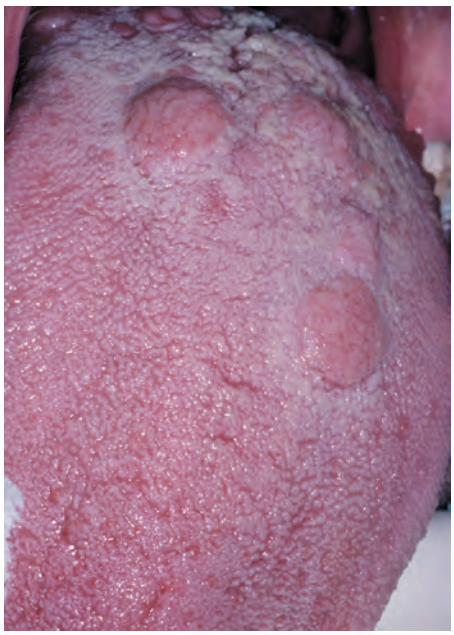
• **Fig. 5.11 Mucous Patch of Secondary Syphilis.** Circumscribed and thickened white plaque noted in the midline of the soft palate.



which is widespread and can even affect the palmar and plantar areas. On occasion, a cutaneous papule may develop in the crease of the nasal alar or the oral commissure and demonstrate a central fissure in association with the crease, forming the clinically distinctive lesion known as a **split papule** (Fig. 5.8). The rash also may involve the oral cavity and appear as red, maculopapular areas. Although the skin rash may result in areas of scarring and hyperpigmentation or hypopigmentation, it heals without scarring in most patients.

Most reported examples of intraoral syphilis are discovered during the secondary stage, and concurrent cutaneous lesions often are not described. Affected patients most often develop sensitive whitish and elevated plaques known as **mucous patches** that develop due to the intense inflammatory response to the spirochete infection (Figs. 5.9–5.11). Occasionally, several adjacent patches can fuse and form a serpentine or snail-track pattern. Subsequently, superficial epithelial necrosis may occur, leading to sloughing and exposure of the underlying raw connective tissue. Less often, thickened/corrugated leukoplakic plaques or erythematous patches like those seen in atrophic candidiasis may be present. Lesions of secondary syphilis may appear on any mucosal surface but are found commonly on the tongue, lip, buccal mucosa, and palate. Occasionally, papillary lesions that may resemble viral papillomas arise during this time and are known as **condylomata lata.** Although these lesions typically occur in the genital or anal regions, rare oral examples occur (Fig. 5.12). In contrast to the isolated chancre noted in the primary stage, multiple lesions are typical of secondary syphilis. Spontaneous resolution usually occurs within 3–12 weeks; however, relapses may occur during the next year.

Tertiary Syphilis

After the second stage, patients enter a period in which they are free of lesions and symptoms, known as **latent syphilis.** This period of latency may last from 1 to 30 years; then the third stage known as *tertiary syphilis* develops in approximately 30% of affected individuals. This stage includes the most serious of all complications. The vascular system can be affected significantly through the effects of the earlier arteritis. Aneurysm of the ascending aorta, left ventricular hypertrophy, aortic regurgitation, and congestive heart failure may occur. Involvement of the central nervous system

dentlearn.ir

• **Fig. 5.12 Condyloma Lata.** Multiple indurated and slightly papillary nodules on the dorsal tongue. (Courtesy of Dr. Karen Novak.)

(CNS) may result in tabes dorsalis, general paralysis, psychosis, dementia, paresis, and death. Ocular lesions such as iritis, choroidoretinitis, and Argyll Robertson pupil may occur. Argyll Robertson pupils constrict upon focusing, but they fail to respond to bright light. Less significant, but more characteristic, are scattered foci of granulomatous inflammation, which may affect the skin, mucosa, soft tissue, bones, and internal organs. This active site of granulomatous inflammation, known as a **gumma,** appears as an indurated, nodular, or ulcerated lesion that may produce extensive tissue destruction. Since the advent of successful antibiotic therapy, intraoral gummas are extremely uncommon; when seen, they usually affect the palate or tongue. When the palate is involved, the ulceration frequently perforates through to the nasal cavity (Fig. 5.13). The tongue may be involved diffusely with gummata and appear large, lobulated, and irregularly shaped. This lobulated pattern is termed **interstitial glossitis** and is thought to be the result of contracture of the lingual musculature after healing of gummas. Diffuse atrophy and loss of the dorsal tongue papillae produce a condition called **luetic glossitis.** In the past, this form of atrophic glossitis was thought to be precancerous, but several more recent publications dispute this concept.

Congenital Syphilis

In 1858, Sir Jonathan Hutchinson described the changes found in congenital syphilis and defined the following three pathognomonic diagnostic features, known as **Hutchinson triad:**

- Hutchinson teeth
- Ocular interstitial keratitis
- Eighth nerve deafness

Like many diagnostic triads, few patients exhibit all three features. In addition to Hutchinson triad, several other alterations may be seen, such as saddle-nose deformity, high-arched palate, frontal bossing, hydrocephalus, intellectual disability, gummas, and neurosyphilis. Table 5.1 delineates the prevalence rates of the stigmata of congenital syphilis in a cohort of affected patients.

TABLE 5.1 Stigmata of Congenital Syphilis

Stigmata of Congenital Syphilis*	Number of Patients	Percentage Affected
Frontal bossing	235	86.7
Short maxilla	227	83.8
High-arched palate	207	76.4
Saddle nose	199	73.4

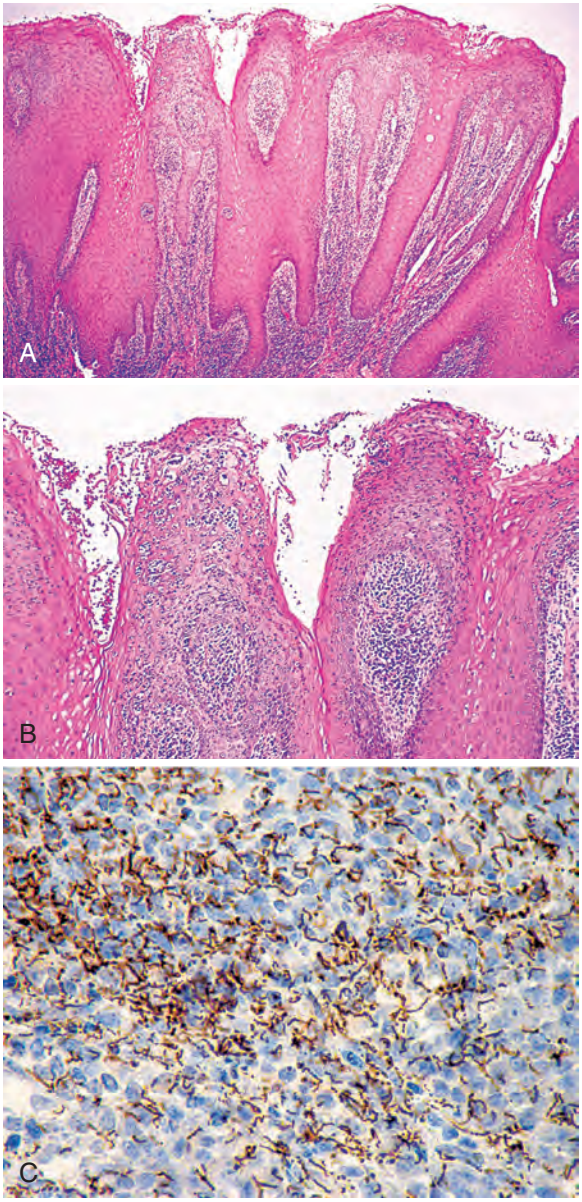
dentlearn.ir

Infants infected with syphilis can display signs within 2–3 weeks of birth. These early findings include growth impairment, fever, jaundice, anemia, hepatosplenomegaly, rhinitis, rhagades (circumoral radial skin fissures), and desquamative maculopapular, ulcerative, or vesiculobullous skin eruptions. Untreated infants who survive often develop tertiary syphilis with damage to the bones, teeth, eyes, ears, and brain. It is these findings that were described well by Hutchinson.

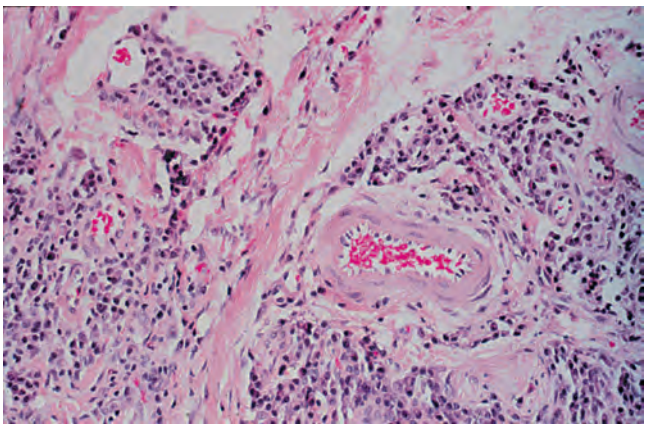
The infection alters the formation of both the anterior teeth **(Hutchinson incisors)** and the posterior dentition **(mulberry molars, Fournier molars, Moon molars).** Hutchinson incisors exhibit their greatest mesiodistal width in the middle third of the crown. The incisal third tapers to the incisal edge, and the resulting tooth resembles a straightedge screwdriver. The incisal edge often exhibits a central hypoplastic notch (Fig. 5.14). Mulberry molars taper toward the occlusal surface with a constricted grinding surface. The occlusal anatomy is abnormal, with numerous disorganized globular projections that resemble the surface of a mulberry (Fig. 5.15).

As mentioned previously, the prevalence of congenital syphilis is on the rise. To reverse this trend, all women should be screened for syphilis early in the pregnancy. In addition, women at high risk for syphilis should be tested again twice during the third trimester. Finally, any fetal death after 20 weeks of gestation should trigger testing of the mother.



• **Fig. 5.14 Hutchinson Incisors of Congenital Syphilis.** Anterior dentition exhibiting crowns tapering toward the incisal edges that demonstrate with hypoplastic notching. (Courtesy of Dr. Roman Carlos.)

• **Fig. 5.15 Mulberry Molar of Congenital Syphilis.** Maxillary molar demonstrating occlusal surface with numerous globular projections.



Histopathologic Features

The histopathologic picture of the oral lesions in the syphilitic patient is not specific. During the first two stages, the pattern is similar. The surface epithelium is ulcerated in primary lesions and may be ulcerated or hyperplastic in the secondary stage. Extensive exocytosis typically is noted and represents a major clue to the diagnosis (Fig. 5.16). The

• **Fig. 5.16 Secondary Syphilis, Condyloma Lata. dentlearn.ir

• **Fig. 5.17 Primary Syphilis.** A chronic perivascular inflammatory infiltrate of plasma cells and lymphocytes. (Courtesy of Dr. John Metcalf.)

underlying lamina propria exhibits an intense chronic inflammatory cellular infiltrate composed predominantly of lymphocytes and plasma cells, which is noted primarily in the superficial stroma and around deeper vascular channels (Fig. 5.17). Although the presence of plasma cells is commonplace within ulcerations and areas of oral mucositis, the combination of heavy exocytosis and an underlying dense lymphoplasmacytic infiltrate often raises the index of suspicion to a level that supports search for the organism. The use of special silver impregnation techniques, such as Warthin-Starry or Steiner stains, or immunoperoxidase reactions directed against the organism often show scattered corkscrew-like spirochetal organisms that frequently are found most easily within the surface epithelium and at the interface between the epithelium and the superficial stroma (see Fig. 5.16, *C*). The organism also can be detected in tissue through direct fluorescent antibody or nucleic acid amplification testing.

Oral tertiary lesions typically exhibit surface ulceration, with peripheral pseudoepitheliomatous hyperplasia. The underlying inflammatory infiltrate usually demonstrates foci of granulomatous inflammation with well-circumscribed collections of histiocytes and multinucleated giant cells. Even with special stains, the organisms are hard to demonstrate in the third stage; researchers believe the inflammatory response is an immune reaction, rather than a direct response to *T. pallidum.*

Diagnosis

The diagnosis of syphilis can be confirmed by demonstrating the spiral organism by biopsy or dark-field examination of a smear of an active lesion. False-positive results in smears are possible in the oral cavity because of morphologically similar oral inhabitants, such as *Treponema microdentium, T. macrodentium,* and *T. mucosum.* Demonstration of the organism on a smear or in biopsy material should be confirmed using specific immunofluorescent antibodies, nucleic acid amplification testing, or serologic evaluation.

Several nonspecific and not highly sensitive serologic screening tests for syphilis are available. These include the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR). The results of these screening tests are reported quantitatively with the serial antibody titers occasionally used to follow treatment response. Due to the delay associated with antibody development, the screening tests can be negative for up to 6 weeks after the initial infection. From this point, the tests remain strongly positive throughout the remainder of the primary stage and the entire secondary stage. This delay in serologic positivity must be remembered because biopsy results of an intraoral chancre could demonstrate definitive evidence of infection weeks before the screening tests reveal a positive result. After the development of latency, the positivity generally subsides with time. As part of appropriate prenatal care, all pregnant women should receive one of the nonspecific screening tests. Because these tests typically are negative in the early primary stage and may be falsely negative in immunosuppressed patients (such as, AIDS), tissue identification of the organism is critical in many patients.

Specific and highly sensitive serologic tests for syphilis also are available. These include the fluorescent treponemal antibody absorption (FTA-ABS), *T. pallidum* hemagglutination assay (TPHA), *T. pallidum* particle agglutination assay (TPPA), and microhemagglutination assay for antibody to *T. pallidum* (MHA-TP). These test results remain positive for life. This lifelong persistence of positivity limits their usefulness in the diagnosis of a second occurrence of infection. Therefore, in cases of possible reinfection, the organisms should be demonstrated within the tissue or exudates.

Treatment and Prognosis

The treatment for syphilis necessitates an individual evaluation and a customized therapeutic approach. The treatment of choice is parenteral penicillin G for all stages of syphilis. The type (benzathine, aqueous procaine, or aqueous crystalline), dosage, and length of treatment varies according to the stage and clinical manifestations. For the patient with a true penicillin allergy, doxycycline is second-line therapy, with tetracycline and ceftriaxone also demonstrating antitreponemal activity.

In some patients, the antibiotic therapy is associated with a release of endotoxin-like products from the dying spirochetes resulting in a symptom-complex termed *Jarisch-Herxheimer reaction*. Affected patients present with acute onset of fever, headache, myalgia, and other symptoms. The reaction is seen most frequently in the early stages of syphilis when the bacterial burden is high.

Even in patients who obtain a clinical and serologic "cure" with penicillin, it must be remembered that *T. pallidum* can escape the lethal effects of the antibiotic when the organism is located within the confines of lymph nodes or the CNS. Therefore, antibiotic therapy may not always result in a total cure in patients with neurologic involvement but may arrest only the clinical presentations of the infection. Patients with immunosuppression, such as those with AIDS, may not respond appropriately to standard antibiotic regimens, and

dentlearn.ir

numerous reports have documented a continuation to neurosyphilis despite seemingly appropriate single-dose therapy.

GONORRHEA

Gonorrhea, a sexually transmitted disease that is produced by *Neisseria gonorrhoeae,* represents the second most common reportable bacterial infection in the United States (after chlamydia) with over 800,000 persons estimated to be infected each year. The disease is epidemic, especially in young adults residing in urban areas; worldwide, millions of people are infected each year. The rate in the United States remains the highest of any industrialized country, and certain segments of the population, such as those with a low socioeconomic or education level, injecting drug users, prostitutes, homosexual men, and military personnel, remain at high risk. In contrast to many other sexually transmitted diseases, women are affected slightly more frequently than men.

Clinical Features

The infection is spread through sexual contact, and most lesions occur in the genital areas. Indirect infection is rare because the organism is sensitive to drying and cannot penetrate intact stratified squamous epithelium. The incubation period is typically 2–5 days. Affected areas often demonstrate significant purulent discharge, but approximately 10% of men and up to 80% of women who contract gonorrhea are asymptomatic.

In men, the most frequent site of infection is the urethra, resulting in purulent discharge and dysuria. Less common primary sites include the anorectal and pharyngeal areas. The cervix is the primary site of involvement in women, and the chief complaints are increased vaginal discharge, intermenstrual bleeding, genital itching, and dysuria. The organism may ascend to involve the uterus and ovarian tubes leading to **pelvic inflammatory disease (PID)** with long-term complications that include ectopic pregnancies or infertility from tubal obstruction.

Between 0.5% and 3.0% of untreated patients with gonorrhea will have disseminated gonococcal infections from systemic bacteremia. The most common signs of dissemination are myalgia, arthralgia, polyarthritis, and dermatitis. In 75% of patients with disseminated disease, a characteristic skin rash develops. The dermatologic lesions consist of discrete papules and pustules that often exhibit a hemorrhagic component and occur primarily on the extremities. Less common alterations secondary to gonococcal septicemia include fever, endocarditis, pericarditis, meningitis, and oral mucosal lesions of the soft palate and oropharynx, which may be similar clinically to aphthous ulcerations.

Most cases of oral gonorrhea appear to be a result of fellatio, although oropharyngeal gonorrhea may be the result of gonococcal septicemia, kissing, or cunnilingus. Most cases are reported in women or homosexual men, with the most common sites being the pharynx, tonsils, and uvula. Although pharyngeal gonorrhea usually is asymptomatic, a mild-to-moderate sore throat may occur and be accompanied by nonspecific, diffuse oropharyngeal erythema. Involved tonsils typically demonstrate edema and erythema, often with scattered, small punctate pustules.

Although most cases of pharyngeal infection resolve spontaneously without adverse sequelae, new findings suggest the infection has important implications, which strongly support the need for treatment to reduce the potential for spreading the infection. Research also has suggested that pharyngeal involvement may play an important role in the development of antibiotic resistance. Several studies have shown that *N. gonorrhoeae* may undergo mutation by acquiring genetic material from other *Neisseria* species that frequent the throat, and drug penetration is low in the pharyngeal tissues. Oropharyngeal infection is associated with increased concern due to the typical lack of associated symptoms, difficulty in confirming infection (see Diagnosis), and resistance to therapy (see Treatment and Prognosis). Pharyngeal gonorrhea in the absence of a concomitant genital infection is relatively common among young people examined at STD clinics, with up to 28% of infections missed without pharyngeal testing. These findings have led to guidelines that recommend periodic extragenital testing among men who have sex with men (MSM). Several studies have suggested this screening should be extended to other high risk non-MSM populations such as commercial sex workers and young adults seeking care for a sexually transmitted disease (STD).

Rarely, lesions have been reported in the anterior portion of the oral cavity, with areas of infection appearing erythematous, pustular, erosive, or ulcerated. Occasionally, the infection may simulate **necrotizing gingivitis (NG),** but some clinicians have reported that the typical *fetor oris* is absent, providing an important clue to the actual cause (Fig. 5.18). Submandibular or cervical lymphadenopathy may be present.

• **Fig. 5.18 Gonorrhea.** Necrosis, purulence, and hemorrhage of the anterior mandibular gingiva. (From Williams LN: The risks of oral-genital contact: a case report, *Gen Dent* 50:282–284, 2002. Published with permission by the Academy of General Dentistry. Copyright 2002 by the American Academy of General Dentistry. All rights reserved.)

dentlearn.ir

During birth, infection of an infant may occur, even from an infected mother who is asymptomatic and possibly result in serious eye involvement, sepsis (associated with arthritis and meningitis), and less severe manifestations such as rhinitis, vaginitis, and urethritis. The eye involvement is called **gonococcal ophthalmia neonatorum** and rapidly can cause perforation of the globe of the eye and blindness. Common signs of infection include significant conjunctivitis and a mucopurulent discharge from the eye. As required by law in most states, erythromycin ophthalmic ointment is placed into both eyes of all newborn infants regardless if delivered vaginally or by caesarean section. Despite the ocular treatment, the best prevention of neonatal gonorrhea is prenatal screening and treatment of pregnant women.

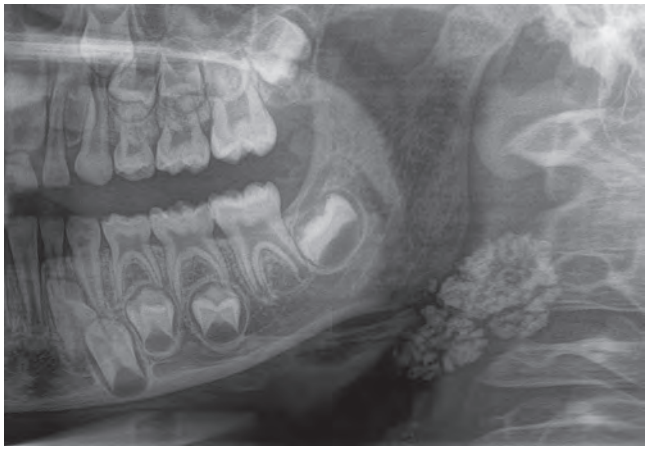
Diagnosis

In males with a urethral discharge, a Gram stain of the purulent material can be used to demonstrate gram-negative diplococci within the neutrophils; additional testing usually is not indicated. Culture and nucleic acid amplification tests (NAATs) are available for diagnostic testing. Although culture has been the previous "gold standard" for diagnosis, the technique demonstrates a much lower sensitivity in the oropharynx with common false-negative results. NAAT is superior to culture in all urogenital and nongenital sites but has been shown to generate false positives in some anatomic sites and is not FDA-cleared for rectal, oropharyngeal, and conjunctival infection. Despite this, some laboratories have met expanded CLIA regulatory requirements to allow use of NAAT in these locations to assist in clinical management. Because up to 80% of women are asymptomatic, annual screening is recommended for all sexually-active women under the age of 25 and older women who are at high risk for infection. Since 90% of men are symptomatic and usually seek treatment, a similar recommendation has not been made for their gender.

Treatment and Prognosis

Treatment has been complicated due to the development of antibiotic resistance by *N. gonorrhoeae* and is becoming increasingly more worrisome. Only one class of antibiotics, the cephalosporins, is considered to be sufficiently effective by the Centers for Disease Control and Prevention (CDC). In addition, coinfection by *Chlamydia trachomatis* is common, leading to a suggested therapy that is effective against both organisms. Although the current cure rate for genital gonorrhea is high, oropharyngeal gonorrhea is harder to resolve and further complicated by the difficulty in diagnosis.

The currently recommended regimen is intramuscular ceftriaxone combined with oral azithromycin. Doxycycline can be used for those allergic to azithromycin, whereas gemifloxacin or gentamycin is recommended for patients allergic to ceftriaxone. Sadly, the effectiveness of cephalosporines appears to be waning, and this trend is expected to continue. Rescreening is recommended 3 months after therapy. The most common cause for treatment failure is reexposure to infected partners, who often are asymptomatic; therefore, the treatment of all recent sexual partners is recommended. Truly resistant infections should be cultured with antimicrobial testing and selection of an appropriate alternate antibiotic.



TUBERCULOSIS

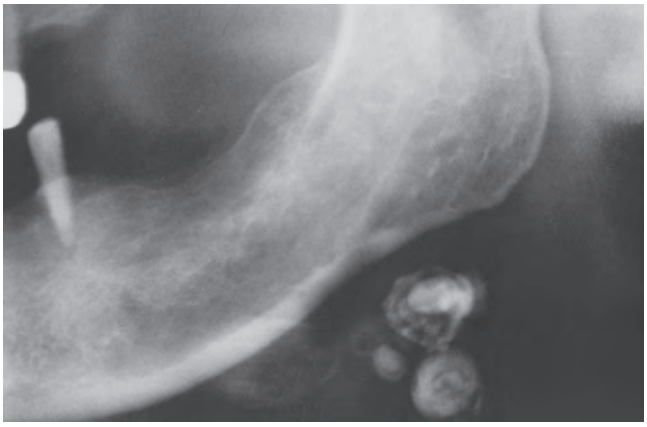
Tuberculosis (TB) is a chronic infectious disease caused by *Mycobacterium tuberculosis* and represents the leading cause of death worldwide related to a single bacterial infectious disease. It is estimated that over 10 million persons with incident tuberculosis and 1.5 million deaths occurred in 2018 with the highest number of affected persons in South-East Asia and Africa. In 1989, the United States embarked on a program to eliminate tuberculosis by rapidly identifying, treating, and contact tracing all cases of tuberculosis. In 2019 (the most recent complete data set available), the United States reported the lowest number of infections since recording began in 1953 with less than 9000 cases. The goal of nationwide elimination of the infection has been complicated by immigration as evidenced by the discovery that over 70% of the cases represented reactivation of latent tuberculosis acquired in the past among non-U.S.-born individuals. Current strategies are stressing increased diagnosis and treatment of latent tuberculosis infections. Worldwide, the prevalence of the infection declined with the introduction of effective antimicrobials, but in recent years it has demonstrated an increased frequency that appears to be associated with emergence of AIDS and drug-resistant strains. **Bacillus Calmette-Guérin (BCG) vaccine** for TB exists but is not available in the United States. The vaccine confers limited and highly variable protection along with several side effects, leading to its removal from the vaccination schedule of several countries.

Nontuberculous mycobacterial disease can occur from a variety of organisms. Before the tuberculin testing of dairy herds, many cases arose from the consumption of milk infected with *Mycobacterium bovis.* Except for HIV-infected individuals, most other cases of nontuberculous mycobacterial disease appear as localized chronic cervical lymphadenitis in otherwise healthy children, with calcification of the involved nodes leading to the diagnosis in some cases (Fig. 5.19). In patients with AIDS (see page 258), *Mycobacterium avium-intracellulare* is a common cause of opportunistic infections.

Infection must be distinguished from active disease. **Primary tuberculosis** occurs in previously unexposed people and almost always involves the lungs. Most infections are the result of direct person-to-person spread through airborne droplets from a patient with active disease. The organism initially elicits a nonspecific, chronic inflammatory reaction. In most individuals, the primary infection results only in a localized, fibrocalcific nodule at the initial site of involvement. However, viable organisms may be present in these nodules and remain dormant for years to life.

dentlearn.ir

• **Fig. 5.19 Atypical Mycobacterial Infection.** Multiple matted and calcified left cervical lymph nodes noted posterior to the angle of the mandible. (Courtesy of Dr. Matt Dahar.)



Only about 5%–10% of patients with TB progress from infection to active disease, and an existing state of immunosuppression often is responsible. In rare instances, active TB may ensue directly from the primary infection. However, active disease usually develops later in life from a reactivation of organisms in a previously infected person. This reactivation is typically associated with compromised host defenses and is called **secondary tuberculosis.** Diffuse dissemination through the vascular system may occur and often produces multiple small foci of infection that grossly and radiographically resemble millet seeds, resulting in the nickname, **miliary tuberculosis.** Secondary TB often is associated with immunosuppressive medications, diabetes, old age, poverty, and crowded living conditions. AIDS represents one of the strongest known risk factors for progression from infection to disease.

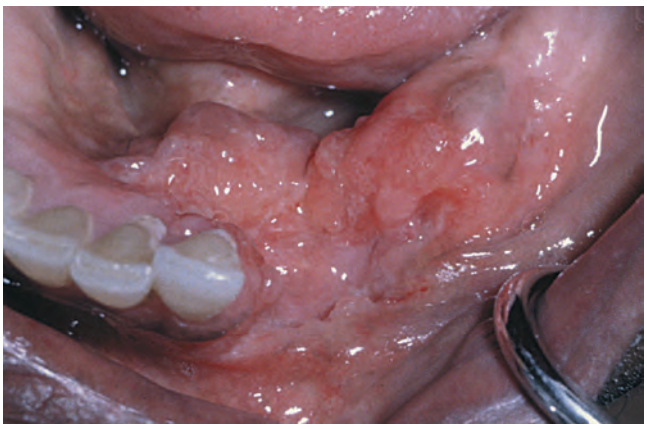
Clinical and Radiographic Features

Primary TB usually is asymptomatic. Occasionally, fever and pleural effusion may occur.

Classically, the lesions of secondary TB occur in the apex of the lungs but may spread to many different sites by expectorated infected material or through the lymphatic or vascular channels. Typically, patients have a low-grade fever, malaise, anorexia, weight loss, and night sweats. With pulmonary progression, a productive cough develops, often with hemoptysis or chest pain. Progressive TB may lead to a wasting syndrome that, in the past, was termed **consumption,** because it appeared that the patient's body was being consumed or destroyed.

Extrapulmonary TB is seen and represents an increasing proportion of the currently diagnosed cases. In patients with AIDS, more than 50% will have extrapulmonary lesions. Any organ system may be involved, including the lymphatic system, skin, skeletal system, CNS, kidneys, and gastrointestinal tract. Involvement of the skin may develop and has been called **lupus vulgaris.**

• **Fig. 5.20 Tuberculosis (TB).** Multiple calcified cervical lymph nodes.



• **Fig. 5.21 Tuberculosis (TB).** Chronic mucosal ulceration of the ventral surface of the tongue on the right side. (Reprinted with permission from the American Dental Association.)

Head and neck involvement may occur. The most common extrapulmonary sites in the head and neck are the cervical lymph nodes followed by the larynx and middle ear. On occasion, calcification of involved cervical lymph nodes may lead to an unexpected diagnosis of tuberculosis (Fig. 5.20). Much less common sites include the nasal cavity, nasopharynx, oral cavity, parotid gland, esophagus, and spine.

Oral lesions of TB are uncommon. The most common presentations for oral involvement are chronic ulcerations or swellings (Fig. 5.21). Less frequent findings include nonhealing extraction sockets, areas of mucosal granularity, or diffuse zones of inflammation (Fig. 5.22). Chronic tongue ulcerations are seen most frequently and followed closely in prevalence by mandibular swellings associated with intrabony involvement. Other affected sites in order of decreasing frequency include the gingiva, lips, buccal mucosa, soft palate, and hard palate.

Often oral ulcerative lesions of TB coexist with palpable lymph nodes. Although this combination most strongly suggests squamous cell carcinoma, the possibility of TB also must be considered, especially in younger patients and those who reside in geographic areas with a high prevalence of the infection.

dentlearn.ir

• **Fig. 5.22 Tuberculosis (TB).** Area of granularity and ulceration of the lower alveolar ridge and floor of mouth. (Courtesy of Dr. Brian Blocher.)

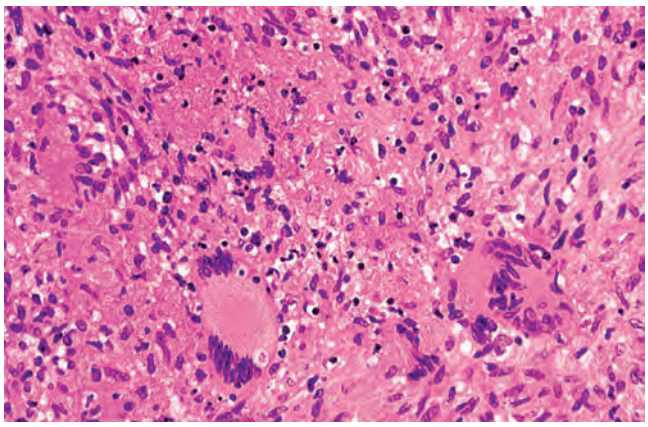
Most of the oral lesions represent secondary infection from the initial pulmonary foci, occurring most frequently in middle-aged adults. It is unclear whether these lesions develop from hematogenous spread or from exposure to infected sputum. The reported prevalence of clinically evident oral lesions varies from 0.5% to 5.0%. The discovery of pulmonary TB because of the investigation of oral lesions occurs but is unusual. Primary oral TB without pulmonary involvement is rare and is more common in children and adolescents.

Nontuberculous mycobacterial infections from contaminated milk currently are rare in the industrialized world because of pasteurization of milk, as well as rapid identification and elimination of infected cows. Drinking contaminated milk can result in a form of mycobacterial infection known as **scrofula.** Scrofula is characterized by enlargement of the oropharyngeal lymphoid tissues and cervical lymph nodes (Fig. 5.23). On occasion, the involved nodes may develop significant caseous necrosis and form numerous sinus tracts through the overlying skin (Fig. 5.24). In addition, areas of nodal involvement may radiographically appear as calcified lymph nodes that may be confused with sialoliths. Pulmonary involvement is unusual in patients with scrofula.

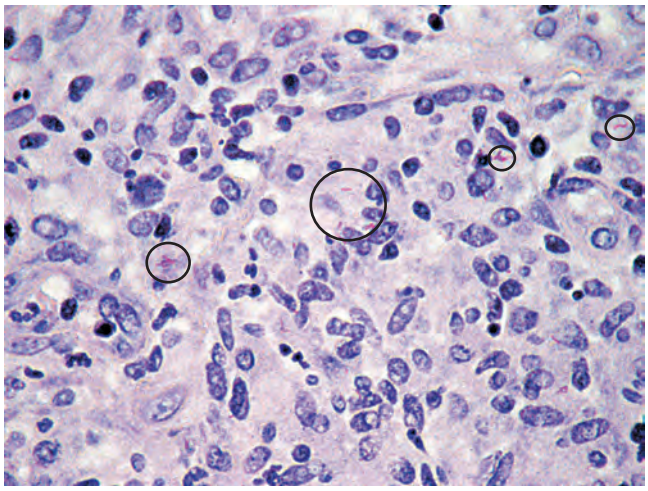
Histopathologic Features

The cell-mediated hypersensitivity reaction is responsible for the classic histopathologic presentation of TB. Areas of infection demonstrate the formation of granulomas, which are circumscribed collections of epithelioid histiocytes, lymphocytes, and multinucleated giant cells, often with central caseous necrosis (Fig. 5.25). The nuclei of the giant cells frequently are arranged along the periphery of the cell in a horseshoe or ring shape *(Langhans giant cells).* In a person with TB, one of these granulomas is called a **tubercle.** Special stains, such as the Ziehl-Neelsen or other acid-fast stains, are utilized to demonstrate the mycobacteria (Fig. 5.26). A newer technique, fluorescence microscopy of auramine-rhodamine stains, is employed by many institutions to increase the ease of finding the organisms. Because of the relative scarcity of the organisms within tissue, the special stains successfully demonstrate the organism in only 27%–60% of cases. Therefore, a negative result does not completely rule out the possibility of TB.

• **Fig. 5.23 Tuberculosis (TB).** Enlargement of numerous cervical lymph nodes. (Courtesy of Dr. George Blozis.)



• **Fig. 5.24 Tuberculosis (TB).** Submandibular sinus tract secondary to involvement of underlying cervical lymph nodes.



Diagnosis

Approximately 2–4 weeks after initial exposure, a cell-mediated hypersensitivity reaction to tubercular antigens develops. This reaction is the basis for the purified protein derivative (PPD) skin test (i.e., tuberculin skin test), which uses a filtered precipitate of heat-sterilized broth cultures of

dentlearn.ir

• **Fig. 5.25 Tuberculosis (TB).** Histopathologic presentation of the same lesion depicted in Fig. 5.22. Sheets of histiocytes are intermixed with multinucleated giant cells and areas of necrosis.

• **Fig. 5.26 Tuberculosis (TB).** Acid-fast stain of specimen depicted in Fig. 5.25 exhibiting scattered mycobacterial organisms presenting as small red rods.

M. tuberculosis. Positivity runs as high as 80% in developing nations; only 5%–10% of the population in the United States is positive. A positive tuberculin skin test result indicates exposure to the organism and does not distinguish infection from active disease. A negative tuberculin skin test result does not totally rule out the possibility of TB. False-negative reactions have been documented in older adults; the immunocompromised; patients with sarcoidosis, measles, or Hodgkin lymphoma; and when the antigen was placed intradermally. The false-negative rate may be as high as 66% in patients with AIDS.

In many areas, the skin test is being replaced with an interferon-gamma release assay (IGRA). This blood test provides results within 24 hours and does not require a second patient visit. In addition, the bacillus Calmette-Guérin vaccination does not cause a false-positive reaction as seen with the skin test.

Special mycobacterial stains and culture of infected sputum or tissue must be used to confirm the diagnosis of active disease. Even if detected with special stains, identification of the organism by culture is appropriate. This identification is important because some forms of nontuberculous mycobacteria have a high level of resistance to traditional antituberculous therapy and frequently require surgical excision. Because 2–6 weeks may be required to identify the organism in culture, antituberculous therapy often is initiated before definitive classification.

In order to reduce the time needed for confirmation of the diagnosis of tuberculosis, nucleic acid amplification tests (NAAT) have been developed to detect DNA of the mycobacterium much faster than the 2–6 weeks required for culture. In 2013, the FDA approved a revolutionary NAAT, the Xpert MTB/RIF assay that simultaneously detects the mycobacterium and determines its resistance to rifampin (a predictor of multidrug-resistant tuberculosis) in less than 2 hours.

Treatment and Prognosis

M. tuberculosis can mutate and develop resistance to single-agent medications. To combat this ability, multiagent therapy is the treatment of choice for an active infection, and treatment usually involves two or more active drugs for several months to years. A frequently used protocol consists of an 8-week course of pyrazinamide, isoniazid, rifampin, and ethambutol, followed by a 16-week course of isoniazid and rifampin. With an alteration of doses and the administration schedule, the response to therapy in patients with AIDS has been good, but relapses and progression of infection have been seen.

A different protocol termed *chemoprophylaxis* is used for patients who have a positive PPD skin test but no signs or symptoms of active disease. Although this situation does not mandate therapy, several investigators have demonstrated the value of therapy, especially in young individuals.

◆ LEPROSY (HANSEN DISEASE)

Leprosy is a chronic infectious disease produced by *Mycobacterium leprae.* Because of worldwide efforts coordinated by the World Health Organization (WHO), a dramatic decrease in the prevalence of leprosy has been seen over the past 20 years. In a 2014 review by the Centers for Disease Control and Prevention, a 17% decrease of new diagnoses was seen in the United States during 1994–2011. As seen with tuberculosis, over 70% of the cases arose in foreign-born persons, a rate 14 times higher than the rate of infection noted among U.S.-born individuals. Although immigrants are screened for clinical evidence of infection at the time of their admission into the United States, only 18% reported having symptoms prior to their arrival. In addition, individuals who did not apply for permanent residency and those who arrived without authorization do not undergo clinical screening. Despite the worldwide reduction in the prevalence of the infection, leprosy remains a public health problem in many areas of the world. Currently, most reported cases are

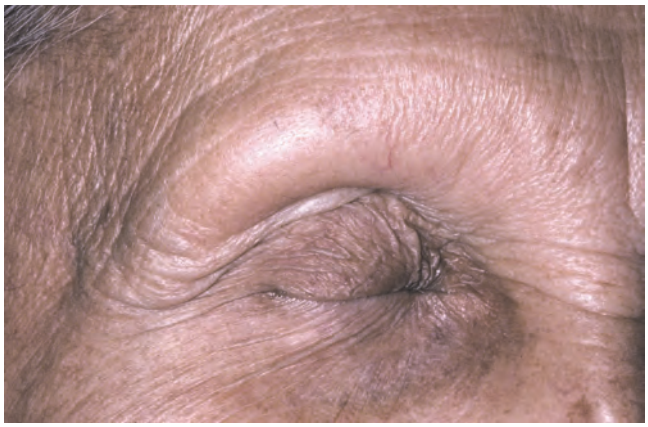
dentlearn.ir

noted in five countries: India, Brazil, Mozambique, Nepal, and Madagascar.

The organism has a low infectivity, and exposure rarely results in clinical disease. Small endemic areas of infection are present in Louisiana and Texas, but most patients in the United States have been infected abroad. Many believe that the organism requires a cool host body temperature for survival. Although the exact route of transmission is not known, the high number of organisms in nasal secretions suggests that in some cases the initial site of infection may be the nasal or oropharyngeal mucosa. Although humans are considered the major host, other animals (e.g., armadillo, chimpanzee, and mangabey monkey) may be additional possible reservoirs of infection.

For decades, leprologists have believed the bacillus is highly temperature dependent and produces lesions primarily in cooler parts of the body, such as the skin, nasal cavity, and palate. This concept has been questioned because the organism may be seen in significant numbers at sites of core body temperature, such as the liver and spleen. Recently, one investigator mapped common sites of oral involvement and compared this pattern to a map of the local temperature. This comparison demonstrated that the oral lesions tend to occur more frequently in the areas of the mouth with a lower surface temperature. The temperature-dependent theory of leprosy infection remains an area of interest and controversy.

The clinical manifestations appear to correlate with the immune response of the host to the mycobacterium, resulting in variability of disease severity and two main clinical presentations. The first, called **tuberculoid leprosy,** develops in patients with a high immune reaction. Typically, the organisms are not found in skin biopsy specimens, skin test results to heat-killed organisms (lepromin) are positive, and the disease usually is localized. The second form, **lepromatous leprosy,** is seen in patients who demonstrate a reduced cell-mediated immune response. These patients exhibit numerous organisms in the tissue, do not respond to lepromin skin tests, and exhibit diffuse disease. Many patients present with intermediate disease that can be divided into three subgroups: borderline-tuberculoid, borderline-borderline, and borderline-lepromatous. Active disease progresses through stages of invasion, proliferation, ulceration, and resolution with fibrosis. The incubation period is prolonged, with an average of 2–5 years for the tuberculoid type and 8–12 years for the lepromatous variant.



Clinical Features

Because laboratory services such as skin smears often are not available, patients increasingly are being classified on clinical grounds using the number of lesions (primarily skin) and the number of body areas affected.

Tuberculoid leprosy exhibits a small number of well-circumscribed, hypopigmented skin lesions. Nerve involvement usually results in anesthesia of the affected skin, often accompanied by a loss of sweating. Oral lesions are rare in this variant.

• **Fig. 5.27 Lepromatous Leprosy.** Numerous thickened facial nodules.

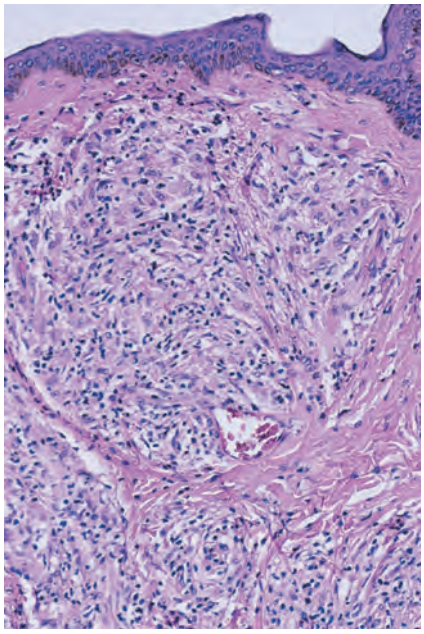
• **Fig. 5.28 Lepromatous Leprosy.** Loss of eyebrows and eyelashes.

Lepromatous leprosy begins slowly with numerous, ill-defined, hypopigmented macules or papules on the skin that, with time, become thickened (Fig. 5.27). The face is a common site of involvement, and the skin enlargements can lead to a distorted facial appearance **(leonine facies).** Hair, including the eyebrows and lashes, often is lost (Fig. 5.28). Nerve involvement leads to a loss of sweating and decreased light touch, pain, and temperature sensors. This sensory loss begins in the extremities and spreads to most of the body. Nasal involvement results in nosebleeds, stuffiness, and a loss of the sense of smell. The hard tissue of the floor, septum, and bridge of the nose may be affected. Collapse of the bridge of the nose is considered pathognomonic.

The reported prevalence of oral lesion varies from a complete absence of lesions to 60%. Several authors believe many reports document an artificially high frequency of oral lesions due to a failure to prove an association with the infection. Well-documented oral lesions occur predominantly in lepromatous leprosy and are rare in the tuberculoid and borderline variants.

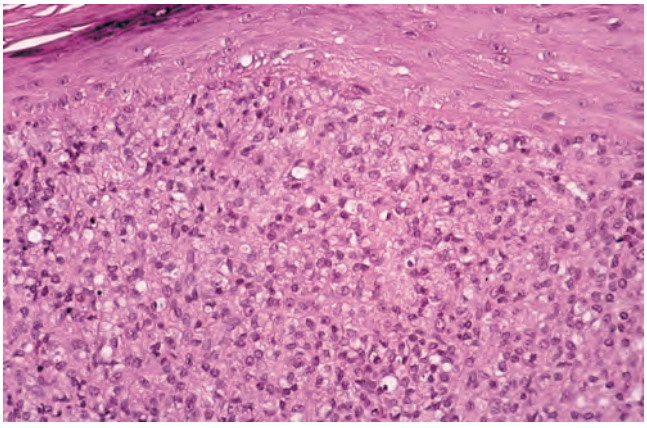
The WHO mapped the frequency and distribution of oral lesions in leprosy patients. The sites that are cooled by the passage of air appear to be affected most frequently. The locations affected in order of frequency are the hard palate, soft

dentlearn.ir



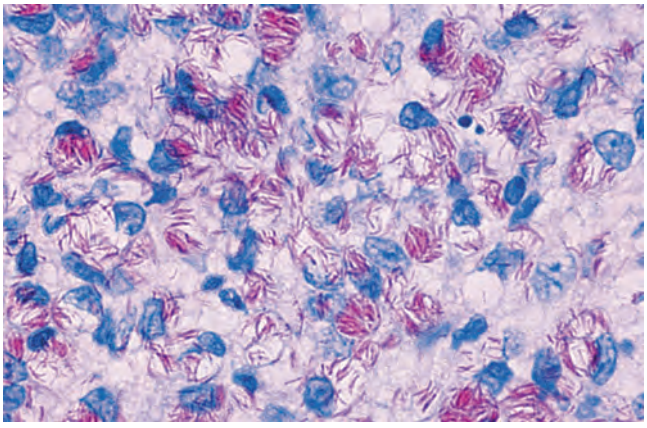
palate, facial maxillary gingiva, tongue, lips, palatal gingiva, mandibular gingiva, and buccal mucosa. Affected soft tissue initially appears as yellowish to red, sessile, firm, enlarging papules that develop ulceration and necrosis, followed by attempted healing by secondary intention. Continuous infection of an area can lead to significant scarring and loss of tissue. Complete loss of the uvula and fixation of the soft palate may occur. The lingual lesions appear primarily in the anterior third and often begin as areas of erosion, which may develop into large nodules. Infection of the lip can result in significant macrocheilia, which can be confused clinically and microscopically with cheilitis granulomatosa (see page 330).

Direct infiltration of the inflammatory process associated with lepromatous leprosy can destroy the bone underlying the areas of soft tissue involvement. Often the infection creates a unique pattern of facial destruction that has been termed **facies leprosa** and demonstrates a triad of lesions consisting of atrophy of the anterior nasal spine, atrophy of the anterior maxillary alveolar ridge, and endonasal inflammatory changes. Involvement of the anterior maxilla can result in significant bone erosion with loss of the teeth in this area. Maxillary involvement in children can affect the developing teeth and produce enamel hypoplasia and short tapering roots. Dental pulp infection can lead to internal resorption or pulpal necrosis. Teeth with pulpal involvement may demonstrate a clinically obvious red discoloration of the crown. The cause of the discoloration is unknown but appears to be related to intrapulpal vascular damage secondary to the infection. Granulomatous involvement of the nasal cavity can erode through the palatal tissues and result in perforation.



Involvement of peripheral nerves is common, with leprosy considered one of the most common causes of treatable peripheral neuropathy in the world. The facial and trigeminal nerves can be involved with the infectious process. Facial paralysis may be unilateral or bilateral. Sensory deficits may affect any branch of the trigeminal nerve, but the maxillary division is the most commonly affected. In addition to sensory deficits, reports of disease-related orofacial pain may be confused with temporomandibular joint discomfort or tooth-related pain.

Histopathologic Features



Biopsy specimens of tuberculoid leprosy typically reveal granulomatous inflammation with well-formed clusters of epithelioid histiocytes, lymphocytes, and multinucleated giant cells (Fig. 5.29). A paucity of organisms exists; when present, they can be demonstrated only when stained with acid-fast stains, such as the Fite method. Lepromatous leprosy demonstrates no well-formed granulomas; the typical finding is sheets of lymphocytes intermixed with vacuolated histiocytes known as **lepra cells** (Fig. 5.30). Unlike tuberculoid leprosy, an abundance of organisms can be demonstrated with acid-fast stains in the lepromatous variant (Fig. 5.31). It has been reported that the organism can be found with special stains in 100% of lepromatous leprosy cases, 75% of borderline cases, and only 5% of tuberculoid cases.

• **Fig. 5.29 Paucibacillary Leprosy.** Well-formed granulomatous inflammation demonstrating clusters of lymphocytes and histiocytes.

• **Fig. 5.30 Multibacillary Leprosy.** Sheets of lymphocytes and histiocytes exhibiting scattered vacuolated lepra cells.

• **Fig. 5.31 Multibacillary Leprosy.** Acid-fast stain exhibiting numerous small mycobacterial organisms seen individually and in clusters.

dentlearn.ir

Diagnosis

The definitive diagnosis is based on the clinical presentation and supported by the demonstration of acid-fast organisms on a smear or in the tissue. The diagnosis is complicated by the failure to demonstrate the organism in a slit-skin smear in almost 70% of all leprosy patients. In addition, the organism cannot be cultivated on artificial media. The search is ongoing to develop an accurate diagnostic test for leprosy, but none has been found that demonstrates the needed sensitivity and specificity to warrant widespread use.

Treatment and Prognosis

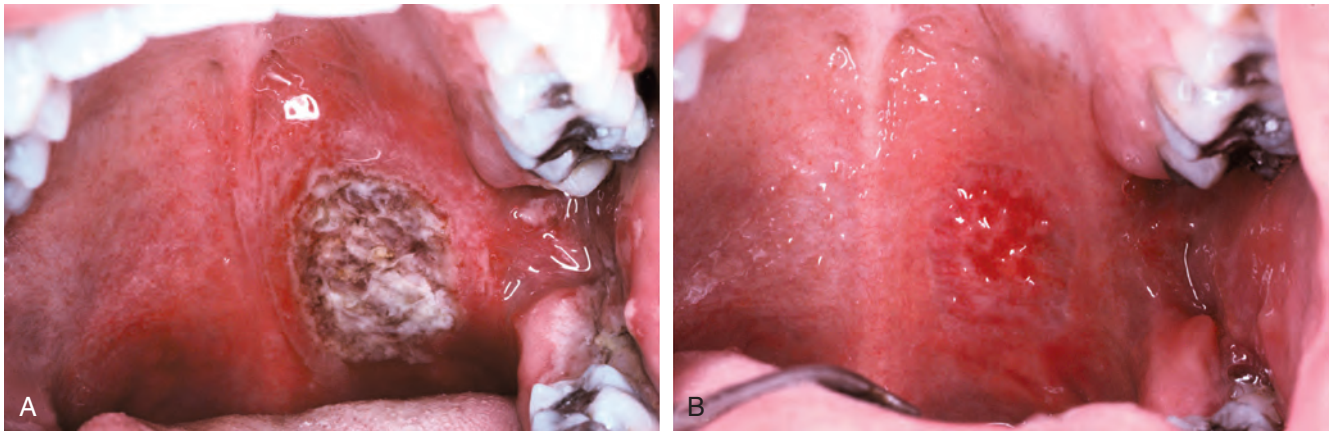
For therapeutic purposes, the WHO has developed a simple classification system based on the bacterial index noted upon biopsy. Those with an index less than 2+ are termed **paucibacillary,** whereas those greater than 2+ are designated **multibacillary.** Paucibacillary patients present clinically as tuberculoid or borderline-tuberculoid variants; multibacillary patients include borderline-borderline, borderline-lepromatous, and lepromatous variants. Patients with multibacillary leprosy receive a combination of rifampicin, clofazimine, and dapsone, whereas those presenting with paucibacillary leprosy receive rifampicin and dapsone. Use of dapsone or rifampicin alone has resulted in development of resistance to that respective drug. Since the introduction of multidrug therapy in 1981, an estimated 15 million patients have been cured, and disabilities have been prevented in another 2–3 million individuals. One of the major reasons for the decreasing prevalence of leprosy is the provision of an uninterrupted supply of free, high-quality medications in calendar blister packs to all patients regardless of the living conditions or remoteness of the location.

◆ NOMA (CANCRUM ORIS; OROFACIAL GANGRENE; GANGRENOUS STOMATITIS; NECROTIZING STOMATITIS)

The term **noma** is derived from the Greek word *nomein,* meaning *to devour.* Noma is a rapidly progressive, polymicrobial, opportunistic infection caused by components of the normal oral flora that become pathogenic during periods of compromised immune status. Historically, the process has been associated with organisms such as *Borrelia vincentii* and *Bacillus fusiformis*, but more recently, many believe the process may not be related to one or more aggressive bacteria but to a more diverse change in the oral microbiota. Some investigators have demonstrated a reduction of bacteria such as *Capnocytophaga* and *Fusobacteria* genera with an increased number of other organisms. *Prevotella intermedia* and *Peptostreptococcus* are thought by many to be key players, interacting with a variety of other bacterial organisms. Culture is thought to underestimate the variety of organisms involved due to the difficulties in growing many of these fastidious bacteria. Studies utilizing PCR for bacterial gene sequences have failed to identify a specific causative organism because the plausible bacteria were noted in both affected and healthy subjects.

The reported predisposing factors include the following:

- Poverty
- Malnutrition or dehydration
- Poor oral hygiene
- Poor sanitation
- Unsafe drinking water
- Proximity to unkempt livestock
- Recent illness
- Malignancy
- An immunodeficiency disorder, including AIDS



In many cases a recent debilitating illness appears to set the stage for the development of noma. Measles most frequently precedes development of noma; other common but less frequent predisposing illnesses include herpes simplex, varicella, scarlet fever, malaria, typhus, tuberculosis, gastroenteritis, and bronchopneumonia. Cases associated with malignancies (e.g., leukemia) are not rare. In many instances, the infection begins as necrotizing gingivitis (NG) (see page 151), and several investigators believe that noma is merely an extension of the same process. Because the disease usually is well advanced at the time of initial presentation, descriptions of the initial stages of the disease are sketchy.

For centuries, noma was common in Europe and the United States but almost disappeared by the end of the 19th century except for victims in the Nazi concentration camps of World War II and an occasional case related to immunosuppressive conditions, such as HIV infection, severe combined immunodeficiency syndrome, or intense immunosuppressive therapy. Currently, most reported cases arise in the "*noma belt*" of sub-Saharan Africa that extends from Senegal to Ethiopia. The World Health Organization (WHO) estimates the global yearly incidence to be approximately 140,000. This number is thought by many to be a gross underestimation, because it is thought that fewer than 15% of acute cases present for therapy.

Clinical Features

Noma usually arises in children from 1 to 10 years of age, although it also can occur in adults with a major debilitating disease (e.g., diabetes mellitus, leukemia, lymphoma, or HIV infection). The infection often begins on the gingiva as necrotizing gingivitis, which may extend either facially or lingually to involve the adjacent soft tissue and form areas called **necrotizing mucositis.** Zones of necrosis also may develop in soft tissue not contiguous with the gingiva, particularly in areas of trauma (Fig. 5.32). The necrosis can extend into deeper tissues; over the next few days, zones of blue-black discoloration of the overlying skin surface may develop (Fig. 5.33). Often the necrotic zone is cone shaped, with a small point of cutaneous necrosis overlying a larger zone of oral mucosal destruction. Unlike other infections, the process does not follow tissue planes and

dentlearn.ir

• **Fig. 5.32 Necrotizing Mucositis.** **A,** Large area of soft tissue necrosis of the posterior soft palate on the left side. **B,** Healing site of necrotizing mucositis 6 days after initiation of tetracycline therapy.

• **Fig. 5.33 Noma.** Extensive blackish orofacial necrosis of the right cheek in an immunocompromised patient.

tends to spread through anatomic barriers, such as muscle. These discolored zones break down into areas of yellowish necrosis that also frequently spreads into adjacent bone, with large areas of osteomyelitis possible. In most instances, the necrotic area is well defined and unilateral. Fetid odor, significant pain, fever, malaise, tachycardia, increased respiratory rate, anemia, leukocytosis, and regional lymphadenopathy are typical. Additional lesions also may occur in distant sites, such as the scalp, neck, ear, shoulders, chest, perineum, and vulva.

Treatment and Prognosis

In addition to using appropriate antibiotics to treat noma, the clinician must direct therapeutic attention not only to local wound care but also toward improving the patient's overall health status. Blood transfusion with intravenous fluids to correct dehydration and electrolyte imbalances is necessary along with a high protein diet and resolution of any associated disease such as malaria or measles. Ampicillin-cloxacillin and metronidazole are the first-line therapeutic antibiotics for necrotizing stomatitis. Conservative débridement of gross necrotic areas is recommended, but aggressive removal is contraindicated because it does not stop the extension of the process and compounds the reconstruction problems.

Most affected children in developing countries have no access to quality health care and demonstrate a mortality rate of 85% due to lack of appropriate intervention. With quality health care, the survival is greater than 90%. Common causes of death include infectious complications, such as pneumonia, diarrhea, and septicemia. Most survivors will have extensive facial deformity with associated difficulties in growth and development, eating, speech, and social interactions. Reconstruction often is extremely challenging and should be delayed until healing is complete. Eradication of this disease is a major humanitarian concern that will require action from national and international organizations to eliminate the underlying extreme poverty, malnutrition, lack of immunizations, poor hygiene, inadequate sanitation, and insufficient oral health care.

◆ ACTINOMYCOSIS

Although the term **actinomycosis** seems to imply a fungal infection, it is an infection of filamentous, branching, gram-positive anaerobic bacteria. Actinomycetes are normal saprophytic components of the oral flora. Documented sites of colonization in healthy patients include the tonsillar crypts, dental plaque and calculus, carious dentin, bone sequestra, salivary calculi, gingival sulci, and periodontal pockets. The colonies within the tonsillar crypts may form plugs and become large enough for the patient to feel the firm masses of bacteria and desquamated keratin within the crypts (see page 176). In surveys of documented actinomycosis, *Actinomyces israelii* is the causative organism in the majority, with *A. viscosus* being a close second. Much less frequent causes of the infection are *A. naeslundii, A. odontolyticus, A. meyeri, A. pyogenes, A. viscosus,* and *A. bovis,* along with *Arachnia propionica* and *Bifidobacterium dentium.* In most such cases, the primary organism is combined synergistically with streptococci and staphylococci.

dentlearn.ir

Clinical Features

Actinomycosis may be either an acute, rapidly progressing infection or a chronic, slowly spreading lesion that is associated with fibrosis. Approximately 55% of cases of actinomycosis are diagnosed in the cervicofacial region, with 25% occurring in the abdominal and pelvic region and 15% in the pulmonary system. The remaining 5% exhibits a variety of patterns, such as superficial skin infections, or infections of the genitourinary region (often linked to use of intrauterine contraceptive devices).

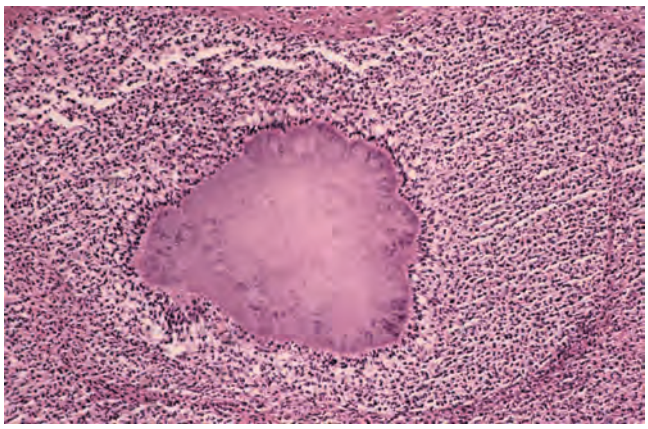
The suppurative reaction of the infection may discharge large yellowish flecks that represent colonies of the bacteria called **sulfur granules.** Although common, sulfur granules are not present invariably. In addition, another infection that also can produce sulfur granules and mimic actinomycosis is **botryomycosis,** an unrelated process that represents an unusual host reaction to *S. aureus* and other bacteria.

In the cervicofacial region, the organism typically enters tissue through an area of prior trauma, such as a soft tissue injury, periodontal pocket, nonvital tooth, extraction socket, or infected tonsil. The infection does not spread along the typical fascial planes and usually disregards the normal lymphatic and vascular routes. Direct extension through soft tissue is seen, and lymph nodes become involved only if they are in the path of the process. The classic description is of a "wooden" indurated area of fibrosis, which ultimately forms a central, softer area of abscess. The infection may extend to the surface, forming a sinus tract (Fig. 5.34). Pain often is minimal. The soft tissues of the submandibular, submental, and cheek areas are common areas of involvement, with the area overlying the angle of the mandible being the most frequently affected site.

Localized abscesses without the associated chronic fibrosing reaction have been reported in soft tissue that has received minor trauma. The tongue is the most frequently mentioned site, but any oral mucosal location is possible. Involvement of the tonsillar crypts may produce infectious symptoms; in most cases, however, the primary change is one of variable hyperplasia. Tonsillar hyperplasia thought to be secondary to actinomycotic infestation of the crypts does not appear responsive to antibiotics, probably because of the superficial location of the bacterial colonies. Tonsillectomy is generally the most effective treatment for this situation.

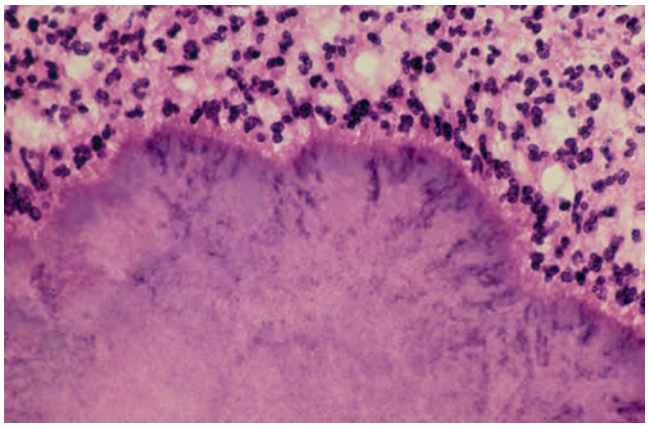
• **Fig. 5.34 Actinomycosis.** Draining sinus tract of the right submandibular area.

Salivary gland involvement also is not unusual. Intraductal colonization by the organism may lead to infections in both the submandibular and parotid glands, resulting in abscess formation in the submandibular and masseter spaces, respectively. In addition, more localized infections occur in minor salivary gland ducts, which also may demonstrate mucous plugs or sialoliths.



Actinomycotic osteomyelitis of the mandible and maxilla has been reported. Trauma, periodontal infections, nonvital teeth, and extraction sites have all provided access. Ill-defined areas of radiolucency, often surrounded by radiopacity are noted on plain films. In cases examined by computed tomography or magnetic resonance imaging, an ill-defined and infiltrative lesion typically is present with a surrounding soft tissue inflammatory response that often extends to the skin. Sinus tract formation and intralesional gas are common, whereas lymphadenopathy usually is not noted (the organism spreads by direct invasion, not by the lymphatics).

Intrabony colonization of dentigerous cysts without other significant clinical or radiographic spread has been reported. Periapical inflammatory lesions involved by the bacteria can result in lesions that are difficult to resolve with standard endodontic treatment, but such lesions typically remain localized and do not evolve into invasive cervicofacial actinomycosis. In a retrospective review of a series of radicular cysts, the presence of actinomycotic colonies was not uncommon, but this finding usually was not associated with any clinical evidence of suppuration, abscess formation or draining sinus tracts. In such localized colonization with or without a focal inflammatory reaction, the investigators suggested the colonies may not have substantial clinical significance when there are no associated signs or symptoms.



Histopathologic Features

The tissue removed from areas of active infection demonstrates a peripheral band of fibrosis encasing a zone of chronically inflamed granulation tissue surrounding large collections of polymorphonuclear leukocytes and, with luck, colonies of organisms (Fig. 5.35). The colonies consist of club-shaped filaments that form a radiating rosette pattern (Fig. 5.36). With hematoxylin and eosin (H&E) stains, the central core stains basophilic and the peripheral portion is eosinophilic. Methenamine silver stains demonstrate the organisms well. If the colonies of actinomycetes become displaced from the exudate, then a rim of neutrophils typically clings to the periphery of the organisms. The histopathologic pattern in which masses of actinomycotic organisms are surrounded by a sea of neutrophils is known as the Splendore-Hoeppli phenomenon. When an actinomycotic infection is not spreading but remains localized within soft tissue, small

• **Fig. 5.36 Actinomycosis.** Actinomycotic colony exhibiting club-shaped filaments arranged in a radiating rosette pattern.

clusters of branching filamentous organisms often are surrounded by a thin rim of neutrophils that is encased in a thick band of granulomatous inflammation.

Diagnosis

The diagnosis of actinomycosis is achieved ideally by culture, but less than 50% of cases are positive because of the overgrowth of associated bacteria, prior antibiotic therapy, or improper anaerobic media conditions. Although a strong presumptive diagnosis can be obtained through a demonstration of the typical colonies in lesional biopsy material, molecular techniques such as PCR or DNA hybridization have been used to identify the bacterial species, with some of these techniques available for paraffin-embedded specimens. The material for culture and histopathologic examination typically is obtained during surgical exploration, with fine-needle aspiration being a satisfactory substitute in many cases. Sulfur granules in infections other than actinomycosis are so rare that their demonstration strongly supports the diagnosis. If desired, then fluorescein-conjugated antiserum can be used on the granules to specifically identify the *Actinomyces* species.

Treatment and Prognosis

The treatment of choice for actinomycosis in chronic fibrosing cases is prolonged high doses of antibiotics in association with abscess drainage and excision of the sinus tracts. A high antibiotic concentration is required to penetrate larger areas of suppuration and fibrosis. Although penicillin remains the standard of care with no documented *in vivo* resistance, some clinicians believe amoxicillin represents a better first-choice antibiotic. Other investigators have demonstrated *in vitro* resistance to penicillin and recommend tetracycline, which is as effective as penicillin and is the drug of choice for patients with a known allergy to penicillin. Early cervicofacial actinomycosis typically responds to a 5–6-week course of penicillin; patients with deep-seated infections may require up to 12 months.

In cases of osteomyelitis caused by actinomycetes, antibiotic therapy alone often is associated with persistent disease. Adequate débridement appears to be the cornerstone of therapy and ultimately determines the success of the subsequent antibiotic treatment. When combined with appropriate surgery, a 3-month course of penicillin usually is curative. In resistant cases, repeated débridement should be combined with cultures to direct future antibiotic therapy. Care should be taken to ensure that colonization of bony sequestra by actinomycotic colonies is not mistaken for invasive actinomycotic osteomyelitis.

Several authors have indicated that localized acute actinomycotic infections may be treated more conservatively than the deep, chronic cases of actinomycosis. Localized periapical and pericoronal actinomycosis, tongue abscesses, and focal subacute sialadenitis with intraductal involvement frequently respond well to surgical removal of infected tissue. It appears best to reserve antibiotics for patients in whom the microorganisms invade the surrounding structures and spread through the soft tissues.

CAT-SCRATCH DISEASE

Cat-scratch disease (CSD) is an infectious disorder that typically begins in the skin but classically spreads to the adjacent lymph nodes. This infection is the most common cause of chronic regional lymphadenopathy in children, with an estimated 24,000 cases occurring annually in the United States. This disease has been recognized since 1931, but the definitive cause was not determined until the 1980s. Isolation and culture of the organism were achieved finally in 1988. The causative organism was named initially *Rochalimaea henselae* but was reclassified as *Bartonella henselae* when the genera *Bartonella* and *Rochalimaea* were combined.

The infection is spread primarily through young kittens infested with the cat flea, *Ctenocephalides felis,* via a cat scratch, cat bite, cat saliva, or cat flea bite. A history of contact with cats has been noted in 90% of the cases, with 60% documenting an associated cat scratch or bite. The highest number of cases are seen between September through March in temperate climates. Kittens typically are born in spring

dentlearn.ir

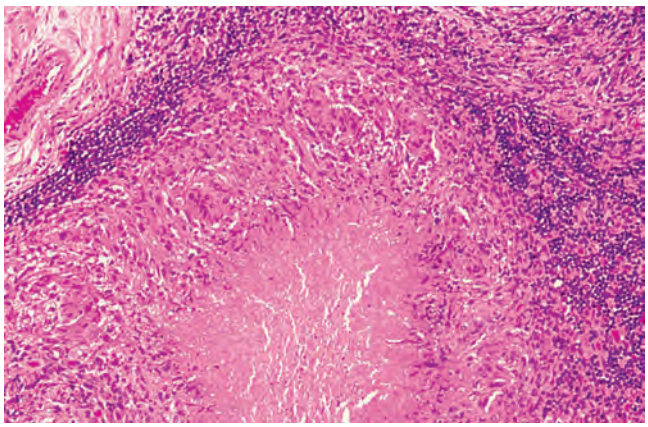
with those under the age of 6 months most at risk of transmitting CSD. Cat fleas are most abundant during fall and winter with the highest risk of feline *B. henselae* bacteremia occurring during the winter. Uncommonly, CSD can arise from other species of *Bartonella* or from other mammal hosts, including dogs. Person-to-person transmission has not been documented.

Clinical Features

Eighty percent of the cases occur in patients younger than 21 years of age. Cat-scratch disease often begins as a papule that develops in 3–14 days along the initial scratch line (Fig. 5.37). The lesion typically progresses through erythematous, vesicular, and papular-crusted stages with resolution usually occurring within 1–3 weeks. About the time the skin lesion heals, lymph node changes arise and may be accompanied by fever or malaise (Fig. 5.38). In about half of the cases, a single node is involved. Multiple regional nodes are affected in about 20%, and nodal enlargement is discovered in multiple sites in about 33%. Suppuration is noted in approximately 10% of affected patients. The most frequently affected nodes are the axillary and epitrochlear (46%), head and neck (26%), and groin (17.5%).

Although most affected patients present with typical cat-scratch disease as described above, a variety of systemic manifestations are noted in 5%–20% of affected individuals, predominantly in older patients or those with immunosuppression. Of these, prolonged fever of unknown origin and hepatosplenic disease are the most common. Less common problems include cardiac, hematologic, neurologic, ocular, orthopedic, and pulmonary manifestations. Although necrotizing granulomas usually are noted in immunocompetent patients, vasoproliferative disorders, such as **bacillary angiomatosis** or **bacillary peliosis hepatis** (a specific form of hepatosplenic *Bartonella* disease) may be seen in immunocompromised patients. Bacillary angiomatosis is an unusual subcutaneous vascular proliferation that has been recognized in patients with AIDS. The affected areas often resemble Kaposi sarcoma (see page 254) and appear as variable numbers of red-to-purple skin lesions. These may be macular, papular, or pedunculated and exhibit a widespread distribution on the skin. Pain and tenderness are common. The larger lesions are friable and bleed easily.

Histopathologic Features



The involved lymph nodes are enlarged because of significant cortical hyperplasia, which classically contains areas of stellate suppurative necrosis surrounded by a band of histiocytes and neutrophils (Fig. 5.39). Upon Warthin-Starry stains or

• **Fig. 5.38 Cat-Scratch Disease.** Submandibular lymphadenopathy has developed after initial trivial injury to skin. (Courtesy of Dr. George Blozis.)

dentlearn.ir

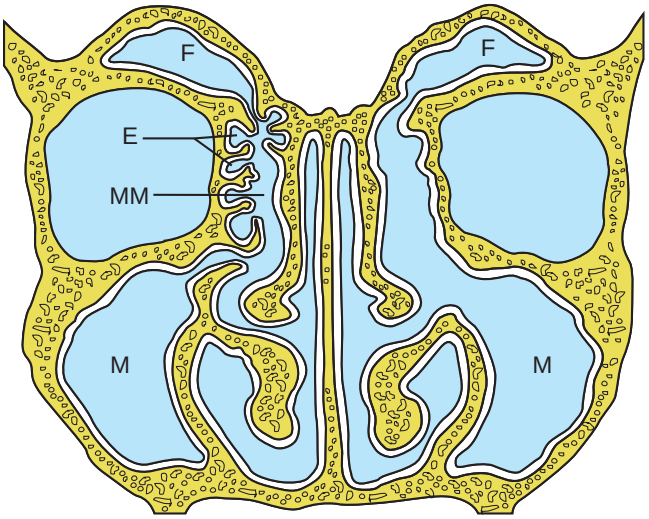
the Brown-Hopps method of Gram staining, cat-scratch bacilli may be found in areas without significant necrosis. As the disease progresses and necrosis increases, the organisms become more difficult to identify. A commercially available monoclonal antibody against *B. henselae* has been used to demonstrate the organisms via immunoperoxidase techniques on paraffin-embedded material. Upon immunostaining, the organisms are highlighted dramatically, an important advance over the previous special stains. Polymerase chain reaction (PCR) techniques also can be employed to detect the *Bartonella* DNA in tissue.

Bacillary angiomatosis reveals lobular proliferations of small blood vessels in an edematous to fibrotic stroma. The supporting connective tissue typically demonstrates a significant number of neutrophils and leukocytoclasis, important clues to the diagnosis. Also present are variably sized amphophilic and granular aggregates that upon Warthin-Starry staining prove to be masses of the causative bacteria.

Diagnosis

Today the diagnosis of cat-scratch disease usually is established by a combination of clinical and serologic criteria. Histopathology can confirm the clinical diagnosis but involves an invasive procedure. In patients with a suggestive clinical presentation, the diagnosis often can be confirmed by negative evaluations for other common causes of adenopathy, combined with positive serology. The most widely used tests are an indirect fluorescent assay (IFA) or enzyme-linked immunosorbent assay (ELISA) for detecting antibodies to *B. henselae*. These tests are somewhat problematic due to variable sensitivity and specificity. In addition, the type and titer of the associated antibody significantly impacts on the diagnosis. Even during the early stages of the infection, IgM antibodies against *B. henselae* seldom are present, and a negative result does not rule out CSD. IgG titers less than 1/64 do not support active disease. Titers between 1/64 and 1/256 are indeterminate and require repeated testing with evidence of rising titers to confirm a diagnosis of CSD. IgG titers over 1/256 strongly support a diagnosis of active CSD. If the serology is inconclusive, nodal biopsy can be performed to confirm or refute the diagnosis.

Treatment and Prognosis



Cat-scratch disease is a self-limiting condition and normally resolves within 4 months. The use of local heat, analgesics, and aspiration of the node on suppuration is the typical pattern of therapy. If persistent discomfort makes nodal aspiration necessary, then drainage should be achieved with a needle that is tunneled into the node laterally through normal skin 1–2 cm away from the lesion. Incision directly into the node could result in a chronic draining sinus.

Although the organism has demonstrated sensitivity to several antibiotics in culture, the results in immunocompetent patients have been inconsistent and difficult to evaluate because the disease is self-limited in most cases. In addition, lack of intracellular penetration and sequestration of the antibiotic within lymph nodes may be responsible for lack of effectiveness in patients despite positive results in culture. Antibiotics typically are reserved for those cases that demonstrate a prolonged course or severe involvement. Use of antibiotic drugs in patients with AIDS and bacillary angiomatosis has produced dramatic resolution within 2 days. Although a number of medications often in combination have been used successfully, the primary antibiotics used for cat-scratch disease or bacillary angiomatosis are azithromycin, trimethoprim-sulfamethoxazole, erythromycin, doxycycline, rifampin, ciprofloxacin, and gentamicin.

◆ RHINOSINUSITIS (SINUSITIS)

Rhinosinusitis is one of the most common health complaints in the United States with an associated annual incidence of 20 million doctor visits. To understand the problem, the clinician must first have some knowledge of sinus anatomy. Adults have bilateral maxillary, frontal, sphenoid, ethmoid, and mastoid sinuses. Except for the mastoid sinuses, these cavities drain into the nose through openings called **ostia.** The frontal, sphenoid, and maxillary sinuses must drain through the middle meatus. In addition, the ethmoids are located bilaterally in this area of the nose and present as a labyrinth of 3–15 small sinuses, which drain through smaller ostia. The ostiomeatal complex, with its numerous narrow openings (Fig. 5.40), is the key to sinus disease, because it is the primary nasal site for the deposition of foreign matter from inspired air.

Normal sinuses are lined by pseudostratified columnar epithelium with cilia. The cilia are necessary to move the

• **Fig. 5.40 The Paranasal Sinuses.** Illustration demonstrating the ostiomeatal complex and its importance to appropriate sinus drainage. The left side demonstrates the typical narrow middle meatus through which all sinus drainage must pass. The right side reveals enlargement of the middle meatus, such as that achieved through corrective endoscopic surgery. *M,* Maxillary sinus; *F,* frontal sinus; *E,* ethmoid sinuses; *MM,* middle meatus.

dentlearn.ir

sinus secretions toward the ostia. Gravity also is beneficial in removing the secretions, except in the maxillary sinus where there is a superior location of the ostial opening and, therefore, the ciliary apparatus becomes even more important.

For a long time, researchers believed that primary inflammation of the lining of the maxillary antrum was the major cause of rhinosinusitis; however, advances have demonstrated that most sinus disease begins from a blockage of the ostiomeatal complex that disrupts normal drainage, decreases ventilation, and precipitates disease. Less common localized sinus infections can occur from focal areas of inflammation within a single sinus, such as a dental infection affecting the maxillary sinus.

Most acute rhinosinusitis cases are viral in origin and arise shortly after an upper respiratory tract infection. In contrast, most examples of chronic rhinosinusitis are bacterial. All the sinuses contain bacteria. With bacteria already present in the sinuses, changes as minor as a slight mucosal thickening in the ostiomeatal complex can lead to improper sinus drainage and infection. The most common predisposing factors for chronic rhinosinusitis are a recent upper respiratory viral infection, allergic rhinitis, or an adjacent odontogenic infection.

Historically, 10%–12% of maxillary rhinosinusitis cases were thought to arise from an odontogenic source, but many current investigators believe the prevalence is closer to 40%. In otherwise healthy patients, the most common bacterial organisms cultured from rhinosinusitis are aerobes such as *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis*, organisms typically unassociated with a dental origin. When rhinosinusitis arises secondary to an odontogenic infection, the causative organisms are usually those that predominate in periodontal or endodontic infections and include anaerobic bacteria, such as *Peptostreptococcus* spp., *Fusobacterium* spp., *Prevotella* spp., *Bacteroides* spp., and *Porphyromonas* spp.

Infrequently, in an environment of chronic rhinosinusitis, an area of dystrophic calcification **(antrolith)** may develop and be detected radiographically. The nidus for this calcification may be endogenous from materials, such as inflamed mucus, pus, or clots. In other cases, the source may be exogenous from tooth roots or foreign bodies, such as dental materials, vegetable matter, paper, glass, and stone. Focal antral calcification also has been seen in sinuses filled with a fungal ball of *Aspergillus fumigatus* (noninvasive mycetoma) (see page 221). A sinus that is unresponsive to therapy and exhibits focal antrolith formation within a diffuse soft tissue opacification is highly suggestive of noninvasive aspergillosis.

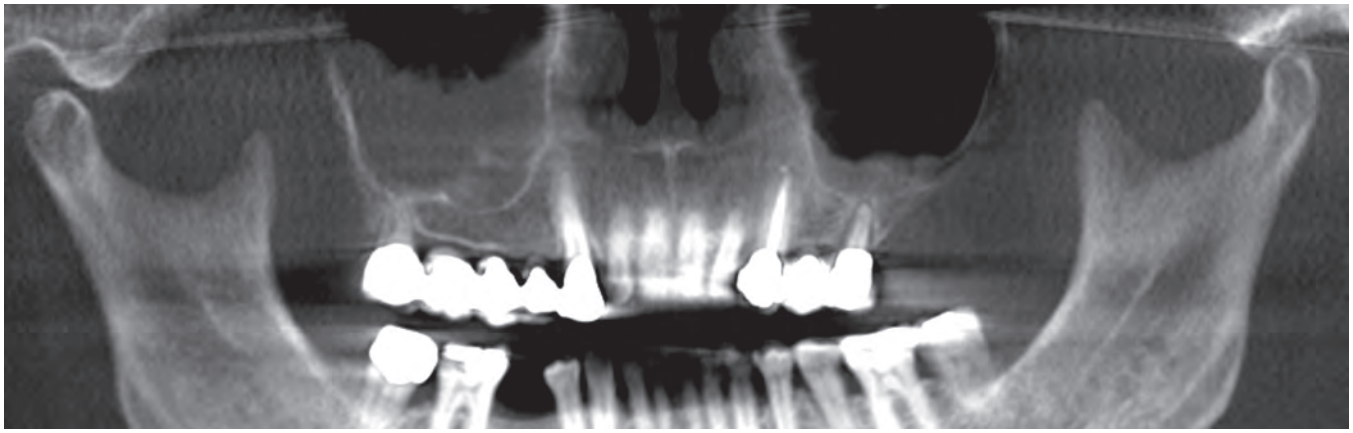
Clinical and Radiographic Features

Presenting symptoms of acute rhinosinusitis in adults include headache, fever, and facial pain over the affected sinus. Anorexia, photophobia, and malaise also may be seen. Anterior nasal or posterior pharyngeal discharge is present; it may be thick or thin in consistency and appear clear, mucoid, or purulent. Children, with their less complex sinuses, typically have only persistent cough, fever, and purulent rhinorrhea. Localized involvement of the maxillary sinus can occur as pain over the cheekbone, toothache, periorbital pain, or temporal headache. Maxillary rhinosinusitis is associated with increased pain when the head is held upright and less discomfort when the patient is supine.

Chronic rhinosinusitis is less diagnostic, and radiographic imaging becomes more important. Frequent complaints include facial pressure, pain, or a sensation of obstruction. In some cases, nonspecific symptoms, such as headache, sore throat, lightheadedness, or generalized fatigue, also may be present or even dominate. Radiographically, the involved sinus has a cloudy, increased density

At times, rhinosinusitis can be confused with an odontogenic infection. In such cases, close examination of periapical radiographs, a thorough periodontal examination, and assessment of tooth vitality often may point to an odontogenic infection. A sinus infection should be strongly considered when patients complain of pain from several teeth, demonstrate tenderness over one or both of the maxillary sinuses, exhibit nasal congestion, or have a nasal discharge accompanied by a fever and headache.

As mentioned previously, up to 40% of maxillary rhinosinusitis cases are related to a dental origin such as tooth extraction, periapical inflammatory disease, advanced periodontitis, or iatrogenic causes such as oroantral fistulas, residual root tips, endodontic filling material, or complications secondary to implant placement or related sinus lift procedures. Odontogenic origin is more likely when unilateral sinus opacification is noted (>75%), and such infections are associated with the molars in more than 90% of the cases. Often, the unilateral opacification is combined with unilateral nasal obstruction, rhinorrhea and/or maxillary tenderness. Foul nasal drainage or extreme mouth odor also are strong clues.



In addition to the patient's symptoms, the diagnosis in the past often was made by procedures (such as, transillumination) and by plain radiographs (such as, periapical radiographs, panoramic images, and the Waters, Caldwell-Luc, lateral, and submental vertex views). Today, when the diagnosis is in question, many clinicians use nasal endoscopy, computed tomography (CT), or cone beam computed tomography (CBCT). Areas of infection and sites of improper drainage will be found. These techniques not only confirm the diagnosis but also pinpoint the primary pathologic alteration that led to the obstructive rhinosinusitis. In cases of odontogenic sinusitis, zones of antral mucosal thickening along the floor of the sinus often are associated with focal areas of bone loss, dehiscence, or foreign bodies adjacent to the offending tooth (Fig. 5.41).

An antrolith appears radiographically as a radiodense focus within the sinus. The calcification often is seen in association with a thickening of the antral lining or diffuse clouding of the affected sinus.

Treatment and Prognosis

Treatment options for acute rhinosinusitis include moisturizing sprays, decongestants, mucolytics, corticosteroids, antibiotics, or mechanical intervention, such as sinus puncture or

dentlearn.ir

• **Fig. 5.41 Odontogenic Sinusitis.** Cloudy right maxillary antrum. The sinusitis is more noticeable on the patient's right side. However, less mucosal thickening is noted in the left antrum in association with the apices of the second premolar, which demonstrates thickening of the periodontal ligament with focal perforation of the sinus floor.

lavage. Although acute rhinosinusitis is usually a self-limiting disease, antibiotics frequently are prescribed. Most cases are viral in origin and resolve within 2 weeks, with or without antibiotic therapy. A Cochrane meta-analysis demonstrated a small benefit associated with antibiotic therapy, but this appeared to be overshadowed by adverse effects, such as diarrhea, abdominal pain, and vomiting.

If antibiotics are used, the first-line therapy for acute sinusitis in otherwise healthy patients is amoxicillin. Doxycycline or clarithromycin are alternatives for patients allergic to penicillin. If amoxicillin is associated with a poor clinical response, other choices include azithromycin, cefoxitin, ceftriaxone, cephalexin, clindamycin, and moxifloxacin. The choice of antibiotics should be guided by local resistance patterns and by appropriately collected cultures.

In otherwise healthy adult patients, chronic rhinosinusitis that is not responsive to typical medical management often is corrected surgically. When located in the maxillary sinus, such invasive therapy should be performed only after a thorough examination to rule out an association with an adjacent odontogenic infection.

Nasal endoscopy has shown that rhinosinusitis is a disease of obstruction, and that mucosal inflammation is usually a secondary development. Functional endoscopic sinus surgery (FESS) removes damaged antral mucosa, enlarges the ostial openings, and corrects blockages in the ostiomeatal complex, often with a rapid resolution of the signs and symptoms (see Fig. 5.38). The surgery is delicate because it extends close to the orbit and the CNS. Each patient's unique anatomy should be evaluated carefully by CT and nasal endoscopy before surgery.

Appropriate diagnosis of odontogenic sinusitis is critical due to several differences in the therapeutic approach. The maxillary sinus does not drain by gravity, because the ostia are located superior to the sinus floor. Healthy cilia must beat in a coordinated fashion to move the mucus up and through the ostia to clear the sinus cavity. It has been shown that impaired function of the ciliary epithelium is present in odontogenic sinusitis. This finding helps to explain why resolution of the dental inflammatory source often fails to resolve the process without medical therapy and FESS to eliminate the causative bacteria, remove the damaged mucosa, and restore proper cilia function. Due to differences in the bacteria involved in odontogenic sinusitis, the first-line antibiotic regimen is amoxicillin-clavulanate; levofloxacin, teicoplanin, or vancomycin is recommended for cases resistant to therapy. Doxycycline is the best choice for patients who are allergic to the penicillins. Although serious complications related to odontogenic sinusitis are rare, the infection can spread and result in pansinusitis, osteomyelitis, meningitis, blindness, and intracranial extension.

Fungal and Protozoal Diseases

◆ CANDIDIASIS

Infection with the yeastlike fungal organism *Candida albicans* is termed **candidiasis** or, as the British prefer, **candidosis.** An older name for this disease is *moniliasis;* the use of this term should be discouraged because it is derived from the archaic designation *Monilia albicans*. Other members of the *Candida* genus, such as *C. tropicalis, C. krusei, C. parapsilosis,* and *C. guilliermondii,* may also be found intraorally, but they rarely cause disease.

Like many other pathogenic fungi, *C. albicans* may exist in two forms—a trait known as **dimorphism.** The yeast form of the organism is believed to be relatively innocuous, but the hyphal form is usually associated with invasion of host tissue.

Candidiasis is by far the most common oral fungal infection in humans and has a variety of clinical manifestations, making the diagnosis difficult at times. In fact, *C. albicans* may be a component of the normal oral microflora, with as many as 30%–50% of people simply carrying the organism in their mouths without clinical evidence of infection. This rate of carriage has been shown to increase with age, and *C. albicans* can be recovered from the mouths of nearly 60% of dentate patients older than 60 years who have no sign of oral mucosal lesions. At least three general factors may determine whether clinical evidence of infection exists:

1. The immune status of the host
2. The oral mucosal environment
3. The strain of *C. albicans*

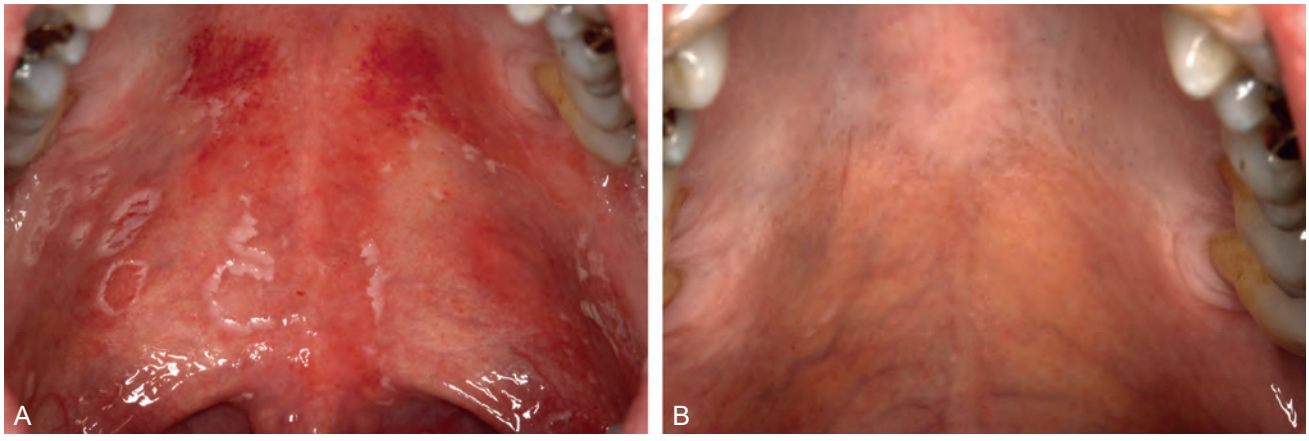
In the past, candidiasis was considered to be only an opportunistic infection, affecting individuals who were debilitated by another disease. Certainly, such patients make up a large percentage of those with candidal infections today. However, now clinicians recognize that oral candidiasis may develop in people who are otherwise healthy. As a result of this complex host and organism interaction, candidal infection may range from mild, superficial mucosal involvement seen in most patients to fatal, disseminated disease in severely immunocompromised patients. This chapter focuses on those clinical presentations of candidiasis that affect the oral mucosa.

Clinical Features

Candidiasis of the oral mucosa may exhibit a variety of clinical patterns, which are summarized in Table 6.1. Many patients display a single pattern, although some individuals exhibit more than one clinical form of oral candidiasis.

Pseudomembranous Candidiasis

The best recognized form of candidal infection is **pseudomembranous candidiasis.** Also known as *thrush,* pseudomembranous candidiasis is characterized by the presence of adherent white plaques that resemble cottage cheese or curdled milk on the oral mucosa (Figs. 6.1 and 6.2). The white plaques are composed of tangled masses of hyphae, yeasts, desquamated epithelial cells, and debris. Scraping them with a tongue blade or rubbing them with a dry gauze sponge can remove these plaques. The underlying mucosa may appear normal or erythematous. If bleeding occurs, then the mucosa has probably also been affected by another process, such as erosive lichen planus or cancer chemotherapy.



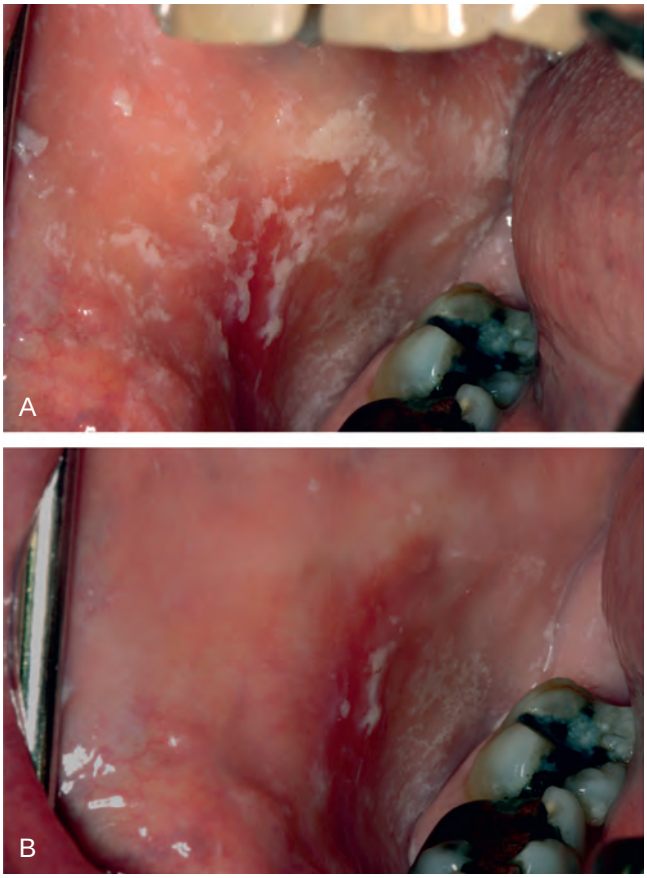
Pseudomembranous candidiasis may be initiated by exposure of the patient to broad-spectrum antibiotics (thus eliminating competing bacteria) or by impairment of the patient's immune system. A common type of local immune impairment resulting in pseudomembranous candidiasis is use of topical corticosteroids for treatment of oral immune-mediated conditions, or inhaled corticosteroids for treatment of asthma. The immune dysfunctions seen in leukemic patients (see page 593) or those infected with human immunodeficiency virus (HIV) (see page 252) are often associated with pseudomembranous candidiasis. Infants may also be affected, ostensibly because of their underdeveloped immune systems. Antibiotic exposure is typically responsible for an acute (rapid) expression of the condition; immunologic problems usually produce a chronic (slow-onset, long-standing) form of pseudomembranous candidiasis.

Symptoms, if present at all, are usually relatively mild, consisting of a burning sensation of the oral mucosa or an unpleasant taste in the mouth, variably described as salty or bitter. Sometimes patients complain of "blisters," when in fact they feel the elevated plaques rather than true vesicles. The plaques are characteristically distributed on the buccal

dentlearn.ir

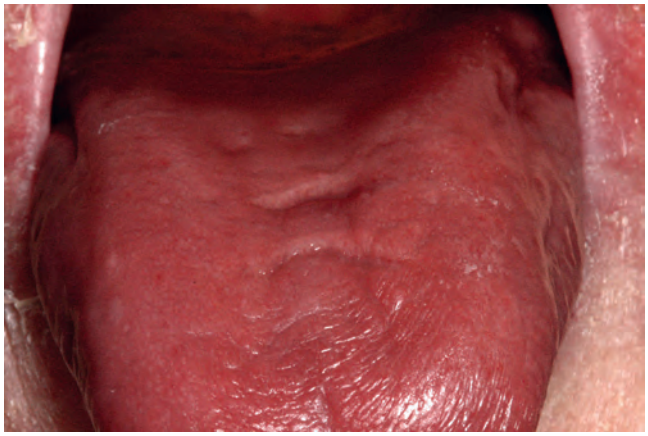
TABLE 6.1 Clinical Forms of Oral Candidiasis

Clinical Type	Appearance and Symptoms	Common Sites	Associated Factors and Comments
Pseudomembranous (thrush)	Creamy-white plaques, removable; burning sensation, foul taste	Buccal mucosa, tongue, palate	Antibiotic therapy, immunosuppression
Erythematous	Red macules, burning sensation	Posterior hard palate, buccal mucosa, dorsal tongue	Antibiotic therapy, xerostomia, immunosuppression, idiopathic
Central papillary atrophy (median rhomboid glossitis)	Red, atrophic mucosal areas; asymptomatic	Midline posterior dorsal tongue	Idiopathic, immunosuppression
Chronic multifocal	Red areas, often with removable white plaques; burning sensation, asymptomatic	Posterior palate, posterior dorsal tongue, angles of mouth	Immunosuppression, idiopathic
Angular cheilitis	Red, fissured lesions; irritated, raw feeling	Angles of mouth	Idiopathic, immunosuppression, loss of vertical dimension
Denture stomatitis (chronic atrophic candidiasis, denture sore mouth)	Red, asymptomatic	Confined to palatal denture-bearing mucosa	Probably not true infection; denture often is positive on culture but mucosa is not
Hyperplastic (candidal leukoplakia)	White plaques that are not removable; asymptomatic	Anterior buccal mucosa	Idiopathic, immunosuppression; care must be taken not to confuse this with other keratotic lesions with superimposed candidiasis
Mucocutaneous	White plaques, some of which may be removable; red areas	Tongue, buccal mucosa, palate	Rare; inherited or sporadic idiopathic immune dysfunction
Endocrine-candidiasis syndromes	White plaques, most of which are not removable	Tongue, buccal mucosa, palate	Rare; endocrine disorder develops after candidiasis



• **Fig. 6.1 Pseudomembranous Candidiasis. A,** Multiple white linear and circular plaques with associated erythema on the soft palate. **B,** Same patient, 2 weeks later, following a course of clotrimazole oral troches.

mucosa, palate, and dorsal tongue. Importantly, retention or over-production of keratin on the filiform papillae, producing a white appearance of the dorsal tongue (so-called coated or hairy tongue; see page 12) should not be confused with oral candidiasis.



Erythematous Candidiasis

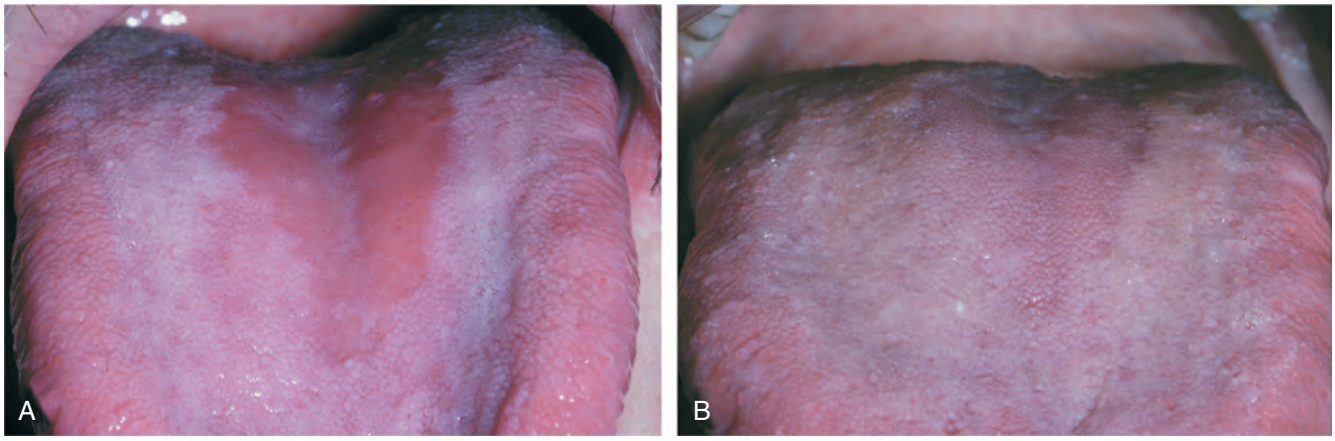
In contrast to the pseudomembranous form, patients with erythematous candidiasis either do not show white flecks, or a white component is not a prominent feature. Erythematous candidiasis is undoubtedly more common than

dentlearn.ir

• **Fig. 6.2 Pseudomembranous Candidiasis. A,** White plaques on an erythematous base, characteristic of pseudomembranous candidiasis. **B,** Removal of several of the pseudomembranous plaques reveals a mildly erythematous mucosal surface but no evidence of bleeding.

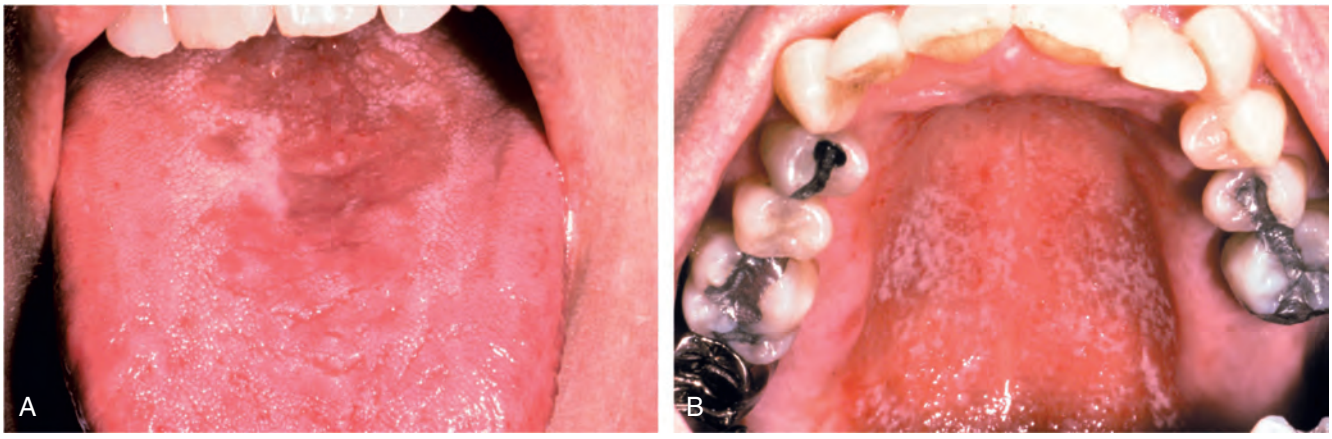
• **Fig. 6.3 Erythematous Candidiasis.** The diffuse erythema with a smooth atrophic appearance of the dorsal tongue represents erythematous candidiasis.

• **Fig. 6.4 Erythematous Candidiasis.** This asymptomatic, ovoid, erythematous patch on the posterior dorsal tongue is commonly caused by chronic infection by *Candida albicans*. The fungiform papillae appear prominent because the filiform papillae have been destroyed by the candidal infection. (Courtesy of Dr. Anthony Lotesto.)



pseudomembranous candidiasis, although it is often overlooked clinically. Several clinical presentations may be seen. **Acute atrophic candidiasis,** or "antibiotic sore mouth," typically follows a course of broad-spectrum antibiotic therapy. Patients often complain that the mouth feels as if a hot beverage had scalded it. This burning sensation is usually accompanied by a diffuse loss of the filiform papillae of the dorsal tongue, resulting in a reddened, "bald" appearance of the tongue (Fig. 6.3). Burning mouth syndrome (see page 868) frequently manifests with a scalded sensation of the tongue; however, the tongue appears normal in that condition. Patients who suffer from xerostomia for any reason (e.g., pharmacologic, postradiation therapy, or Sjögren syndrome) have an increased prevalence of erythematous candidiasis that is commonly symptomatic as well.

Other forms of erythematous candidiasis are usually asymptomatic and chronic. Included in this category is the condition known as **central papillary atrophy** of the tongue, or **median rhomboid glossitis** (Fig. 6.4). In the past, this was thought to be a developmental defect of the tongue, occurring in 0.01%–1.00% of adults. The lesion was supposed to have resulted from a failure of the embryologic tuberculum impar to be covered by the lateral processes of the tongue. Theoretically, the prevalence of central papillary atrophy in children should be identical to that seen in adults; however, in one study in which 10,000 children were examined, not a single lesion was detected. Other investigators have noted a consistent relationship between the lesion and *C. albicans,* and similar lesions have been induced experimentally on the dorsal tongues of rats.



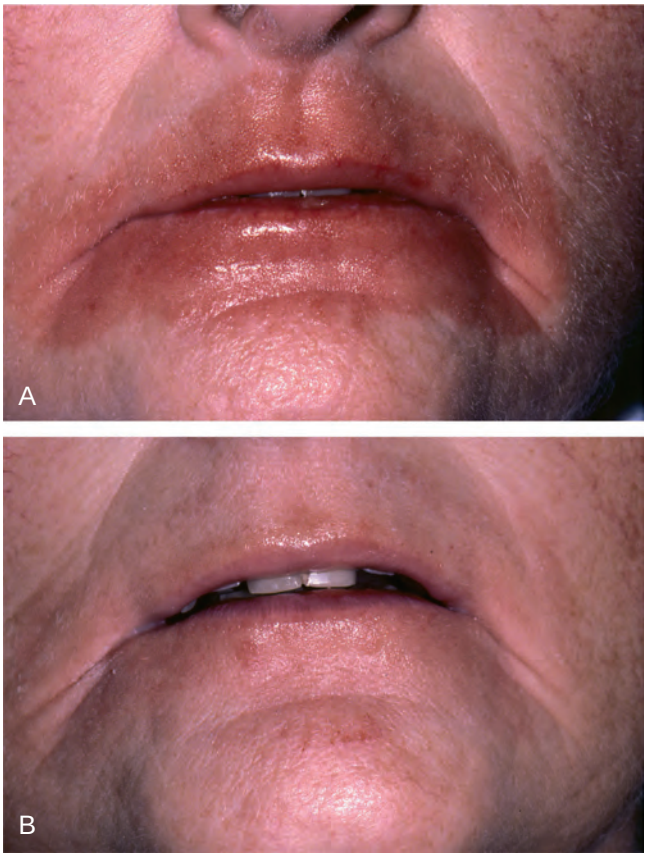
Clinically, central papillary atrophy appears as a well-demarcated erythematous zone that affects the midline, posterior dorsal tongue and often is asymptomatic (Fig. 6.5). The erythema is due in part to the loss of the filiform papillae in this area. The lesion is usually symmetrical, and its surface may range from smooth to lobulated. Often the mucosal alteration resolves with antifungal therapy, although occasionally only partial resolution can be achieved.

Some patients with central papillary atrophy may also exhibit signs of oral mucosal candidal infection at other sites. This presentation of erythematous candidiasis has been termed **chronic multifocal candidiasis.** In addition to the

dentlearn.ir

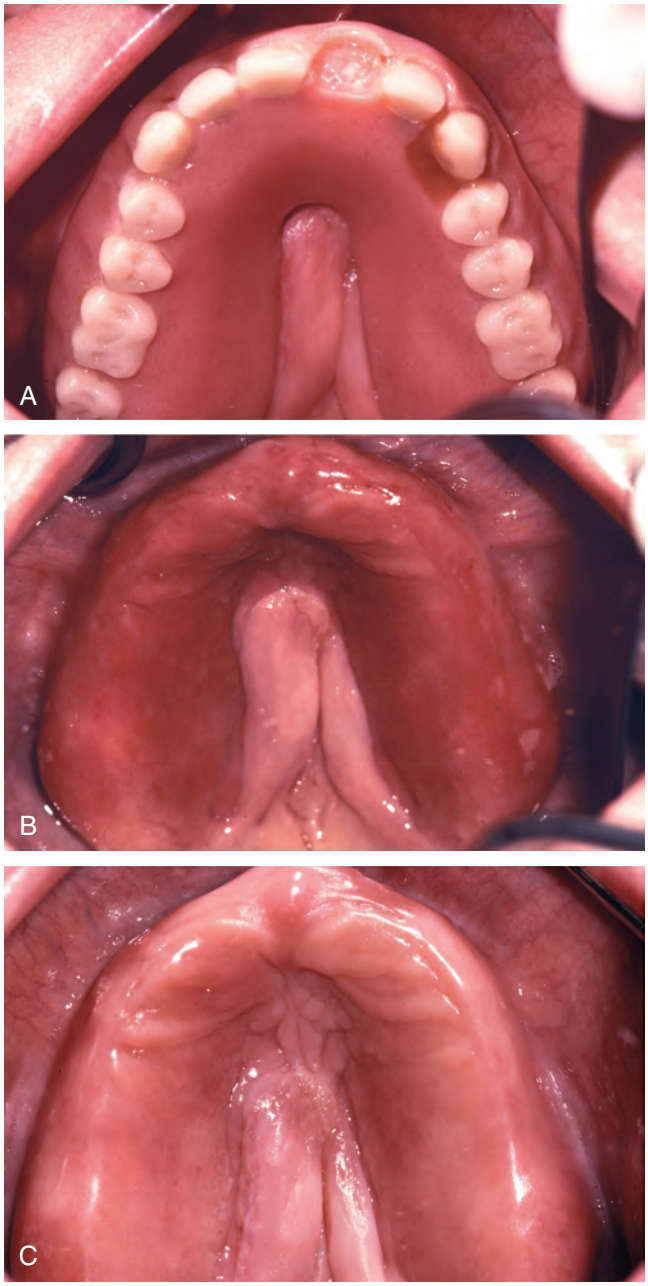
• **Fig. 6.5 Erythematous Candidiasis. A,** Severe presentation of central papillary atrophy. In this patient, the lesion was asymptomatic. **B,** Marked regeneration of the dorsal tongue papillae occurred 2 weeks after antifungal therapy with fluconazole.

• **Fig. 6.6 Candidiasis. A,** Multifocal oral candidiasis characterized by central papillary atrophy of the tongue and other areas of involvement. **B,** Same patient showing a "kissing" lesion of oral candidiasis on the hard palate.



dorsal tongue, the sites that show involvement include the junction of the hard and soft palate and the angles of the mouth. The palatal lesion appears as an erythematous area that, when the tongue is at rest, contacts the dorsal tongue lesion, resulting in what is called a "kissing lesion" because of the intimate proximity of the involved areas (Fig. 6.6).

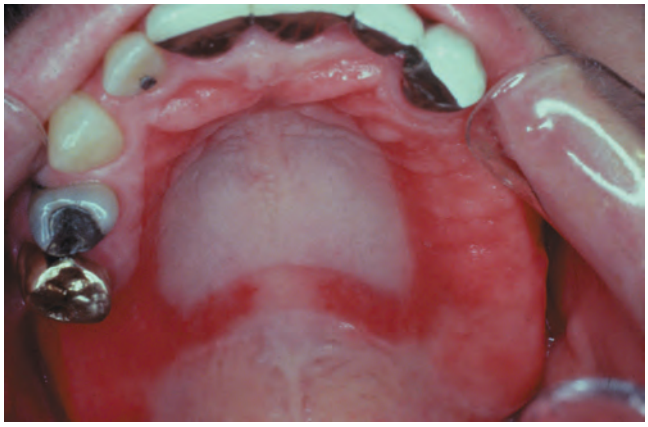
The involvement of the angles of the mouth **(angular cheilitis, perlèche)** is characterized by erythema, fissuring, and scaling (Fig. 6.7). Sometimes this condition is seen as a component of chronic multifocal candidiasis, but it often occurs alone, typically in an older person with reduced vertical dimension of occlusion and accentuated folds at the corners of the mouth. Saliva tends to pool in these areas, keeping them moist and thus favoring a yeast infection. Patients often indicate that the severity of the lesions waxes and wanes. Microbiologic studies have suggested that 20% of these cases



• **Fig. 6.7 Angular Cheilitis.** Characteristic lesions appear as mildly fissured, erythematous alterations of the skin at the corners of the mouth.

dentlearn.ir

• **Fig. 6.8 Cheilocandidiasis. A,** Candidal infection of the perioral skin caused by use of a petrolatum-based product. The condition started as angular cheilitis, but the patient continuously applied petroleum jelly to the corners of the mouth and perioral skin, sealing moisture into the keratin layer of the epidermis, thereby allowing the candidal organisms to thrive. **B,** Two weeks after discontinuing the petroleum jelly and using topical iodoquinol with triamcinolone.



• **Fig. 6.9 Denture Stomatitis. A,** Maxillary denture with incomplete palatal vault associated with midline tissue hyperplasia. **B,** Mucositis corresponds to the outline of the prosthesis. **C,** Resolution of mucositis after antifungal therapy and appropriate denture cleansing.

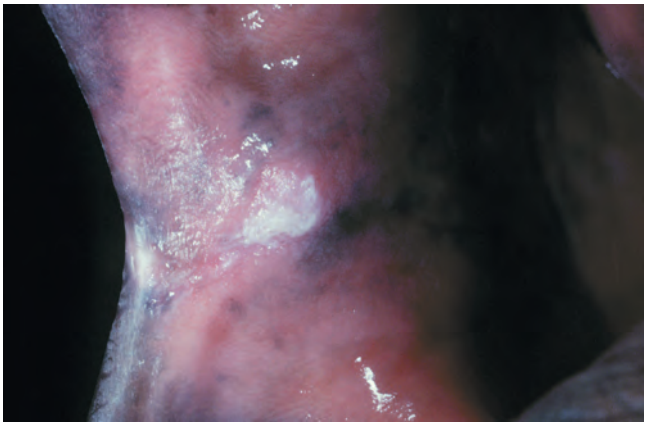
are caused by *C. albicans* alone, 60% are due to a combined infection with *C. albicans* and *Staphylococcus aureus,* and 20% are associated with *S. aureus* alone. Infrequently, the candidal infection more extensively involves the perioral skin, usually secondary to actions that keep the skin moist (e.g., chronic lip licking, thumb sucking, chronic use of petrolatum-based salves), creating a clinical pattern known as **cheilocandidiasis** (Fig. 6.8). Other causes of exfoliative cheilitis often must be considered in the differential diagnosis (see page 294).

Denture stomatitis should be mentioned because it is often classified as a form of erythematous candidiasis, and some authors may use the term *chronic atrophic candidiasis* synonymously. This condition is characterized by varying degrees of erythema, sometimes accompanied by petechial hemorrhage, localized to the denture-bearing areas of a maxillary removable dental prosthesis (Figs. 6.9 and 6.10). Although the clinical appearance can be striking, the process is rarely symptomatic. Usually the patient admits to wearing the denture continuously, removing it only periodically to clean it. Whether this represents actual infection by *C. albicans* or is simply a tissue response by the host to the various microorganisms living beneath the denture remains controversial. The clinician should also rule out the possibility that this reaction could be caused by improper design of the denture (which could cause unusual pressure on the mucosa), allergy to the denture base, or inadequate curing of the denture acrylic.

Although *C. albicans* is often associated with this condition, biopsy specimens of denture stomatitis seldom show candidal hyphae actually penetrating the keratin layer of the host epithelium. Therefore, this lesion does not meet one of the main defining criteria for the diagnosis of infection—host tissue invasion by the organism.

dentlearn.ir

• **Fig. 6.10 Denture Stomatitis.** Denture stomatitis, not associated with *Candida albicans,* confined to the denture-bearing mucosa of a maxillary partial denture framework.



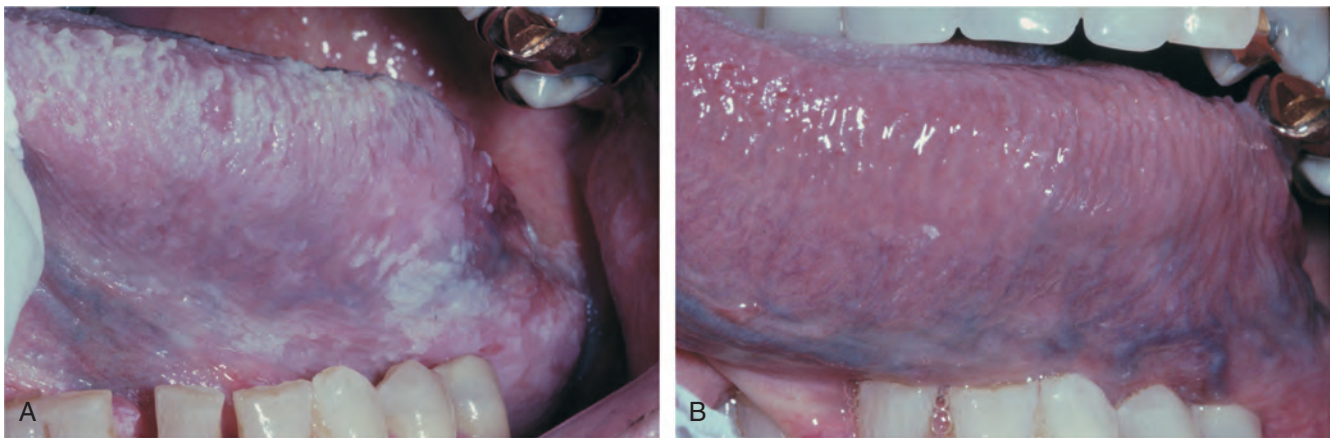
• **Fig. 6.11 Denture Stomatitis.** This Sabouraud agar slant has been streaked with swabs obtained from erythematous palatal mucosa *(left side of the slant)* and the tissue-bearing surface of the denture *(right side of the slant).* Extensive colonization of the denture is demonstrated, whereas little evidence of yeast associated with the mucosa is noted.

Furthermore, if the palatal mucosa and tissue-contacting surface of the denture are swabbed and separately streaked onto a Sabouraud agar slant, then the denture typically shows much heavier colonization by yeast (Fig. 6.11).

Chronic Hyperplastic Candidiasis (Candidal Leukoplakia)

In some patients with oral candidiasis, there may be a white patch that cannot be removed by scraping; in this case the term *chronic hyperplastic candidiasis* is appropriate. This form of candidiasis is the least common and is also somewhat controversial. Some investigators believe that this condition simply represents candidiasis that is superimposed on a preexisting leukoplakic lesion, a situation that may certainly exist at times. In some instances, however, the candidal organism alone may be capable of inducing a hyperkeratotic lesion. Such lesions are usually located on the anterior buccal mucosa and cannot clinically be distinguished from a routine leukoplakia (Fig. 6.12). Often the leukoplakic lesion associated with candidal infection has a fine intermingling of red and white areas, resulting in a speckled leukoplakia (see page 384). Such lesions may have an increased frequency of epithelial dysplasia histopathologically.

• **Fig. 6.12 Hyperplastic Candidiasis.** This lesion of the anterior buccal mucosa clinically resembles a leukoplakia because it is a white plaque that cannot be removed by rubbing. With antifungal therapy, such a lesion should resolve completely.



The diagnosis is confirmed by the presence of candidal hyphae associated with the lesion and, more importantly, by complete resolution of the lesion after antifungal therapy (Fig. 6.13). If the lesion remains following antifungal therapy, then biopsy of the persistent white patch is indicated.

Mucocutaneous Candidiasis

Severe oral candidiasis may also be seen as a component of a relatively rare group of immunologic disorders known as *mucocutaneous candidiasis.* Several distinct immunologic dysfunctions have been identified, and the severity of the candidal infection correlates with the severity of the immunologic defect. Most cases are sporadic, although an autosomal recessive pattern of inheritance has been identified in some families. Several studies have suggested that the cytokine IL-17 is critical in mucosal immunity related to *C. albicans*, and mutations of the gene responsible for producing this cytokine appear to cause some forms of mucocutaneous candidiasis. More recently, gain-of-function mutations in the STAT1 gene have been identified, resulting in abnormal Th1 and Th17 T-helper cell function. This increases the patient's susceptibility to candidiasis, as well as some bacterial infections. The STAT1 mutations now appear to be the genetic basis for the majority of mucocutaneous candidiasis cases. The immune problem usually becomes evident during the first few years of life, when the patient begins to have candidal infections of the mouth, nails, skin, and other mucosal surfaces. The oral lesions are usually described as thick, white plaques that typically do not rub off (essentially chronic hyperplastic candidiasis), although the other clinical forms of candidiasis may also be seen.

In some patients with mucocutaneous candidiasis, mutations in the autoimmune regulator (AIRE) gene have been documented, with the resultant formation of autoantibodies directed against the person's own tissues (Fig. 6.14). In most instances, the immunologic attack is directed against the endocrine glands; however, the reasons for this tissue specificity are currently unclear. Autoimmune destruction of the T-lymphocytes that produce interleukin-17 (IL-17) and

dentlearn.ir

• **Fig. 6.13 Hyperplastic Candidiasis. A,** These diffuse white plaques clinically appear as leukoplakia, but they actually represent an unusual presentation of hyperplastic candidiasis. **B,** Treatment with clotrimazole oral troches shows complete resolution of the white lesions within 2 weeks, essentially confirming the diagnosis of hyperplastic candidiasis. If any white mucosal alteration had persisted, a biopsy of that area would have been mandatory.

IL-22 appears to be responsible for the candidal infections seen in these individuals. Young patients with mucocutaneous candidiasis should be evaluated periodically because any one of a variety of endocrine abnormalities (i.e., **endocrine-candidiasis syndrome**, **autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy [APECED] syndrome/autoimmune polyendocrine syndrome, type 1**), as well as iron-deficiency anemia, may develop in addition to the candidiasis. These endocrine disturbances include hypothyroidism, hypoparathyroidism, hypoadrenocorticism (Addison disease), and diabetes mellitus. Typically, the endocrine abnormality develops months or even years after the onset of the candidal infection. Two studies have documented increased prevalence of oral and esophageal carcinoma in this condition, with these malignancies affecting approximately 6%–10% of adults with APECED syndrome. The mean age of APECED patients with oral cancer was significantly younger than that of oral carcinoma patients in the general population. This finding of increased prevalence of oral and esophageal malignancies represents another justification for periodic reevaluation of these individuals, including esophageal endoscopy every 2–3 years.

Interestingly, the candidal infection remains relatively superficial rather than disseminating throughout the body. Both the oral lesions and any cutaneous involvement (usually presenting as roughened, foul-smelling cutaneous plaques and nodules) can be usually controlled with continuous use of relatively safe systemic antifungal drugs. As with any long-term antibiotic treatment, development of drug-resistant organisms can occur, however.

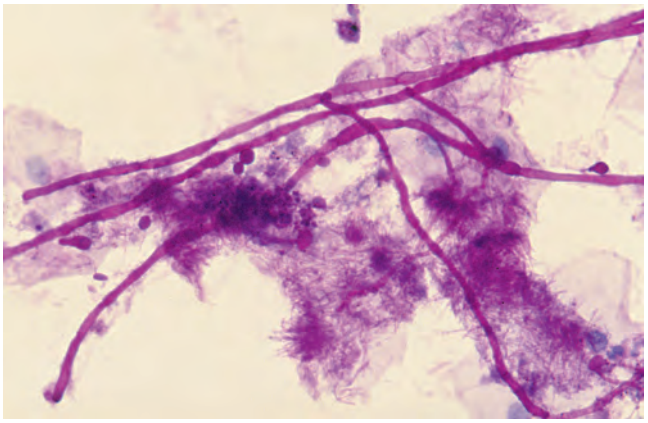
Histopathologic Features

The candidal organism can be seen microscopically in either an exfoliative cytologic preparation or in tissue sections obtained from a biopsy specimen. On staining with the periodic acid-Schiff (PAS) method or the Grocott-Gomori methenamine silver (GMS) method, the candidal hyphae and yeasts can be readily identified (Fig. 6.15). Both techniques stain carbohydrates, contained in abundance by fungal cell walls; the organisms appear bright-magenta with the PAS stain or black with the GMS stain. To make a diagnosis of candidiasis, one must be able to see hyphae or pseudohyphae (which are essentially elongated yeast cells). These hyphae are approximately 2 μm in diameter, vary in their length, and may show branching. Often the hyphae are accompanied by variable numbers of yeasts, squamous epithelial cells, and inflammatory cells.

A 10%–20% potassium hydroxide (KOH) preparation may also be used to rapidly evaluate specimens for the presence of fungal organisms. With this technique, the KOH lyses the background of epithelial cells, allowing the more resistant yeasts and hyphae to be visualized.

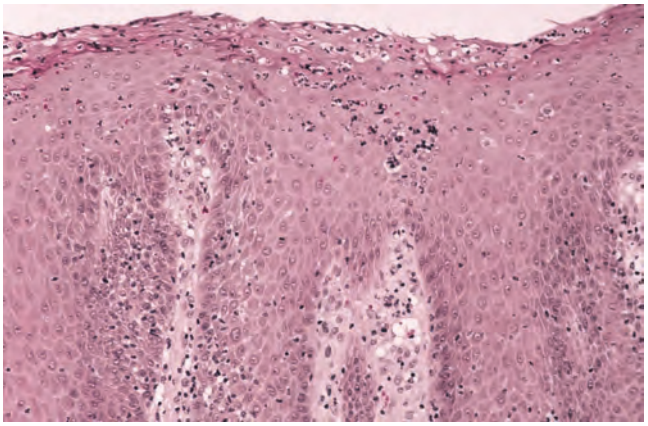
The disadvantages of the KOH preparation include the following:

- Lack of a permanent record
- Greater difficulty in identifying the fungal organisms, compared with PAS staining
- Inability to assess the nature of the epithelial cell population with respect to other conditions, such as epithelial dysplasia or pemphigus vulgaris

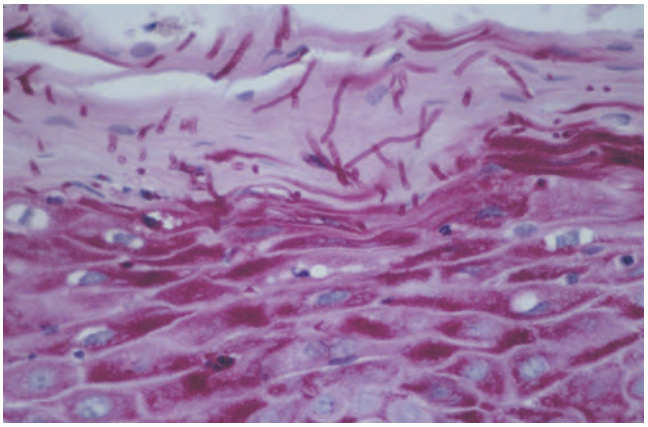


The histopathologic pattern of oral candidiasis may vary slightly, depending on which clinical form of the infection has been submitted for biopsy. The features that are found in common include an increased thickness of parakeratin on the surface of the lesion in conjunction with elongation of the epithelial rete ridges (Fig. 6.16). Typically, a chronic inflammatory cell infiltrate can be seen in the connective tissue immediately subjacent to the infected epithelium, and small collections of neutrophils (microabscesses) are often identified in the parakeratin layer and the superficial spinous cell layer near the organisms (Fig. 6.17). The candidal hyphae are embedded in the parakeratin layer and, unless the patient is extremely immunocompromised, rarely penetrate into the viable cell layers of the epithelium. This is also

dentlearn.ir



• **Fig. 6.14 Autoimmune Polyendocrinopathy-Candidiasis-Ectodermal Dystrophy (APECED) Syndrome. A,** Erythematous candidiasis diffusely involving the dorsal tongue of a 32-year-old man. **B,** Same patient showing nail dystrophy. **C,** Corneal keratopathy is also noted. Patient had a history of the onset of hypoparathyroidism and hypoadrenocorticism, which were both diagnosed in the second decade of life.



the finding in oral lesions of epithelial dysplasia or oral lichenoid lesions with superimposed candidiasis, suggesting that the organism is merely interested in "grazing" on the dead, keratinized surface cells. Sometimes this superficial infection will elicit the characteristic host response described above, but occasionally this response is lacking, which may be related to the candidal strain.

dentlearn.ir

Diagnosis

The diagnosis of candidiasis is usually established by the clinical signs in conjunction with exfoliative cytologic examination. Although a culture can definitively identify the organism as *C. albicans,* this process may not be practical in most office settings. The cytologic findings should demonstrate the hyphal phase of the organism, and antifungal therapy can then be instituted. If the lesion is clinically suggestive of chronic hyperplastic candidiasis but does not respond to antifungal therapy, then a biopsy should be performed to rule out the possibility of *C. albicans* superimposed on epithelial dysplasia, squamous cell carcinoma, or lichen planus.

The definitive identification of the organism can be made by means of culture. A specimen for culture is obtained by rubbing a sterile cotton swab over the lesion and then streaking the swab on the surface of a Sabouraud agar slant. *C. albicans* will grow as creamy, smooth-surfaced colonies after 2–3 days of incubation at room temperature.

Treatment and Prognosis

Several antifungal medications have been developed for managing oral candidiasis, each with its advantages and disadvantages (Table 6.2).

Polyene Agents

Nystatin

In the 1950s, the polyene antibiotic nystatin was the first effective treatment for oral candidiasis. Nystatin is formulated for oral use as a suspension or pastille (lozenge). Many patients report that nystatin has a very bitter taste, which may reduce patient compliance; therefore, the taste has to be disguised with sucrose and flavoring agents. If the candidiasis is due to xerostomia, the sucrose content of the nystatin preparation may contribute to xerostomia-related caries in these patients. The gastrointestinal tract poorly absorbs nystatin and the other polyene antibiotic, amphotericin; therefore, their effectiveness depends on direct contact with the candidal organisms. This necessitates multiple daily doses so that the yeasts are adequately exposed to the drug. Nystatin combined with triamcinolone acetonide cream or ointment can be applied topically and is effective for angular cheilitis that does not have a bacterial component.

Amphotericin B

For many years in the United States, the use of amphotericin B was restricted to intravenous (IV) treatment of life-threatening systemic fungal infections. This medication subsequently became available as an oral suspension for the management of oral candidiasis. Unfortunately, the interest in this formulation of the drug was scant, and it is no longer marketed in the United States.

Imidazole Agents

The imidazole-derived antifungal agents were developed during the 1970s and represented a major step forward in the management of candidiasis. The two drugs of this group that are used most frequently are clotrimazole and ketoconazole.

Clotrimazole

Like nystatin, clotrimazole is not well absorbed and must be administered several times each day. It is formulated as a pleasant-tasting troche (lozenge) and produces few side effects. The efficacy of this agent in treating oral candidiasis can be seen in Fig. 6.13. Clotrimazole cream is also effective treatment for angular cheilitis, because this drug has antibacterial and antifungal properties.

Ketoconazole

Ketoconazole was the first antifungal drug that could be absorbed across the gastrointestinal tract, thereby providing systemic therapy by an oral route of administration. Patients could not take antacids or H2-blocking agents, because an acidic environment is required for proper absorption. The single daily dose was much easier for patients to use; however, several significant disadvantages have been identified. The most serious is idiopathic liver toxicity caused by this drug, occurring in approximately 1 in 10,000 individuals. Furthermore, ketoconazole has been implicated in drug interactions with macrolide antibiotics (e.g., erythromycin), which may produce potentially life-threatening cardiac arrhythmias. For these reasons, the US Food and Drug Administration has stated that ketoconazole should not be used to treat routine oral candidiasis.

Triazoles

The triazoles are among the more recently developed antifungal drugs. Both fluconazole and itraconazole have been approved for treating candidiasis in the United States.

Fluconazole

Fluconazole appears to be more effective than ketoconazole; it is well absorbed systemically, and an acidic environment is not required for absorption. A relatively long half-life allows for once-daily dosing, and liver toxicity is rare at the doses used to treat oral candidiasis. Some reports have suggested that fluconazole may not be appropriate for long-term preventive therapy because resistance to the drug seems to develop in some instances. Known drug interactions include a potentiation of the effects of phenytoin (Dilantin), an antiseizure medication; warfarin compounds (anticoagulants); and sulfonylureas (oral hypoglycemic agents). Other drugs that may interact with fluconazole are summarized in Table 6.2.

Itraconazole

Itraconazole has proven efficacy against a variety of fungal diseases, including histoplasmosis, blastomycosis, and fungal conditions of the nails. Recently, itraconazole solution was approved for management of oropharyngeal candidiasis, and this appears to have an efficacy equivalent to clotrimazole and fluconazole. As with fluconazole, significant drug interactions are possible, and itraconazole is contraindicated for patients taking erythromycin, triazolam, and midazolam. (See Table 6.2 for other potential drug interactions.)

dentlearn.ir

TABLE 6.2 Antifungal Medications

Generic Name	Trade Name	Indications	Dosage
Nystatin	Mycostatin oral suspension	Oral candidiasis	1–2 tsp as a mouthrinse, q.i.d., p.c. and h.s., for 10–14 days. Hold each dose in the mouth as long as possible
Clotrimazole	Mycelex oral troches	Oral candidiasis	Dissolve 1 troche (10 mg) slowly in the mouth, 5 times daily for 10–14 days
Ketoconazole	Nizoral tablets	Oral candidiasis Blastomycosis Coccidioidomycosis Histoplasmosis Paracoccidioidomycosis	Not to be used as initial therapy for oral candidiasis One tablet (200 mg) daily for 1–2 weeks for candidiasis Minimum treatment period for systemic mycoses is 6 months
Fluconazole	Diflucan tablets	Oral candidiasis Cryptococcal meningitis	For oral candidiasis: two tablets (200 mg) on day 1 and then one tablet (100 mg) daily for 1–2 weeks
Itraconazole	Sporanox capsules	Blastomycosis Histoplasmosis Aspergillosis refractory to amphotericin B therapy	For blastomycosis and histoplasmosis: two capsules (200 mg) daily, increasing by 100-mg increments up to 400 mg daily in divided doses if no clinical response is noted For aspergillosis: 200–400 mg daily For life-threatening situations: loading dose of 200 mg t.i.d. for first 3 days, then dose can be reduced Treatment should continue for at least 3 months for all of the above
Itraconazole	Sporanox oral solution	Oral candidiasis	10 mL (100 mg) vigorously swished in the mouth and swallowed, twice daily for 1–2 weeks

h.s., Hora somni (at bedtime); *p.c.,* post cibum (after meals); *q.i.d.,* quarter in die (four times a day); *t.i.d.,* ter in die (three times a day).

Posaconazole

This triazole compound has been shown to be effective in the management of oropharyngeal candidiasis in patients with HIV infection. Given the cost of this drug and the proven effectiveness of other, less expensive, oral antifungal agents, the use of this medication for treatment of routine oral candidiasis would be difficult to justify.

Isavuconazole

This recently developed triazole is well absorbed as its pro-drug, isavuconazonium sulfate, and is converted by esterases in the serum to isavuconazole. Isavuconazole may have fewer drug interactions compared to other compounds in the triazole class. Although this medication has a relatively wide spectrum of activity against a number of pathogenic fungi, it is currently approved in the United States only for treatment of invasive aspergillosis and invasive mucormycosis in adults.

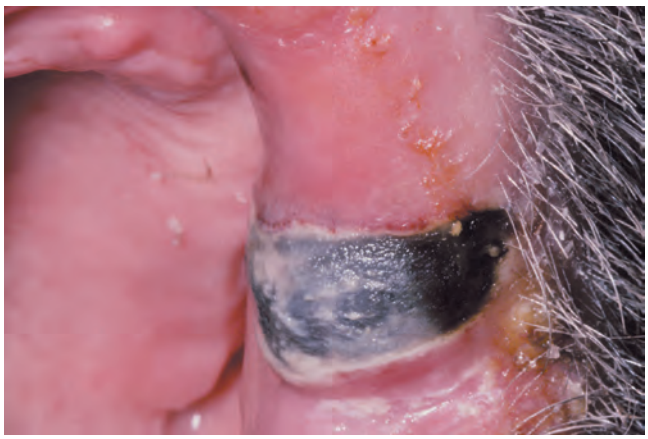
Echinocandins

This relatively new class of antifungal drugs acts by interfering with candidal cell wall synthesis. The formation of β-1,3-glucan, which is a principal component of the candidal cell wall, is disrupted and results in permeability of the cell wall with subsequent demise of the candidal organism. These medications are not well absorbed; consequently they must be administered intravenously

dentlearn.ir

Side Effects/Adverse Reactions	Drug Interactions
Usually well tolerated, although the taste may be unacceptable (bitter) for some patients	None known
Mild elevations of liver enzymes in 15% of patients Periodic assessment of liver function in patients with hepatic impairment Nausea, vomiting	No significant drug interactions
Serious hepatotoxicity in 1:10,000 patients Monitoring of liver function is indicated for patients with preexisting hepatic problems, patients who develop symptoms of hepatic failure, or patients treated for more than 28 days Serum testosterone is lowered Nausea, vomiting Anaphylaxis	Serious and/or life-threatening interactions with erythromycin Metabolism of cyclosporine, tacrolimus, methylprednisolone, midazolam, triazolam, coumarin-like drugs, phenytoin, and rifampin may be altered
Rare cases of hepatotoxicity, ranging from mild transient elevation of liver enzymes to hepatic failure Headache, nausea, vomiting, abdominal pain, diarrhea	Clinically or potentially significant side effects have been noted with the following medications: oral hypoglycemic agents, coumarin-like drugs, phenytoin, cyclosporine, rifampin, theophylline, rifabutin, and tacrolimus
Rare cases of hepatoxicity	Serious and/or life-threatening interactions with erythromycin, pimozide, quinidine, oral triazolam, and oral midazolam
Liver function should be monitored in patients with preexisting hepatic problems on therapy for more than 1 month Nausea, diarrhea, vomiting	Lovastatin and simvastatin should be discontinued Increased plasma concentrations may be seen with warfarin, ritonavir, indinavir, vinca alkaloid agents, diazepam, cyclosporine, dihydropyridine medications, tacrolimus, digoxin, and methylprednisolone
Rare cases of hepatotoxicity Liver function should be monitored in patients with preexisting hepatic problems on therapy for more than 1 month Nausea, diarrhea, vomiting	Serious and/or life-threatening interactions with erythromycin, oral triazolam, and oral midazolam Lovastatin and simvastatin should be discontinued

and are reserved for more life-threatening candidal infections. Examples include caspofungin, micafungin, and anidulafungin.



Other Antifungal Agents

Iodoquinol

Although not strictly an antifungal drug, iodoquinol has antifungal and antibacterial properties. When compounded in a cream base with a corticosteroid, this material is very effective as topical therapy for angular cheilitis.

In most cases, oral candidiasis is an annoying superficial infection that is easily resolved by antifungal therapy. If infection should recur after treatment, then a thorough investigation of potential factors that could predispose to candidiasis may be necessary. Often the predisposing factor represents a contaminated acrylic mouth guard, bite plane, or maxillary denture, as candidal colonization of the tissue-bearing aspect of these appliances is common. Soaking the appliance in a dilute sodium hypochlorite (bleach) solution for an 8-hour period daily, during the period that the patient is treating their mucosal infection, is recommended. Immune suppression, in the form of topical, inhaled, or systemic corticosteroids, is also a common predisposing factor. Acquired immune suppression, such as that associated with HIV infection (see page 250) or uncontrolled diabetes mellitus, may need to be considered as well. In only the most

dentlearn.ir

• **Fig. 6.18 Candidiasis.** This necrotic lesion of the upper lip developed in a man with uncontrolled type I diabetes mellitus. Biopsy and culture showed a rare example of invasive oral infection by *Candida albicans*.

severely compromised patient will candidiasis cause deeply invasive disease (Fig. 6.18).

◆ HISTOPLASMOSIS

Histoplasmosis, the most common systemic fungal infection in the United States, is caused by the organism *Histoplasma capsulatum.* Like several other pathogenic fungi, *H. capsulatum* is dimorphic, growing as a yeast at body temperature in the human host and as a mold in its natural environment. Humid areas with soil enriched by bird or bat excrement are especially suited to the growth of this organism. This habitat preference explains why histoplasmosis is seen endemically in fertile river valleys, such as the region drained by the Ohio and Mississippi Rivers in the United States. Airborne spores of the organism are inhaled, pass into the terminal passages of the lungs, and germinate.

Approximately 500,000 new cases of histoplasmosis are thought to develop annually in the United States. Other parts of the world, such as Central and South America, Europe, Asia, and Australia, also report numerous cases. Epidemiologic studies in endemic areas of the United States suggest that 80%–90% of the population in these regions has been infected.

Clinical and Radiographic Features

Most cases of histoplasmosis produce either no symptoms or such mild symptoms that the patient does not seek medical treatment. The expression of disease depends on the quantity of spores inhaled, the immune status of the host, and perhaps the strain of *H. capsulatum.* Most individuals who become exposed to the organism are relatively healthy and do not inhale a large number of spores; therefore, they have either no symptoms or they have a mild, flulike illness for 1–2 weeks. The inhaled spores are ingested by macrophages within 24–48 hours, and specific T-lymphocyte immunity develops in 2–3 weeks. Antibodies directed against the organism usually appear several weeks later. With these defense mechanisms, the host is usually able to destroy the invading organism, although sometimes the macrophages simply surround and confine the fungus so that viable organisms can be recovered years later. Thus patients who formerly lived in an endemic area may have acquired the organism and later express the disease at some other geographic site if they become immunocompromised.

Acute histoplasmosis is a self-limited pulmonary infection that probably develops in only about 1% of people who are exposed to a low number of spores. With a high concentration of spores, as many as 50%–100% of individuals may experience acute symptoms. These symptoms (e.g., fever, headache, myalgia, nonproductive cough, and anorexia) result in a clinical picture similar to that of influenza. Patients are usually ill for 2 weeks, although calcification of the hilar lymph nodes may be detected as an incidental finding on chest radiographs years later.

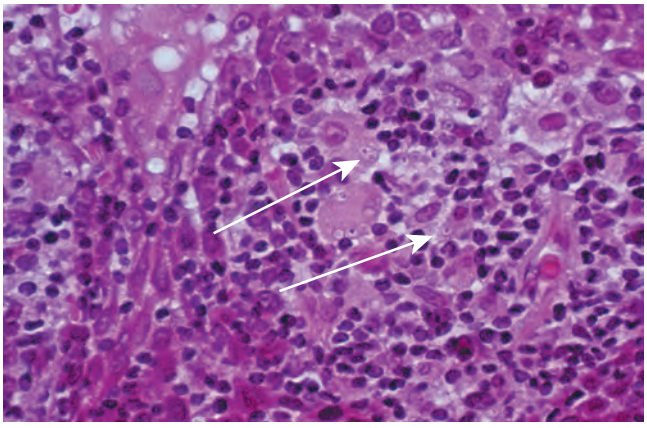
Chronic histoplasmosis also primarily affects the lungs, although it is much less common than acute histoplasmosis. The chronic form usually affects older, emphysematous, white men or immunosuppressed patients. Clinically, it appears similar to tuberculosis. Patients typically exhibit cough, weight loss, fever, dyspnea, chest pain, hemoptysis, weakness, and fatigue. Chest roentgenograms show upper-lobe infiltrates and cavitation.

Disseminated histoplasmosis is even less common than the acute and chronic types. It occurs in 1 of 2000–5000 patients who have acute symptoms. This condition is characterized by the progressive spread of the infection to extrapulmonary sites. It usually occurs in either older, debilitated, or immunosuppressed patients. In some areas of the United States, 2%–10% of patients with **acquired immunodeficiency syndrome (AIDS)** (see page 262) develop disseminated histoplasmosis. Patients who are being treated with a tumor necrosis factor-alpha (TNF-α) inhibitor (such as, infliximab, etanercept, or adalimumab) and who live in endemic geographic regions also are at risk for disseminated disease, probably due to reactivation of the organism. Tissues that may be affected include the spleen, adrenal glands, liver, lymph nodes, gastrointestinal tract, central nervous system (CNS), kidneys, and oral mucosa. Adrenal involvement may produce hypoadrenocorticism **(Addison disease)** (see page 843).

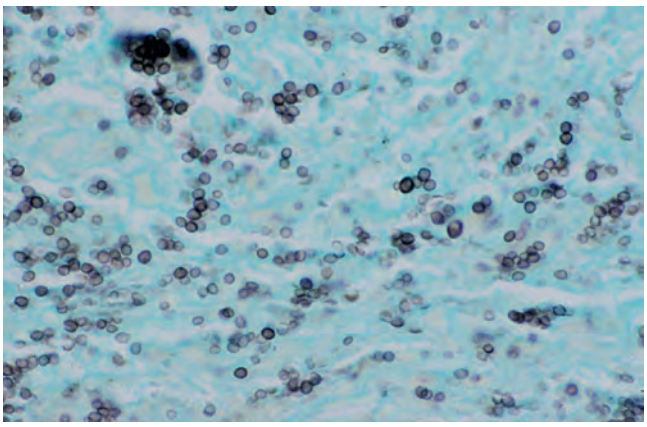
Most oral lesions of histoplasmosis occur with the disseminated form of the disease. The most commonly affected sites are the tongue, palate, and buccal mucosa. The condition usually appears as a solitary, variably painful ulceration of several weeks' duration; however, some lesions may appear erythematous or white with an irregular surface (Fig. 6.19). The ulcerated lesions have firm, rolled margins, and they may be indistinguishable clinically from a malignancy (Fig. 6.20).

Histopathologic Features

Microscopic examination of lesional tissue shows either a diffuse infiltrate of macrophages or, more commonly, collections of macrophages organized into granulomas (Fig. 6.21). Multinucleated giant cells are usually seen in association with the



dentlearn.ir



• **Fig. 6.19 Histoplasmosis.** This ulcerated granular lesion involves the right mandibular labial vestibule and gingivae, and is easily mistaken clinically for carcinoma. Biopsy established the diagnosis. (Courtesy of Douglas Damm, with appreciation to Dr. Robert Clark.)

• **Fig. 6.20 Histoplasmosis.** This chronic ulceration of the ventral and lateral tongue represents an oral lesion of histoplasmosis that had disseminated from the lungs. The lesion clinically resembles carcinoma; because of this high-risk site, biopsy is mandatory.

• **Fig. 6.21 Histoplasmosis.** This medium-power photomicrograph shows scattered epithelioid macrophages admixed with lymphocytes and plasma cells. Some macrophages contain organisms of *Histoplasma capsulatum (arrows)*.

• **Fig. 6.22 Histoplasmosis.** This high-power photomicrograph of a tissue section readily demonstrates the small yeasts of *Histoplasma capsulatum*. (Grocott-Gomori methenamine silver stain.)

granulomatous inflammation. The causative organism can be identified with some difficulty in the routine hematoxylin and eosin (H&E)-stained section; however, special stains, such as the PAS and Grocott-Gomori methenamine silver methods, readily demonstrate the characteristic 1- to 3-μm yeasts of *H. capsulatum* (Fig. 6.22).

Diagnosis

The diagnosis of histoplasmosis can be made by histopathologic identification of the organism in tissue sections or by culture. Other helpful diagnostic studies include serologic testing in which antibodies directed against *H. capsulatum* are demonstrated and antigen produced by the yeast is identified.

Treatment and Prognosis

Acute histoplasmosis, because it is a self-limited process, generally warrants no specific treatment other than supportive care with analgesic and antipyretic agents. Often the disease is not treated because the symptoms are so nonspecific and the diagnosis is not readily evident.

Patients with chronic histoplasmosis require treatment, despite the fact that up to half of them may recover spontaneously. Often the pulmonary damage is progressive if it remains untreated, and death may result in up to 20% of these cases. For severe cases of chronic histoplasmosis, the treatment of choice is IV administration of one of the lipid preparations of amphotericin B, which are significantly less toxic than standard formulations of amphotericin B deoxycholate. Itraconazole may be used in nonimmunosuppressed patients because it is associated with even fewer side effects and is less expensive, but this medication requires daily dosing for 12–24 months.

Disseminated histoplasmosis occurring in an immunesuppressed individual is a very serious condition that results in death in 80%–90% of patients if they remain untreated. One of the lipid preparations of amphotericin B is indicated for such patients; once the life-threatening phase of the

dentlearn.ir

disease is under control, daily itraconazole is necessary for at least 12 months. Despite therapy, however, a mortality rate of 7%–23% is observed. Itraconazole alone may be used if the patient is nonimmunocompromised and has relatively mild to moderate disease; however, the response rate is slower than for patients receiving amphotericin B, and the relapse rate may be higher.

BLASTOMYCOSIS

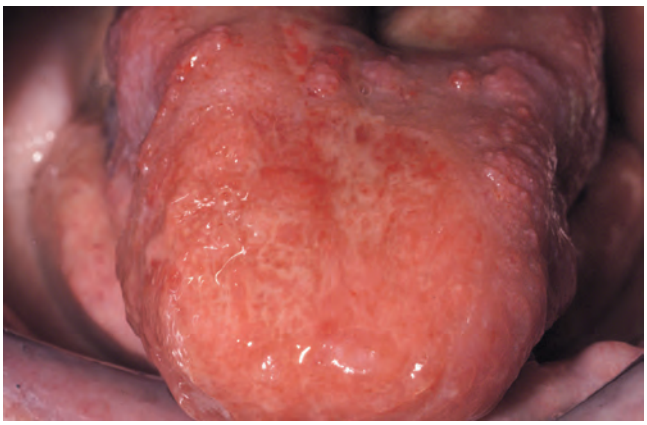
Blastomycosis is a relatively uncommon disease caused by two dimorphic fungi known as *Blastomyces dermatitidis*, and a more recently identified species, *Blastomyces gilchristii*. Although the organism is rarely isolated from its natural habitat, it seems to prefer rich, moist soil, where it grows as a mold. Much of the region in which it grows overlaps the territory associated with *H. capsulatum* (affecting the eastern half of the United States). The range of blastomycosis extends farther north, however, including Wisconsin, Minnesota, and the Canadian provinces surrounding the Great Lakes. Sporadic cases have also been reported in Africa, India, Europe, and South America. By way of comparison, histoplasmosis appears to be at least ten times more common than blastomycosis. In some series of cases, a prominent adult male predilection has been noted, often with a male-to-female ratio as high as 9:1. Although some researchers have attributed this to the greater degree of outdoor activity (e.g., hunting, fishing) by men in areas where the organism grows, others have noted that these series were typically reported from VA hospital data, which has an inherent male bias. The occurrence of blastomycosis in immunocompromised patients is relatively rare.

Clinical and Radiographic Features

Blastomycosis is almost always acquired by inhalation of spores, particularly after a rain. The spores reach the alveoli of the lungs, where they begin to grow as yeasts at body temperature. In most patients, the infection is probably halted and contained in the lungs, but it may become hematogenously disseminated in a few instances. In order of decreasing frequency, the sites of dissemination include skin, bone, prostate, meninges, oropharyngeal mucosa, and abdominal organs.

Although most cases of blastomycosis are either asymptomatic or produce only very mild symptoms, patients who do experience symptoms usually have pulmonary complaints. **Acute blastomycosis** resembles pneumonia, characterized by high fever, chest pain, malaise, night sweats, and productive cough with mucopurulent sputum. Rarely, the infection may precipitate life-threatening adult respiratory distress syndrome.

Chronic blastomycosis is more common than the acute form, and it may mimic tuberculosis; both conditions are often characterized by low-grade fever, night sweats, weight loss, and productive cough. Chest radiographs may appear normal, or they may demonstrate diffuse infiltrates or one or more pulmonary or hilar masses. Unlike the situation with tuberculosis and histoplasmosis, calcification is not typically present. Cutaneous lesions usually represent the spread of infection from the lungs, although occasionally they are the only sign of disease. Such lesions begin as erythematous nodules that enlarge, becoming verrucous or ulcerated (Figs. 6.23 and 6.24).

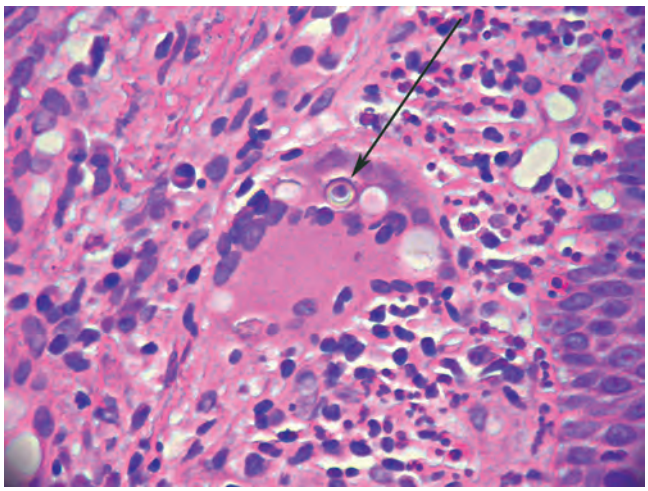


• **Fig. 6.23 Blastomycosis.** This granular erythematous plaque of cutaneous blastomycosis has affected the facial skin. (Courtesy of Dr. William Welton.)

• **Fig. 6.24 Blastomycosis.** Severe cutaneous infection by *Blastomyces dermatitidis*. (Courtesy of Dr. Emmitt Costich.)

dentlearn.ir

• **Fig. 6.25 Blastomycosis.** These irregular ulcerations of the tongue represent blastomycosis. Direct inoculation was thought to have occurred from the patient's habit of chewing dried horse manure ("Kentucky field candy"), in which the organism was probably growing.



• **Fig. 6.26 Blastomycosis.** Granular exophytic and indurated mass on the buccal mucosa.

Oral lesions of blastomycosis may result from either extrapulmonary dissemination or local inoculation with the organism. These lesions may have an irregular, erythematous, or white intact surface, or they may appear as ulcerations with irregular rolled borders and varying degrees of pain (Figs. 6.25 and 6.26). Clinically, because the lesions resemble squamous cell carcinoma, biopsy and histopathologic examination are required.

Histopathologic Features

Histopathologic examination of lesional tissue typically shows a mixture of acute inflammation and granulomatous inflammation surrounding variable numbers of yeasts. These organisms are 8–20 μm in diameter. They are characterized by a doubly refractile cell wall (Fig. 6.27) and a broad attachment between the budding daughter cell and the parent cell. Like many other fungal organisms, *B. dermatitidis* can be detected more easily using special stains, such as the Grocott-Gomori methenamine silver and PAS methods. Identification of these organisms is especially important,

• **Fig. 6.27 Blastomycosis.** This high-power photomicrograph shows the large yeasts of *Blastomyces dermatitidis (arrow)* within a multinucleated giant cell.

because this infection often induces a benign reaction of the overlying epithelium in mucosal or skin lesions called **pseudoepitheliomatous (pseudocarcinomatous) hyperplasia.** Because this benign elongation of the epithelial rete ridges may look like squamous cell carcinoma at first glance under the microscope, careful inspection of the underlying inflamed lesional tissue is mandatory.

Diagnosis

Rapid diagnosis of blastomycosis can be performed by microscopic examination of either histopathologic sections or an alcohol-fixed cytologic preparation. The most rapid means of diagnosis, however, is the KOH preparation, which may be used for examining scrapings from a suspected lesion. The most accurate method of identifying *B. dermatitidis* is by obtaining a culture specimen from sputum or fresh biopsy material and growing the organism on Sabouraud agar. This can be a slow technique, however, sometimes taking as long as 3–4 weeks for the characteristic yeast-to-mycelium conversion to take place. A specific DNA probe has been developed, allowing immediate identification of the mycelial phase. Serologic studies and skin testing are usually not helpful because of lack of reactivity and specificity.

Treatment and Prognosis

As stated previously, most patients with blastomycosis are asymptomatic or have only mild symptoms, so treatment may not be given because the disease is often not suspected. In the case of documented symptomatic acute or chronic pulmonary blastomycosis, itraconazole should be prescribed for mild to moderate disease, whereas systemic administration of a lipid formulation of amphotericin B is indicated for severe cases.

Immunosuppressed patients or those with extrapulmonary lesions also need treatment with amphotericin B, followed by

dentlearn.ir

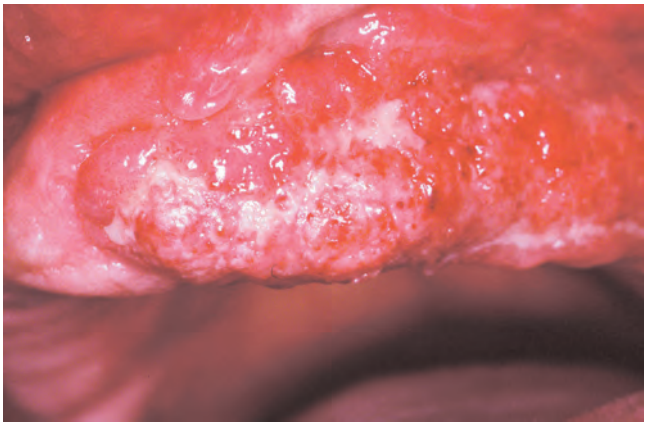
6–12 months of itraconazole. Although ketoconazole and fluconazole are active against *B. dermatitidis,* these drugs have been shown to be less effective than itraconazole.

Disseminated blastomycosis occurs in only a small percentage of infected patients and, with proper treatment, the outlook for the patient is reasonably good. Still, mortality rates ranging from 4% to 22% have been described over the past 20 years, with men, blacks, and patients with HIV infection tending to have less favorable outcomes.

◆ PARACOCCIDIOIDOMYCOSIS (SOUTH AMERICAN BLASTOMYCOSIS)

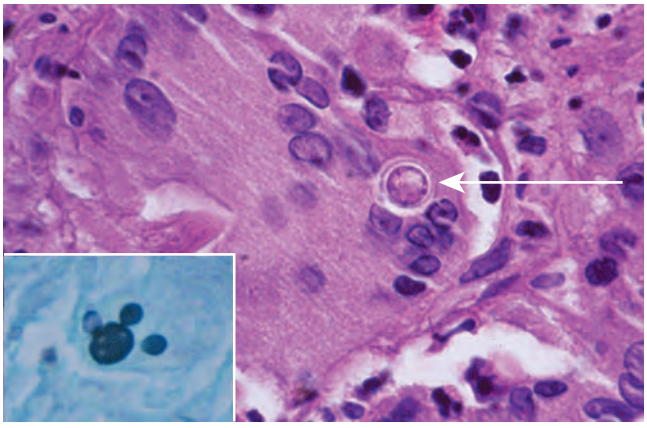
Paracoccidioidomycosis is a deep fungal infection that is caused by either *Paracoccidioides brasiliensis* or *Paracoccidioides lutzii*. The condition is seen most frequently in patients who live in either South America (primarily Brazil, Colombia, Venezuela, Uruguay, and Argentina) or Central America. However, immigrants from those regions and visitors to those areas can acquire the infection. Within some endemic areas, the nine-banded armadillo has been shown to harbor *P. brasiliensis* (similar to the situation seen with leprosy) (see page 188). Although there is no evidence that the armadillo directly infects humans, it may be responsible for the spread of the organism in the environment.

Paracoccidioidomycosis has a distinct predilection for males, with a 13:1 male-to-female ratio typically reported. This striking difference is thought to be attributable to a protective effect of female hormones (because β-estradiol inhibits the transformation of the hyphal form of the organism to the pathogenic yeast form). This theory is supported by the finding of an equal number of men and women who have antibodies directed against the yeast.



Clinical Features

Patients with paracoccidioidomycosis are typically middle-aged at the time of diagnosis, and most are employed in agriculture. Most cases of paracoccidioidomycosis are thought to appear initially as pulmonary infections after exposure to the spores of the organism. Although infections are generally self-limiting, *P. brasiliensis* and *P. lutzii* may spread by a hematogenous or lymphatic route to a variety of tissues, including lymph nodes, skin, and adrenal glands. Adrenal involvement often results in hypoadrenocorticism **(Addison disease)** (see page 843).



Oral lesions are frequently observed and appear as mulberry-like ulcerations that most commonly affect the alveolar mucosa, gingiva, and palate (Fig. 6.28). The lips, tongue, oropharynx, and buccal mucosa are also involved in a significant percentage of cases. In most patients with oral lesions, more than one oral mucosal site is affected.

Histopathologic Features

Microscopic evaluation of tissue obtained from an oral lesion may reveal pseudoepitheliomatous hyperplasia in addition to ulceration of the overlying surface epithelium. These

• **Fig. 6.28 Paracoccidioidomycosis.** This granular, erythematous, and ulcerated lesion of the maxillary alveolus represents infection by *Paracoccidioides brasiliensis.* (Courtesy of Dr. Ricardo Santiago Gomez.)

• **Fig. 6.29 Paracoccidioidomycosis.** This high-power photomicrograph shows a large yeast of *Paracoccidioides brasiliensis (arrow)* within the cytoplasm of a multinucleated giant cell. A section stained with the Grocott-Gomori methenamine silver method *(inset)* illustrates the characteristic "Mickey Mouse ears" appearance of the budding yeasts. (Courtesy of Dr. Ricardo Santiago Gomez.)

organisms elicit a granulomatous inflammatory host response that is characterized by collections of epithelioid macrophages and multinucleated giant cells (Fig. 6.29). Scattered, large (up to 30 μm in diameter) yeasts are readily identified after staining of the tissue sections with the Grocott-Gomori methenamine silver or PAS method. The organisms often show multiple daughter buds on the parent cell, resulting in an appearance that has been described as resembling "Mickey Mouse ears" or the spokes of a ship's steering wheel ("mariner's wheel").

Diagnosis

Demonstration of the characteristic multiple budding yeasts in the appropriate clinical setting is usually adequate to establish a diagnosis of paracoccidioidomycosis. Specimens for culture can be obtained, but *P. brasiliensis* and *P. lutzii* grow quite slowly.

dentlearn.ir

Treatment and Prognosis

The method of management of patients with paracoccidioidomycosis depends on the severity of the disease presentation. Sulfonamide derivatives have been used since the 1940s to treat this infection. These drugs, such as trimethoprim/sulfamethoxazole, are still used today in many instances to treat mild-to-moderate cases, particularly in developing countries with limited access to the newer, more expensive antifungal agents. For severe involvement, IV amphotericin B is usually indicated, and this is followed by oral itraconazole. Non–life-threatening cases are best managed by oral itraconazole alone, although therapy may be needed for several months. Ketoconazole can also be used, although the side effects are typically greater than those associated with itraconazole.

◆ COCCIDIOIDOMYCOSIS (SAN JOAQUIN VALLEY FEVER; VALLEY FEVER; COCCI)

Molecular genetic studies have identified two species, *Coccidioides immitis* and *Coccidioides posadasii,* as the fungal organisms responsible for **coccidioidomycosis.** *C. immitis* grows saprophytically in the alkaline, semiarid, desert soil of the southwestern United States and Mexico primarily, whereas *C. posadasii* is generally found in similar isolated arid regions in Central and South America, with some overlap in their ranges. As with several other pathogenic fungi, *C. immitis* and *C. posadasii* are dimorphic organisms, appearing as a mold in the natural environment of the soil and as a yeast in tissues of the infected host. Arthrospores produced by the mold become airborne and can be inhaled into the lungs of the human host, producing infection. Both *Coccidioides* species produce clinically identical signs and symptoms.

Coccidioidomycosis is confined to the Western hemisphere and is endemic throughout the desert regions of southwestern United States and Mexico; however, with modern travel taking many visitors to and from the Sunbelt, this disease can be encountered virtually anywhere in the world. It is estimated that 100,000 people are infected annually in the United States, although 60% of this group are asymptomatic.

Clinical Features

Even though most infections with *C. immitis* are asymptomatic, approximately 40% of infected patients experience a flu-like illness and pulmonary symptoms within 1–3 weeks after inhaling the arthrospores. Fatigue, cough, chest pain, myalgias, and headache are commonly reported, lasting several weeks with spontaneous resolution in most cases. Occasionally, the immune response may trigger a hypersensitivity reaction that causes the development of an erythema multiforme–like cutaneous eruption (see page 781) or erythema nodosum. Erythema nodosum is a condition that usually affects the skin of the legs and is characterized by the appearance of multiple painful erythematous inflammatory nodules in the subcutaneous connective tissue. This hypersensitivity reaction occurring in conjunction with coccidioidomycosis is termed **valley fever**, and it resolves as the host cell–mediated immune response controls the pulmonary infection.

Chronic progressive pulmonary coccidioidomycosis is relatively rare. It mimics tuberculosis, with its clinical presentation of persistent cough, hemoptysis, chest pain, low-grade fever, and weight loss.

Disseminated coccidioidomycosis occurs when the organism spreads hematogenously to extrapulmonary sites. This occurs in less than 1% of cases, but it is a more serious problem. The most commonly involved areas include skin, lymph nodes (including cervical lymph nodes), bone and joints, and the meninges. Immunosuppression greatly increases the risk of dissemination. The following groups are particularly susceptible:

- Patients taking large doses of systemic corticosteroids (e.g., organ transplant recipients)
- Patients who are being treated with cancer chemotherapy
- Patients who are being treated with TNF-α inhibitors
- Patients in the end stages of HIV infection
- Patients who are pregnant (especially in the third trimester or immediately postpartum)

Infants and older adult patients, both of whom may have suboptimally functioning immune systems, also may be at increased risk for disseminated disease. Persons of color (e.g., blacks, Filipinos, and Native Americans) also seem to have an increased risk, but it is unclear whether their susceptibility is due to genetic causes or socioeconomic factors, such as occupation or poor nutrition.

The cutaneous lesions may appear as papules, subcutaneous abscesses, verrucous plaques, and granulomatous nodules. Of prime significance to the clinician is the predilection for these lesions to develop in the area of the central face, especially the nasolabial fold. Oral lesions are distinctly uncommon, and these have been described as ulcerated granulomatous nodules (Fig. 6.30).

• **Fig. 6.30 Coccidioidomycosis.** This ulcerated nodule involving the mid-dorsal tongue represents disseminated coccidioidomycosis. (Courtesy of Dr. Craig Fowler.)

dentlearn.ir

Histopathologic Features

Biopsy material shows large (20–60 μm), round spherules that may contain numerous endospores. The host response may be variable, ranging from a suppurative, neutrophilic infiltrate to a granulomatous inflammatory response. In some cases, the two patterns of inflammation are seen concurrently. Special stains, such as the PAS and Grocott-Gomori methenamine silver methods, enable the pathologist to identify the organism more readily.

Diagnosis

The diagnosis of coccidioidomycosis can be confirmed by culture or identification of characteristic organisms in biopsy material. If the organisms do not have a classic microscopic appearance, then *in situ* hybridization studies using specific complementary DNA probes for *C. immitis* can be performed to definitively identify the fungus. Cytologic preparations from bronchial swabbing or sputum samples may also reveal the organisms.

Serologic studies are helpful in supporting the diagnosis, and they may be performed at the same time as skin testing. Skin testing by itself may be of limited value in determining the diagnosis, because many patients in endemic areas have already been exposed to the organism and have positive test findings.

Treatment

The decision whether or not to treat a particular patient affected by coccidioidomycosis depends on the severity and extent of the infection and the patient's immune status. Relatively mild symptoms in an immunocompetent person do not warrant treatment. Amphotericin B is administered for the following groups:

- Immunosuppressed patients
- Patients with severe pulmonary infection
- Patients who have disseminated disease
- Patients who are pregnant
- Patients who appear to be in a life-threatening situation concerning the infection

For many cases of coccidioidomycosis, fluconazole or itraconazole is the drug of choice, usually given in high doses for an extended period of time. Although the response of the disease to these oral azole medications may be somewhat slower than that of amphotericin B, the side effects and complications of therapy are far fewer. Newer triazole medications, such as voriconazole, can be used if resolution is not seen with fluconazole or itraconazole.

◆ CRYPTOCOCCOSIS

Cryptococcosis is a relatively uncommon fungal disease caused primarily by the yeast *Cryptococcus neoformans* in North America. This organism normally causes no problem in immunocompetent people, but it can be devastating to the immunocompromised patient. The incidence of cryptococcosis increased dramatically during the 1990s, primarily because of the AIDS epidemic. At that time, this was the most common life-threatening fungal infection in these patients. However, with the advent of combination antiretroviral therapy (cART) (see page 264), this complication has become less of a problem in the United States. In countries where the population cannot afford cART, cryptococcosis remains a significant cause of death for AIDS patients. The disease has a worldwide distribution because of its association with the pigeon (with the organism living in the deposits of excreta left by the birds). Unlike many other pathogenic fungi, *C. neoformans* grows as a yeast both in the soil and in infected tissue. The organism usually produces a prominent mucopolysaccharide capsule that appears to protect it from host immune defenses.

The disease is acquired by inhalation of *C. neoformans* spores into the lungs, resulting in an immediate influx of neutrophils, which destroys most of the yeasts. Macrophages soon follow, although resolution of infection in the immunocompetent host ultimately depends on an intact cell-mediated immune system.

Over the past couple of decades, molecular genetic studies have identified another species of *Cryptococcus,* designated *Cryptococcus gattii,* which had initially been thought to be a serotype of *C. neoformans.* This organism seems to be more capable of producing infection in otherwise normal immunocompetent individuals. Although *C. gattii* is more commonly found in tropical and subtropical environments, outbreaks have been documented in the Pacific Northwest in North America. At the molecular level, microbiologists now recognize at least six different genotypes of these yeasts in what may be described as the *C. neoformans/gattii* species complex.

Clinical Features

Primary cryptococcal infection of the lungs is often asymptomatic; however, a mild flulike illness may develop. Patients complain of productive cough, chest pain, fever, and malaise. Most patients with a diagnosis of cryptococcosis have a significant underlying medical problem related to immune suppression (e.g., systemic corticosteroid therapy, cancer chemotherapy, malignancy, or AIDS). It is estimated that 5%–10% of AIDS patients acquire this infection (see page 250).

Dissemination of the infection is common in these immunocompromised patients, and the most frequent site of involvement is the meninges, followed by skin, bone, and the prostate gland.

Cryptococcal meningitis is characterized by headache, fever, vomiting, and neck stiffness. In many instances, this is the initial sign of the disease.

Cutaneous lesions develop in 10%–15% of patients with disseminated disease. These are of particular importance to the clinician, because the skin of the head and neck is often

dentlearn.ir

• **Fig. 6.31 Cryptococcosis.** These papules of the facial skin represent disseminated cryptococcal infection in a patient infected with human immunodeficiency virus (HIV). (Courtesy of Dr. Catherine Flaitz.)

involved. The lesions appear as erythematous papules or pustules that may ulcerate, discharging a puslike material rich in cryptococcal organisms (Fig. 6.31).

Although oral lesions are relatively rare, they have been described either as craterlike, nonhealing ulcers that are tender on palpation or as friable papillary erythematous plaques. Dissemination to salivary gland tissue also has been reported rarely.

Histopathologic Features

Microscopic sections of a cryptococcal lesion generally show a granulomatous inflammatory response to the organism. The extent of the response may vary, however, depending on the host's immune status and the strain of the organism. The yeast appears as a round-to-ovoid structure, 4–6 μm in diameter, surrounded by a clear halo that represents the capsule. Staining with the PAS or Grocott-Gomori methenamine silver method readily identifies the fungus; moreover, a mucicarmine stain uniquely demonstrates its mucopolysaccharide capsule.

Diagnosis

The diagnosis of cryptococcosis can be made by several methods, including biopsy and culture. Detection of cryptococcal polysaccharide antigen in the serum or cerebrospinal fluid is also useful as a diagnostic procedure.

Treatment and Prognosis

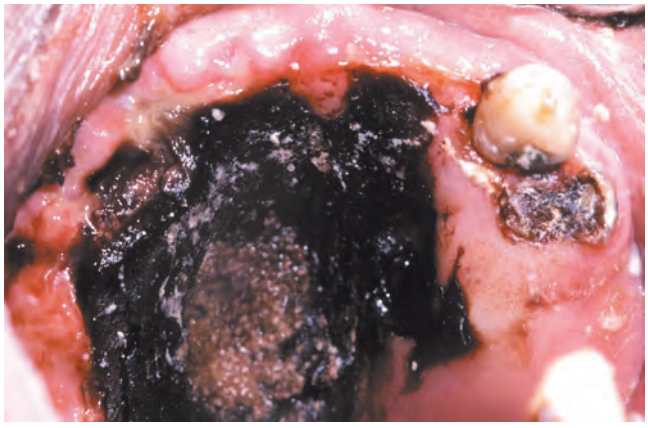
Management of cryptococcal infections can be very difficult because most of the affected patients have an underlying medical problem. Before amphotericin B was developed, cryptococcosis was almost uniformly fatal. For cryptococcal meningitis, a combination of systemic amphotericin B and another antifungal drug (flucytosine) is used initially for 2 weeks in most cases to treat this disease. Then, either fluconazole or itraconazole is given for an additional minimal period of 10 weeks. For relatively mild cases of pulmonary cryptococcosis, only fluconazole or itraconazole may be used. These drugs produce far fewer side effects than do amphotericin B and flucytosine, and they have proven to be important therapeutic tools for managing this type of infection.

◆ MUCORMYCOSIS (ZYGOMYCOSIS; PHYCOMYCOSIS)

Mucormycosis is an opportunistic, frequently fulminant, fungal infection that is caused by normally saprobic organisms of the subphylum Mucoromycotina, including such genera as *Absidia, Mucor, Rhizomucor*, and *Rhizopus.* The term *zygomycosis* is still used extensively in the literature, although recent molecular genetic studies have indicated that the class Zygomycetes actually is comprised of several unrelated fungi. Mucoromycotina organisms are found throughout the world, growing in their natural state on a variety of decaying organic materials. Numerous spores may be liberated into the air and inhaled by the human host.

Mucormycosis may involve any one of several areas of the body, but the rhinocerebral form is most relevant to the oral health care provider. Mucormycosis is noted especially in insulin-dependent diabetics who have uncontrolled diabetes and are ketoacidotic; ketoacidosis inhibits the binding of iron to transferrin, allowing serum iron levels to rise. The growth of these fungi is enhanced by iron, and patients who are taking deferoxamine (an iron-chelating agent used in the treatment of diseases, such as thalassemia) are also at increased risk for developing mucormycosis. As with many other fungal diseases, this infection affects immunocompromised patients as well, including bone marrow transplant recipients, patients with AIDS, and those receiving systemic corticosteroid therapy. Only rarely has mucormycosis been reported in apparently healthy individuals in the oral region.

Clinical and Radiographic Features

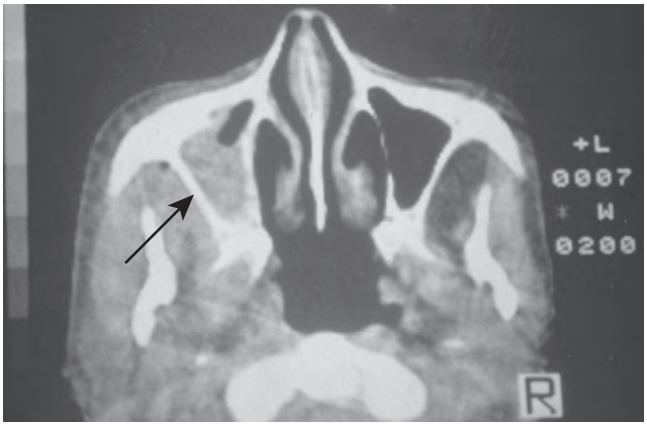


The presenting symptoms of rhinocerebral mucormycosis may be exhibited in several ways. Patients may experience nasal obstruction, bloody nasal discharge, facial pain or headache, facial swelling or cellulitis, and visual disturbances with concurrent proptosis. Symptoms related to cranial nerve involvement (e.g., facial paralysis) are often present. With progression of disease into the cranial vault, blindness, lethargy, and seizures may develop, followed by death.

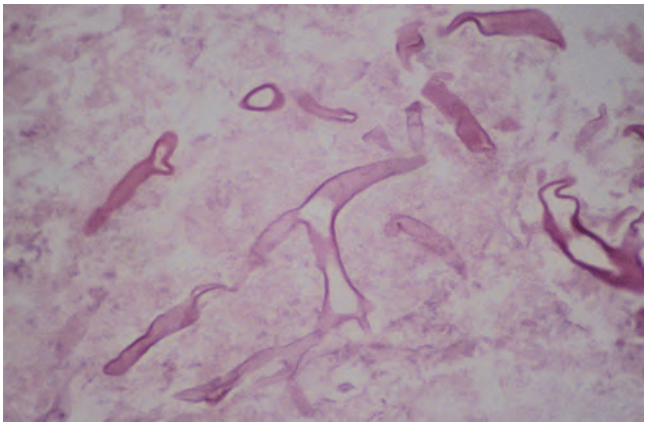
If the maxillary sinus is involved, the initial presentation may be seen as intraoral swelling of the maxillary alveolar process, the palate, or both. If the condition remains untreated, palatal ulceration may evolve, with the surface of the ulcer typically appearing black and necrotic. Massive tissue destruction may result if the condition is not treated (Figs. 6.32 and 6.33).

dentlearn.ir

• **Fig. 6.32 Mucormycosis.** Diffuse tissue destruction involving the nasal and maxillary structures caused by a *Mucor* species. (Courtesy of Dr. Sadru Kabani.)



• **Fig. 6.33 Mucormycosis.** The extensive black, necrotic lesion of the palate represents mucormycotic infection that extended from the maxillary sinus in a patient with poorly controlled type I diabetes mellitus. (Courtesy of Dr. Michael Tabor.)



Radiographically, opacification of the sinuses may be observed in conjunction with patchy effacement of the bony walls of the sinuses (Fig. 6.34). Such a picture may be difficult to distinguish from that of a malignancy affecting the sinus area.

Histopathologic Features

Histopathologic examination of lesional tissue shows extensive necrosis with numerous large (6–30 μm in diameter), branching, nonseptate hyphae at the periphery (Fig. 6.35). The hyphae tend to branch at 90-degree angles. The extensive tissue destruction and necrosis associated with this disease are undoubtedly attributable to the preference of the fungi for invasion of small blood vessels. This disrupts normal blood flow to the tissue, resulting in infarction and necrosis. A neutrophilic infiltrate usually predominates in the viable tissue, but the host inflammatory cell response to the infection may be minimal, particularly if the patient is immunosuppressed.

• **Fig. 6.34 Mucormycosis.** This computed tomography (CT) scan demonstrates the opacification of the left maxillary sinus *(arrow).*

• **Fig. 6.35 Mucormycosis.** This high-power photomicrograph shows the large, nonseptate fungal hyphae characteristic of the mucormycotic organisms.

Diagnosis

Diagnosis of mucormycosis is usually based on the histopathologic findings. Because of the grave nature of this infection, appropriate therapy must be instituted in a timely manner (often without the benefit of definitive culture results).

Treatment and Prognosis

Successful treatment of rhinocerebral mucormycosis consists of rapid accurate diagnosis of the condition, followed by radical surgical débridement of the infected, necrotic tissue and systemic administration of high doses of one of the lipid formulations of amphotericin B. Posaconazole or isavuconazole can be added for long-term treatment after initial control with amphotericin B. Recent studies have suggested that isavuconazole alone, given as initial therapy, may be as effective as amphotericin B for treatment of mucormycosis. Magnetic resonance imaging (MRI) of the head may be useful in determining the extent of disease involvement so that surgical margins can be planned. Evaluation of frozen sections of curetted tissue, which has been stained with Calcofluor white and examined with

dentlearn.ir

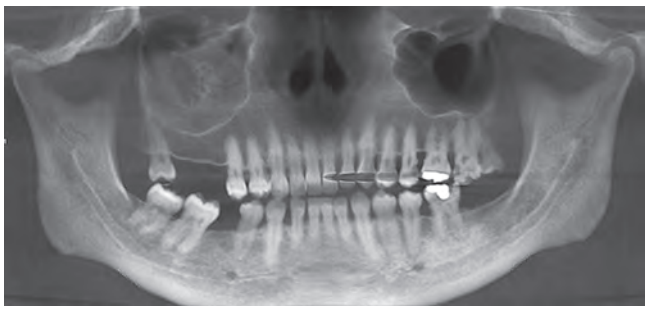
fluorescence microscopy, can also be used to guide the extent of débridement. In addition, control of the patient's underlying disease (e.g., diabetic ketoacidosis) must be attempted.

Despite such therapy, the prognosis is usually poor, with approximately 40%–50% of patients who develop rhinocerebral mucormycosis dying of their disease. Because their underlying systemic disease can usually be controlled, diabetic patients typically have a better prognosis than those who are immunosuppressed. If the patient survives, the massive tissue destruction that remains presents a challenge both functionally and aesthetically. Prosthetic obturation of palatal defects may be necessary.

◆ ASPERGILLOSIS

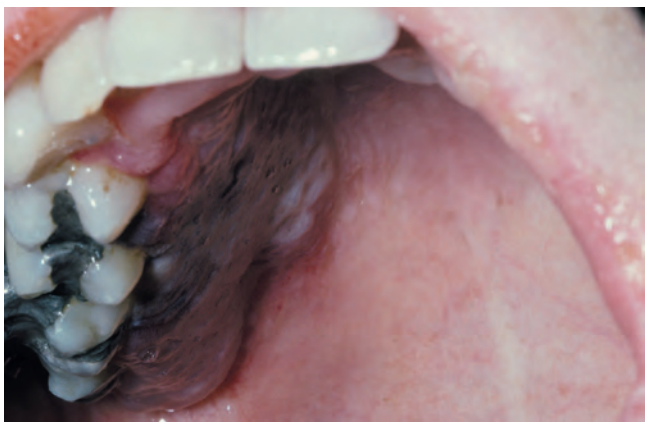
Aspergillosis is a fungal disease that is characterized by noninvasive and invasive forms. Noninvasive aspergillosis usually affects a normal host, appearing either as an allergic reaction or a cluster of fungal hyphae. Localized invasive infection of damaged tissue may be seen in a normal host, but a more extensive invasive infection is often evident in the immunocompromised patient. With the advent of intensive chemotherapeutic regimens, the AIDS epidemic, and both solid-organ and bone marrow transplantation, the prevalence of invasive aspergillosis has increased dramatically in the past 20 years. Patients with uncontrolled diabetes mellitus are also susceptible to *Aspergillus* spp. infections. Rarely, invasive aspergillosis has been reported to affect the paranasal sinuses of apparently normal immunocompetent individuals.

Normally, the various species of the *Aspergillus* genus reside worldwide as saprobic organisms in soil, water, or decaying organic debris. Resistant spores are released into the air and inhaled by the human host, resulting in opportunistic fungal infection second in frequency only to candidiasis. Interestingly, most species of *Aspergillus* cannot grow at 37°C; only the pathogenic species have the ability to replicate at body temperature.



The two most commonly encountered species of *Aspergillus* in the medical setting are *A. flavus* and *A. fumigatus,* with *A. fumigatus* being responsible for most cases of aspergillosis. The patient may acquire such infections in the hospital (**"nosocomial"** infection), especially if remodeling or building construction is being performed in the immediate area. Such activity often stirs up the spores, which are then inhaled by the patient.

Clinical Features



The clinical manifestations of aspergillosis vary, depending on the host immune status and the presence or absence of tissue damage. In the normal host, the disease may appear as an allergy affecting either the sinuses **(allergic fungal sinusitis)** or the bronchopulmonary tract. An asthma attack may be triggered by inhalation of spores by a susceptible person. Sometimes a low-grade infection becomes established in the maxillary sinus, resulting in a mass of fungal hyphae called a **fungus ball,** although **aspergilloma** and **mycetoma** are terms that are also sometimes used (Fig. 6.36). Occasionally, the mass will undergo dystrophic calcification, producing a radiopaque body called an **antrolith** within the sinus.

Another presentation that may be encountered by the oral health care provider is aspergillosis after tooth extraction or endodontic treatment, especially in the maxillary posterior segments. Presumably, tissue damage predisposes the sinus to infection, resulting in symptoms of localized pain and tenderness accompanied by nasal discharge. Immunocompromised patients are particularly susceptible to oral aspergillosis, and some investigators have suggested that the portal of entry may be the marginal gingiva and gingival sulcus. Painful gingival ulcerations are initially noted, and peripherally the mucosa and soft tissue develops diffuse swelling with a gray or violaceous hue (Fig. 6.37). If the disease is not treated, extensive necrosis, which is seen clinically as a yellow or black ulcer, and facial swelling evolve.

Disseminated aspergillosis occurs principally in immunocompromised patients, particularly in those who have leukemia or who are taking high daily doses of corticosteroids. Such patients usually exhibit symptoms related to the primary site of inoculation: the lungs. The patient typically has chest pain, cough, and fever, but such symptoms are vague. Therefore, obtaining an early, accurate diagnosis may be difficult. Once the fungal organism obtains access

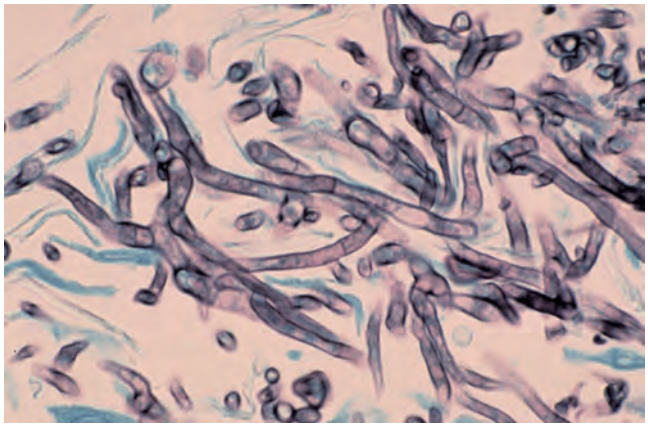
dentlearn.ir

to the bloodstream, infection can spread to such sites as the CNS, eye, skin, liver, gastrointestinal tract, bone, and thyroid gland.



Histopathologic Features

Tissue sections of invasive *Aspergillus* spp. lesions show varying numbers of branching, septate hyphae, 3–4 μm in diameter (Figs. 6.38 and 6.39). These hyphae show a tendency to branch at an acute angle and to invade adjacent small blood vessels. Occlusion of the vessels often results in the characteristic pattern of necrosis associated with this disease. In the immunocompetent host, a granulomatous inflammatory response—in addition to necrosis—can be expected. In the immunocompromised patient, however, the inflammatory response is often weak or absent, leading to extensive tissue destruction.

Noninvasive forms of aspergillosis have histopathologic features that differ from invasive aspergillosis, however. The fungus ball, for example, is characterized by a tangled mass of hyphae with no evidence of tissue invasion. Because the fungus ball develops in a paranasal sinus (where it is exposed to air), spore-bearing structures called *fruiting bodies* are formed (see Fig. 6.38). Allergic fungal sinusitis, on the other hand, histopathologically exhibits large pools of eosinophilic inspissated mucin with interspersed sheetlike collections of lymphocytes and eosinophils. Relatively few fungal hyphae are identified, and then only with careful examination after Grocott-Gomori methenamine silver staining.

• **Fig. 6.38 Aspergillosis.** This photomicrograph reveals fungal hyphae and a fruiting body of an *Aspergillus* species.

• **Fig. 6.39 Aspergillosis.** This high-power photomicrograph shows the characteristic septate hyphae of *Aspergillus* species. (Grocott-Gomori methenamine silver stain.)

Diagnosis

Although the diagnosis of fungal infection can be established by identification of hyphae within tissue sections, this finding is only suggestive of aspergillosis because other fungal organisms may appear similar microscopically. Ideally, the diagnosis should be supported by culture of the organism from the lesion; however, from a practical standpoint, treatment may need to be initiated immediately to prevent the patient's demise. Culture specimens of sputum and blood are of limited value, because they are often negative despite disseminated disease.

Treatment and Prognosis

Treatment depends on the clinical presentation of aspergillosis. For immunocompetent patients with a noninvasive aspergilloma, surgical débridement may be all that is necessary. Patients who have allergic fungal sinusitis are treated with débridement and corticosteroid drugs. For localized invasive aspergillosis in the immunocompetent host, débridement followed by antifungal medication is indicated. Although systemic amphotericin B deoxycholate therapy was considered appropriate in the past, studies have shown that voriconazole, a triazole antifungal agent, is more effective for treating these patients. In one large series of patients with invasive aspergillosis, 71% of those treated with voriconazole were alive after 12 weeks of therapy, compared with 58% survival in the group who received standard amphotericin B treatment. For patients who cannot tolerate voriconazole, alternative drugs include isavuconazole, liposomal amphotericin B, or one of the echinocandins, such as caspofungin or micafungin. Immunocompromised patients who have invasive aspergillosis should be treated by aggressive débridement of necrotic tissue, combined with systemic antifungal therapy as described previously.

The prognosis for immunocompromised patients is much worse compared with immunocompetent individuals, particularly if the infection is disseminated. Even with appropriate therapy, only about one third of these patients survive. Because aspergillosis in the immunocompromised patient usually develops while the individual is hospitalized, particular attention should be given to the ventilation system in the hospital to prevent patient exposure to the airborne spores of *Aspergillus* spp.

◆ TOXOPLASMOSIS

Toxoplasmosis is a relatively common disease caused by the obligate intracellular protozoal organism *Toxoplasma gondii.* For normal, healthy adults, the organism poses no problems,

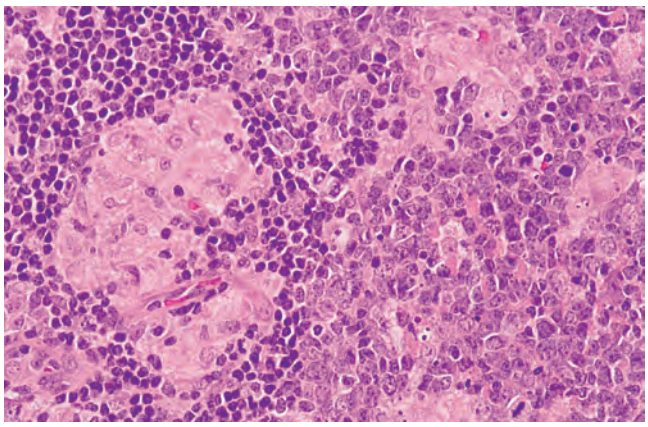
dentlearn.ir

and an estimated 8%–22% of adults in the United States may have had asymptomatic infection, based on an epidemiologic study that examined serologic samples from more than 4000 randomized individuals. However, the prevalence of infection has considerable geographic variation around the world. Unfortunately, the disease can be devastating for the developing fetus or the immunocompromised patient. Other mammals, particularly members of the cat family, are vulnerable to infection, and cats are considered to be the definitive host. *T. gondii* multiplies in the intestinal tract of the cat by means of a sexual life cycle, discharging numerous oocysts in the cat feces. Another animal or human can ingest these oocysts, resulting in the production of disease.

Clinical Features

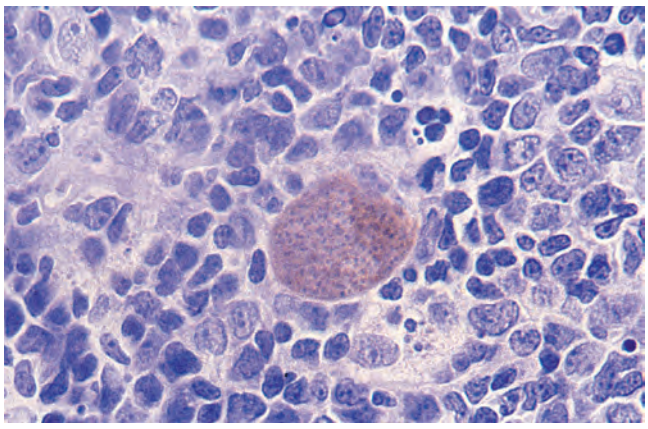
In the normal, immunocompetent individual, infection with *T. gondii* is often asymptomatic. If symptoms develop, they are usually mild and resemble infectious mononucleosis; patients may have a low-grade fever, cervical lymphadenopathy, fatigue, and muscle or joint pain. These symptoms may last from a few weeks to a few months, although the host typically recovers without therapy. Sometimes the lymphadenopathy involves one or more of the lymph nodes in the paraoral region, such as the buccal or submental lymph node. In such instances, the oral health care provider may discover the disease.

In immunosuppressed patients, toxoplasmosis may represent a new, primary infection or, more frequently, reactivation of previously encysted organisms. The principal groups at risk include the following:



- AIDS patients
- Transplant recipients
- Cancer patients

Manifestations of infection can include necrotizing encephalitis, pneumonia, and myositis or myocarditis. In the United States, it is estimated that from 3% to 10% of AIDS patients who are not being treated with combination antiretroviral therapy (cART) (see page 264) will experience CNS involvement. CNS infection is very serious. Clinically, the patient may complain of headache, lethargy, disorientation, and hemiparesis.



Congenital toxoplasmosis occurs when a non-immune mother contracts the disease during her pregnancy and the organism crosses the placental barrier, infecting the developing fetus. The potential effects of blindness, intellectual impairment, and delayed psychomotor development are most severe if the infection occurs during the first trimester of pregnancy.

Histopathologic Features

Histopathologic examination of a lymph node obtained from a patient with active toxoplasmosis shows characteristic reactive germinal centers exhibiting an accumulation of eosinophilic macrophages. The macrophages encroach on the germinal centers and accumulate within the subcapsular and sinusoidal regions of the node (Fig. 6.40).

• **Fig. 6.40 Toxoplasmosis.** This high-power photomicrograph shows an accumulation of eosinophilic macrophages within a lymph node. (Courtesy of Dr. John Kalmar.)

• **Fig. 6.41 Toxoplasmosis.** In this high-power photomicrograph, an encysted organism of toxoplasmosis is highlighted by an immunohistochemical study. (Courtesy of Dr. John Kalmar.)

Diagnosis

The diagnosis of toxoplasmosis is usually established by identification of rising serum antibody titers to *T. gondii* within 10–14 days after infection. Immunocompromised patients, however, may not be able to generate an antibody response; therefore, the diagnosis may rest on the clinical findings and the response of the patient to therapy.

Biopsy of an involved lymph node may suggest the diagnosis, and the causative organisms can sometimes be detected immunohistochemically using antibodies directed against *T. gondii*–specific antigens (Fig. 6.41). The diagnosis should also be confirmed by serologic studies, if possible.

Treatment and Prognosis

Most healthy adults with toxoplasmosis require no specific treatment because of the mild symptoms and self-limiting course. Perhaps more importantly, pregnant women should avoid situations that place them at risk for the disease. Handling or eating raw meat, eating raw, unpeeled fruits or vegetables, or cleaning a cat litter box should be avoided until

dentlearn.ir

after delivery. If exposure during pregnancy is suspected, treatment with a combination of sulfadiazine and pyrimethamine often prevents transmission of *T. gondii* to the fetus, although pyrimethamine is contraindicated in the first trimester due to its potential teratogenicity. Because these drugs act by inhibiting folate metabolism of the protozoan, folinic acid is given concurrently to help prevent hematologic complications in the patient. A similar drug regimen is used to treat immunosuppressed individuals with toxoplasmosis, although clindamycin may be substituted for sulfadiazine in managing patients who are allergic to sulfa drugs. Because most cases of toxoplasmosis in AIDS patients represent reactivation of encysted organisms, prophylactic administration of trimethoprim and sulfamethoxazole is generally recommended, particularly if the patient's CD4+ T-lymphocyte count is less than 100 cells/μL.

◆ LEISHMANIASIS

Leishmaniasis is a protozoal infection that is transmitted to humans by the bite of certain species of sandfly. Both Old World and New World forms of the disease are recognized, and they are caused by different species of sandfly as well as different species of *Leishmania*. Although the disease has been reported on every continent except Australia and Antarctica, most of the cases are found in relatively few countries, particularly India (Bihar State), Afghanistan, Saudi Arabia, Syria, Algeria, Peru, and Brazil. Of course, because of international travel to these areas, leishmaniasis can be seen in virtually every corner of the earth.

Dogs and other mammals are the primary reservoir for leishmaniasis, and in the mammalian host the organism is an obligate intracellular parasite. When an infected animal is bitten by the female sandfly, macrophages containing the amastigote (lacking flagella) phase of the organism are ingested by the fly as it drinks the animal's blood. In the gut of the sandfly, the amastigote organisms develop into free-living promastigotes (having flagella). When the fly later bites a human (or another mammal), the promastigote organisms are injected into the subcutaneous tissues, where they are phagocytosed by macrophages, neutrophils, or dendritic cells. Once ingested, the promastigote transforms into an amastigote, which multiplies within the host cells, completing the parasitic cycle. Sometimes the replication is so pronounced that the phagocytic host cells ruptures, releasing amastigotes into the bloodstream, and causing infection of more host cells.

Clinical Features

Depending on the *Leishmania* species and the immune status of the human host, at least three presentations of disease are generally recognized:

- Cutaneous—either Old World or New World; New World cases caused by *Leishmania mexicana* complex
- Mucocutaneous—primarily New World; caused by *Leishmania braziliensis* complex

• **Fig. 6.42 Leishmaniasis.** Ulceration and granulomatous enlargement of the palatal mucosa in a patient with mucocutaneous leishmaniasis. (Courtesy of Dr. Ricardo Santiago Gomez.)

- Visceral ("kala-azar")—either Old World or New World; caused primarily by *Leishmania donovani* in the Old World; *L. braziliensis* in the New World

Cutaneous leishmaniasis is by far the most common form of the disease. Individual lesions develop 3–6 weeks after the person is bitten, presenting as an elevated erythematous papule or nodule with a depressed, ulcerated center, often said to resemble a volcano. Such lesions persist for months but often eventually heal. Significant scarring is usually noted, however.

Mucocutaneous leishmaniasis is not as common as cutaneous leishmaniasis, but it is much more destructive. Most of the *Leishmania* species responsible for this form of the disease are found in South America. The skin of affected patients shows more diffuse involvement, characterized by scaly and ulcerative plaques and nodules. From several months to as long as 5 years later, mucosal involvement develops. Typically this begins with the nasal mucosa, but oral, pharyngeal, tracheal, and laryngeal mucosa often are involved eventually (Fig. 6.42). Perforation of the nasal septum or the hard and soft palate, as well as destruction of the alveolar bone, may be present. The extent of the damage may be so severe that it can be a life-threatening process.

Visceral leishmaniasis (also known as *kala-azar,* which is Hindi for "black fever") is characterized by grayish discoloration of the skin in some patients, hepatosplenomegaly, fever (usually related to pancytopenia), and weight loss. The severity of disease expression is undoubtedly related to the health of the patient prior to infection.

Histopathologic Features

The amastigote *Leishmania* organisms can be detected within the cytoplasm of histiocytes in touch preparations of infected tissue or in histopathologic sections. The protozoans may be seen in routine H&E-stained sections, but other stains such as Giemsa, Brown-Hopps (a tissue Gram stain), or Leishman

dentlearn.ir

methods may aid identification. In older, chronic lesions, the organisms may be sparse, making the diagnosis more challenging.

Diagnosis

Although the diagnosis of leishmaniasis often can be made on the cytologic or histopathologic findings, it is sometimes necessary to obtain tissue for culture or polymerase chain reaction (PCR) studies. These latter techniques are usually available only at specialized laboratories. Serologic studies can be difficult to interpret at times because many individuals in endemic areas have had exposure to the organism, although they may not have active disease.

Treatment and Prognosis

Since the 1920s, antimony compounds have been used to treat leishmaniasis, but these drugs often have significant side effects because they are heavy metals. Liposomal amphotericin B is ideally the drug of choice, but this less toxic compound is often too expensive for widespread use in developing countries. Most leishmaniasis patients receive treatment with pentavalent antimonial compounds, with the antiprotozoal drug pentamidine used for patients who cannot tolerate antimonial compounds. Attempts to develop a vaccine have not met with success.

The prognosis of leishmaniasis can be affected by both host factors (e.g., malnutrition and immune suppression) and organism factors, which are related to the *Leishmania* species responsible for infection. Without treatment, visceral leishmaniasis has an ominous prognosis and often results in death, whereas cutaneous leishmaniasis is typically a chronic, bothersome superficial infection. Mucocutaneous leishmaniasis has an intermediate course, although significant morbidity results from tissue destruction by the infection. All forms of leishmaniasis generally require weeks to months of therapy, and relapses are relatively common.

7 Viral Infections

HUMAN HERPESVIRUSES

The human herpesvirus (HHV) family **(Herpetoviridae)** constitutes a large family of double-stranded DNA viruses. The best-known member of this family is **herpes simplex virus (HSV),** which includes HSV type 1 (HSV-1 or HHV-1) and HSV type 2 (HSV-2 or HHV-2). Other members of the HHV family include **varicella-zoster virus** (VZV or HHV-3), **Epstein–Barr virus** (EBV or HHV-4), **cytomegalovirus** (CMV or HHV-5), and more recently discovered members, HHV-6, HHV-7, and HHV-8. Humans are the only natural reservoir for these viruses, which are endemic worldwide.

The term **herpes** derives from the ancient Greek word meaning to creep or crawl, which apparently alludes to a tendency for spreading, latent, or recurrent infection. All eight types cause a primary infection and remain latent within specific cell types for the life of the individual. On reactivation, these viruses cause recurrent infections that may be symptomatic or asymptomatic. The viruses are shed in saliva or other secretions, providing an avenue for infection of new hosts. Each type is known to transform cells in tissue culture, with several strongly associated with specific malignancies. The following sections concentrate on HSV, VZV, CMV, and EBV. Much less is known about herpesvirus types 6, 7, and 8.

Human herpesvirus 6 (HHV-6) and **7 (HHV-7)** are closely related, usually transmitted by saliva or respiratory droplets, and exhibit infection rates close to 90% by age 5 in the United States. Primary infection usually is asymptomatic but may cause an acute febrile illness followed by an erythematous maculopapular eruption. This pattern of symptomatic primary infection—termed **roseola (exanthema subitum, sixth disease)**—most often is caused by HHV-6 but also may be caused by HHV-7. Both viruses may replicate in salivary glands and establish latency in CD4+ T lymphocytes or other cell types. Reactivation occurs most frequently in immunocompromised patients and can result in widespread multiorgan infection, including encephalitis, pneumonitis, bone-marrow suppression, and hepatitis.

Human herpesvirus 8 (HHV-8) is involved in the pathogenesis of **Kaposi sarcoma (KS)** (see page 564) and has been termed **Kaposi sarcoma–associated herpesvirus (KSHV).** In immunocompetent persons, primary infection usually is asymptomatic, with male-to-male sexual contact being the most common mode of transmission in Western countries. The virus is found without difficulty in saliva, suggesting another possible pattern of transmission. Associated symptoms, such as transient fever, lymphadenopathy, and arthralgias, are rarely reported. Circulating B lymphocytes appear to be the major cell of latency. In addition to Kaposi sarcoma, HHV-8 is associated with certain types of lymphoma and a benign lymphoid proliferation known as *Castleman disease.*

HERPES SIMPLEX VIRUS

The two herpes simplex viruses are similar in structure and disease mechanisms but differ in antigenicity, anatomic site predilection, and epidemiology. Differences in envelope glycoproteins account for their distinct antigenicity. Nevertheless, there is potential for antibody cross-reactivity, and antibodies directed against one type may decrease the likelihood or severity of infection with the other type.

HSV-1 is spread predominantly through infected saliva or active perioral lesions and adapted best to the oral, facial, and ocular areas. The pharynx, intraoral mucosa, lips, eyes, and skin above the waist are involved most frequently. In addition, transmission via sexual contact is possible. Over the past few decades, there has been an increase in the proportion of genital herpes caused by HSV-1 in developed nations; indeed, recent studies have attributed as many as 60% of new genital herpes cases to HSV-1 in some cohorts. This trend may reflect an increase in oral-genital sexual behavior and lower rates of nonsexual HSV-1 acquisition in childhood.

HSV-2 is adapted best to the genital zones, is transmitted predominantly through sexual contact, and typically involves the genitalia and skin below the waist. Oral and pharyngeal infection with HSV-2 is also possible but infrequent.

The natural history of HSV infection includes primary infection, latency, and recurrent infection. **Primary infection** refers to initial exposure of an individual without antibodies to the virus. The virus can infect a susceptible host through disturbances in the epithelial barrier, which may be induced by physical injury, other infections, or overgrowth of commensal organisms. Primary infection with HSV-1 typically occurs at a young age, may be asymptomatic, and usually does not cause significant morbidity. For symptomatic cases, the usual incubation period is 3–9 days.

dentlearn.ir

After primary infection is established, the virus is taken up by sensory nerves and transported to the associated sensory or, less frequently, autonomic ganglia where the virus remains in a latent state. The most common site of latency for HSV-1 is the trigeminal ganglion, but other possible sites include the geniculate ganglion of the facial nerve, vestibular ganglion of the vestibulocochlear nerve, nodose ganglion of the vagus nerve, dorsal root ganglia, and brain. The virus uses the axons of the sensory neurons to travel back and forth to the skin or mucosa.

Recurrent (secondary) infection occurs with reactivation of the virus. Factors associated with reactivation include advanced age, ultraviolet light, physical or emotional stress, fatigue, heat, cold, pregnancy, allergy, trauma, dental treatment, respiratory illnesses, fever, menstruation, systemic diseases, and malignancy. Depending on the number of infected epithelial cells, secondary infection may manifest as asymptomatic viral shedding, prodromal symptoms without any detectable lesion (**false prodrome**), or clinically evident lesions (**recrudescence**) that may or may not be preceded by prodromal symptoms. Symptomatic recurrences are fairly common and affect the epithelium supplied by the sensory ganglion. However, reactivation with asymptomatic viral shedding greatly exceeds symptomatic cases. The reported frequency of asymptomatic viral shedding varies from 2 to 219 days per person per year, although this variation may reflect differences in study design and methods. Spread to an uninfected host can occur from symptomatic, active lesions or asymptomatic viral shedding. In addition, the virus may spread to other sites in the same host to establish residency at the sensory ganglion of the new location.

The estimated worldwide prevalence of HSV-1 infection is 67% among individuals younger than 50 years. Prevalence varies by region from approximately 45% in the Americas to 87% in Africa. Crowding and poor hygiene promote exposure to HSV-1. Furthermore, lower socioeconomic status correlates with earlier exposure. In Africa and Southeast Asia, most individuals are exposed via nonsexual oral transmission by 5 years of age, and virtually no new infections are seen in adulthood. In contrast, in the Americas, about half of new HSV-1 infections occur between the ages of 15 and 49 years, with approximately a fourth of these cases representing genital infection. The clinical presentation of symptomatic primary oral HSV-1 infection varies by age, with young individuals tending to exhibit gingivostomatitis and those exposed later in life often demonstrating pharyngotonsillitis.

HSV-2 infection represents one of the most common sexually transmitted infections worldwide. In the United States, HSV-2 seroprevalence among individuals between 14 and 49 years of age is approximately 12% and has been decreasing over the past few decades. Exposure increases linearly with age from 0.8% among adolescents 14–19 years to 21% among adults 40–49 years. Because many infected with HSV-2 refrain from sexual activity when active lesions are present, investigators believe that at least 70% of primary infections are contracted from individuals during asymptomatic viral shedding. Importantly, HSV-2 infection is associated with an increased risk for human immunodeficiency virus (HIV) infection (see page 250). It is uncertain whether this finding reflects sexual activity as a common risk factor for HIV and HSV-2 infection versus increased disease susceptibility due to biologic interactions between these viruses.

In addition to clinically evident infections, HSV has been implicated in several noninfectious processes. For example, more than 15% of cases of **erythema multiforme** are preceded by a symptomatic recurrence of HSV 3–10 days earlier (see page 781), and some investigators believe that up to 70% of mucosal erythema multiforme may be triggered by HSV. In some individuals, erythema multiforme outbreaks are frequent enough to warrant antiviral prophylaxis. In a small subset of patients, asymptomatic release of HSV coincides with attacks of aphthous stomatitis (see page 321). In these cases, the ulcerations are not infected with the virus. Instead the virus may be responsible for the initiation of immune dysregulation, or the immune dysregulation that produces aphthae may allow the release of virions. Nevertheless, the association between HSV and aphthae is weak, and prophylactic antiviral therapy generally does not decrease the recurrence of aphthous stomatitis. Furthermore, HSV and other herpesviruses have been associated with oral carcinomas, but much of the evidence is circumstantial. HSV DNA has been extracted from some tumors but not others, and elevated HSV-1 IgG antibodies have been detected in patients with oral cancer or precancer. HSV may aid carcinogenesis through the promotion of mutations, but its oncogenic role, if any, is uncertain.

Clinical Features

Acute herpetic gingivostomatitis (primary herpes) is the most common pattern of symptomatic primary HSV infection, and more than 90% of cases are caused by HSV-1. Most affected individuals are between the ages of 6 months and 5 years, with the peak prevalence occurring between 2 and 3 years of age. However, occasional cases have been reported in patients older than 60 years. Development before 6 months of age is rare because of protection by maternal anti-HSV antibodies. The onset is abrupt and often accompanied by anterior cervical lymphadenopathy, chills, fever (103 °F to 105 °F), nausea, anorexia, irritability, and sore mouth lesions. The manifestations vary from mild to severely debilitating.

Initially the affected mucosa develops numerous pinhead vesicles, which rapidly collapse to form numerous small, red lesions. These lesions enlarge slightly and develop central ulceration covered by yellow fibrin (Fig. 7.1). Adjacent ulcerations may coalesce to form larger, shallow, irregular ulcerations (Fig. 7.2). Both the movable and attached oral mucosa can be affected, and the number of lesions is highly variable. In all cases, the gingiva is enlarged, painful, and extremely erythematous (Fig. 7.3). In addition, the affected gingiva often exhibits distinctive punched-out erosions along the midfacial free gingival margins (Fig. 7.4). It is not

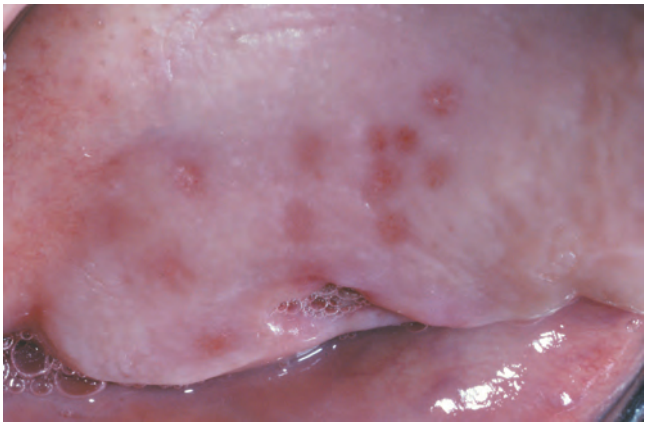
• **Fig. 7.4 Acute Herpetic Gingivostomatitis.** Painful, enlarged, and erythematous facial gingiva. Note erosions of the free gingival margin. (Courtesy of Dr. Gina Liford.)

unusual for involvement of the labial mucosa to extend past the wet line to include the adjacent vermilion border. Satellite vesicles of the perioral skin are fairly common. Self-inoculation of the fingers, eyes, and genital areas can occur. Mild cases usually resolve within 5–7 days; severe cases may last 2 weeks. Rare complications include keratoconjunctivitis, esophagitis, pneumonitis, meningitis, and encephalitis.

As mentioned previously, primary infection in adults may cause **pharyngotonsillitis.** Sore throat, fever, malaise, and headache are the initial symptoms. Numerous small vesicles develop on the tonsils and posterior pharynx. The vesicles rapidly rupture to form shallow ulcers, which often coalesce and develop an overlying diffuse, gray-yellow exudate. Involvement of the oral mucosa anterior to Waldeyer ring occurs in less than 10% of cases. HSV appears to be a significant cause of pharyngotonsillitis in young adults who are from higher socioeconomic groups with previously negative test findings for HSV antibodies. Most cases are caused by HSV-1, but the proportion caused by HSV-2 is increasing. The clinical presentation closely resembles pharyngitis secondary to streptococci or infectious mononucleosis, making the true frequency difficult to determine.

Infrequently, primary HSV-1 infection may spread along nerve tracts beyond the trigeminal ganglion, especially if the host is immunocompromised. Spread via the lingual nerve to the geniculate ganglion of the facial nerve may result in Bell palsy (see page 861). In addition, the virus may reach the vestibular ganglion of the vestibulocochlear nerve, resulting in vestibular neuritis and sudden hearing loss.

Recurrent (secondary) herpes simplex infections may occur either at the site of primary inoculation or in adjacent areas of surface epithelium supplied by the involved ganglion. The most common clinical pattern of recurrent HSV-1 infection is **herpes labialis** ("cold sore" or "fever blister"), which involves the vermilion border and skin adjacent to the lips. Prevalence studies suggest that 15%–45% of the United States population has a history of herpes labialis. In some patients, ultraviolet light or trauma can trigger recurrences. Prodromal signs and symptoms (e.g., pain, burning, itching, tingling, localized warmth, erythema) arise 6–24 hours before the lesions appear. Multiple small, erythematous papules develop and form clusters of fluid-filled vesicles (Fig. 7.5). The vesicles rupture and crust within 2 days. Healing usually occurs within 7–10 days. Pain is



dentlearn.ir

• **Fig. 7.5 Herpes Labialis.** Multiple fluid-filled vesicles on the lip vermilion.

• **Fig. 7.6 Herpes Labialis.** Multiple sites of recurrent herpetic infection secondary to spread of viral fluid over cracked lips.

• **Fig. 7.7 Intraoral Recurrent Herpetic Infection.** Early lesions exhibiting as multiple erythematous macules on the hard palate. Lesions appeared a few days after extraction of a tooth.

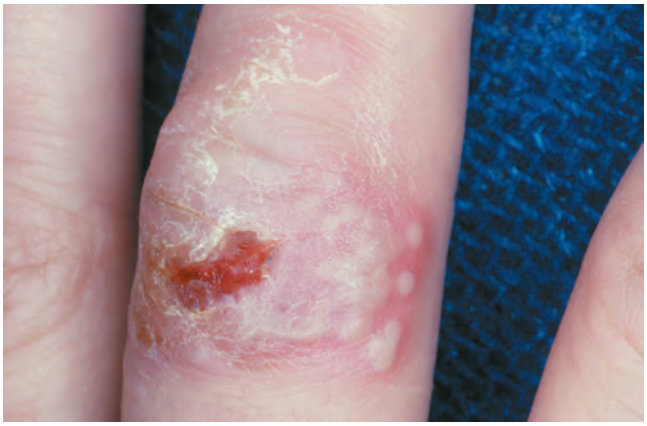
most severe in the first 8 hours and usually resolves within 4–5 days. Viral shedding is greatest upon vesicular rupture, and most active viral replication is complete within 48–72 hours. Rupture of vesicles and release of virus-filled fluid may result in spreading of the lesions on lips previously cracked from sun exposure (Fig. 7.6). Recurrences are observed less commonly on the skin of the nose, chin, or cheek. The majority of those affected experience approximately 2–4 recurrences annually, but a small percentage may experience outbreaks that occur monthly or even more frequently.

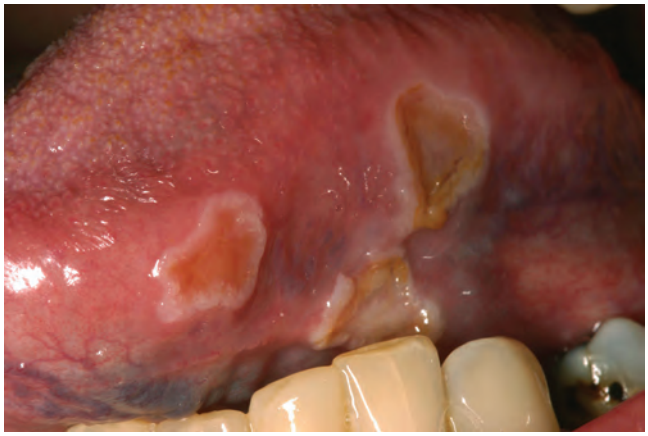


On occasion, some lesions arise almost immediately after a known trigger and appear without any preceding prodromal symptoms. These rapidly developing recurrences tend to respond less favorably to treatment.

Recurrences also can affect the intraoral mucosa. In the immunocompetent patient, **recurrent intraoral herpes (recurrent herpetic stomatitis)** almost always involves keratinized mucosa bound to bone (attached gingiva and hard palate). These sites often exhibit subtle changes, and the symptoms tend to be relatively mild. The lesions begin as 1- to 3-mm vesicles that rapidly collapse to form a cluster of erythematous macules that may coalesce or slightly enlarge (Figs. 7.7 and 7.8). The damaged epithelium is lost, and a yellowish ulceration with irregular borders develops. Healing occurs within 7–10 days. In about a fourth of cases, recurrent intraoral herpes may be accompanied by recurrent herpes labialis.

Several less common presentations also exist. Primary or recurrent HSV infection of the fingers is known as **herpetic whitlow (herpetic paronychia)** (Fig. 7.9). This condition may result from self-inoculation in children with orofacial HSV-1 infection or adults with genital HSV-2 infection. Before the uniform use of gloves, medical and dental personnel could infect their digits from contact with infected patients and represented the most commonly affected group. Recurrent digital infection may result in paresthesia and permanent scarring.

Cutaneous herpetic infections also can arise in areas of previous epithelial damage. Parents kissing skin injuries in children represent one vector. Wrestlers and rugby players also may contaminate areas of abrasion and develop lesions known as **herpes gladiatorum** or **scrumpox.** On occasion, herpes simplex has been spread over the bearded region of the



dentlearn.ir

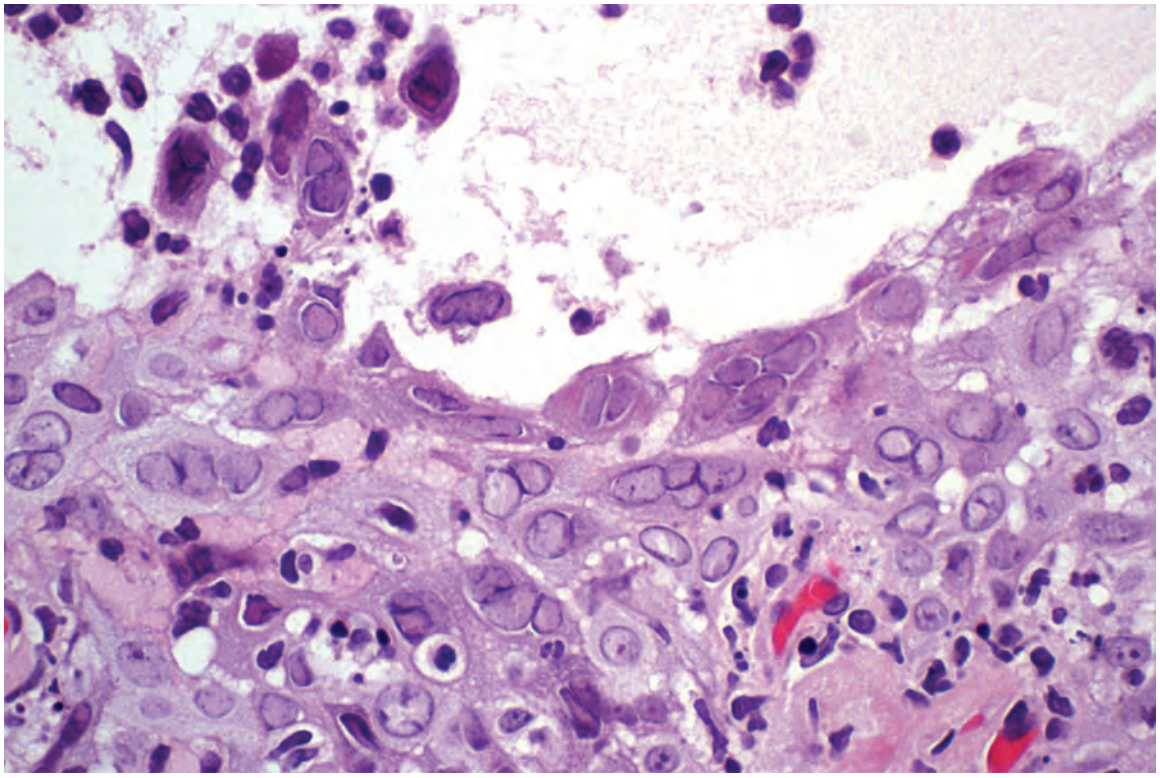
• **Fig. 7.12 Herpes Simplex.** Intraepithelial vesicle.



face into minor injuries created by daily shaving, leading to a condition known as **herpes barbae.** Ocular involvement may occur by self-inoculation in children and, with multiple recurrences, may result in blindness. Patients with diffuse, chronic skin diseases, such as eczema, pemphigus, and Darier disease, may develop diffuse life-threatening HSV infection, known as **eczema herpeticum (Kaposi varicelliform eruption).** Newborns may become infected after delivery through a birth canal contaminated with HSV, usually HSV-2. Without treatment, there is a greater than 50% mortality rate.

HSV recurrence in immunocompromised hosts can be significant. Without proper immune function, recurrent herpes can persist, spread, and potentially be fatal. Skin lesions may continue to enlarge with formation of broad zones of superficial erosion. Likewise, herpes labialis may be severe, with extensive areas of involvement. Intraoral lesions usually begin on bound mucosa but often spread to unbound mucosa as well. The lesions may appear as brownish, necrotic epithelium raised above the surface of the adjacent intact epithelium. Typically, these areas are much larger than the usual pinhead lesions in immunocompetent patients. With continued enlargement, a zone of superficial necrosis or erosion with a distinctive circinate, raised, yellow border develops (Figs. 7.10 and 7.11). HSV infection in a chronic ulcer on the movable oral mucosa is ominous and should prompt thorough evaluation for possible immune dysfunction. In addition, immunocompromised patients may develop persistent oral ulcers that lack the distinctive curvilinear border, are nonspecific clinically, and may mimic aphthous stomatitis, necrotizing stomatitis, or ulcerative periodontal disease. Biopsy may reveal any of a number of infectious processes, such as HSV infection, at times combined with CMV or EBV infection.

Histopathologic Features

HSV-infected epithelial cells exhibit acantholysis, nuclear clearing, and nuclear enlargement (termed **ballooning degeneration**) (Fig. 7.12). The acantholytic epithelial cells may be referred to as **Tzanck cells.** (This term refers to free-floating epithelial cells in any intraepithelial vesicle and is not specific for herpes.) Nucleolar fragmentation occurs with a condensation of chromatin around the periphery of the nucleus. Multinucleated epithelial cells are formed by fusion between adjacent cells (see Fig. 7.12).

dentlearn.ir

• **Fig. 7.13 Herpes Simplex.** Altered epithelial cells exhibiting ballooning degeneration, margination of chromatin, and multinucleation. (High-power magnification of the same case shown in Fig. 7.12.)

Intercellular edema develops and leads to the formation of an intraepithelial vesicle (Fig. 7.13). Mucosal vesicles rupture rapidly; those on the skin often persist and become infiltrated by inflammatory cells. Once they have ruptured, the mucosal lesions demonstrate a surface fibrinopurulent membrane. Often at the edge of the ulceration or mixed within the fibrinous exudate are the scattered Tzanck or multinucleated epithelial cells.

Diagnosis

The clinician often can make a strong presumptive clinical diagnosis of HSV infection. However, on occasion, HSV infection can be confused with other diseases, and laboratory confirmation is desirable.

The traditional method for diagnosis is viral isolation from tissue culture inoculated with the fluid of intact vesicles. However, intact vesicles are rare in the oral cavity, and culture of ruptured oral lesions is unreliable because of the potential for contamination with saliva that may contain coincidentally released HSV from asymptomatic viral shedding. Another problem with viral culture is that up to 2 weeks may be required for a definitive result.

The most commonly used sampling methods for diagnosis are the cytologic smear and tissue biopsy, with the former being the least invasive and most cost-effective. Microscopic examination shows characteristic changes in infected epithelial cells. Only VZV produces similar changes, but these two infections usually can be differentiated on a clinical basis. If necessary, direct immunofluorescence, immunohistochemistry, in situ hybridization, or PCR may be performed for more definitive HSV detection and typing.

If diagnostic features of HSV are discovered in a biopsy of a persistent ulceration in an immunocompromised patient, additional studies should be performed to rule out coinfection with other viruses, such as CMV and EBV. The histopathologic features of CMV can be missed easily, resulting in patients not receiving the most appropriate therapy.

Serologic testing is useful in documenting recent or past exposure to HSV and is used primarily in epidemiologic studies. HSV antibodies typically begin to appear 4–8 days after initial exposure. Confirmation of primary infection by serology requires a negative sample obtained within 3 days of initial presentation and a positive sample obtained approximately 4 weeks later.

Treatment and Prognosis

In the past, primary herpetic gingivostomatitis was treated only symptomatically; however, if administered early, antiviral medications can be beneficial. Acyclovir suspension initiated during the first 3 symptomatic days and administered by a rinse-and-swallow technique five times daily for 5 days (children: 15 mg/kg up to the adult dose of 200 mg) results in significant acceleration of clinical resolution. Once therapy is initiated, development of new lesions ceases. In addition, associated eating and drinking difficulties, pain, healing time, duration of fever, and viral shedding are shortened

dentlearn.ir

dramatically. In conjunction with acyclovir, additional medications—such as dyclonine hydrochloride spray, tetracaine hydrochloride lollipops (prepared by a compounding pharmacist), or nonsteroidal anti-inflammatory drugs (NSAIDs)—may be used for more immediate pain relief. Viscous lidocaine and topical benzocaine should be avoided in pediatric patients because of reports of lidocaine-induced seizures in children and an association between topical benzocaine and methemoglobinemia. Intravenous fluids also may be administered to address fluid and electrolyte imbalances. In addition, patients should be instructed to restrict contact with active lesions to prevent autoinoculation or spread to others.

Recurrent herpes labialis has been treated with everything from ether to voodoo; nothing has solved the problem for all patients. Acyclovir ointment in polyethylene glycol was the first topical antiviral formulation available. Acyclovir ointment has been of limited benefit for herpes labialis in immunocompetent patients, because its base is thought to prevent significant absorption. Subsequently, penciclovir cream became available in a base that allows increased absorption through the vermilion border. This formulation has produced reduction in healing time and pain by approximately 1 day. Although the best results are obtained if penciclovir cream is initiated during the prodrome, late application also has produced a measurable clinical benefit. Additional choices are acyclovir cream and over-the-counter 10% docosanol cream. All three of these creams are associated with statistically significant, albeit clinically minimal, reduction in healing time and pain, with penciclovir exhibiting the greatest efficacy and docosanol the least efficacy.

Systemic acyclovir and two newer medications, valacyclovir and famciclovir, demonstrate similar effectiveness against HSV. However, valacyclovir and famciclovir exhibit improved bioavailability and more convenient oral dosing schedules. In particular, a valacyclovir regimen—consisting of 2 g during the prodrome followed by another 2 g 12 hours later—has been most successful in minimizing recurrences. The effects of this treatment are reduced significantly if it is not initiated during the prodrome. Although much less convenient, 400 mg of acyclovir taken five times daily for 5 days appears to produce similar results. For patients whose recurrences appear to be associated with dental procedures, a regimen of 2 g of valacyclovir taken twice on the day of the procedure and 1g taken twice the next day may suppress or minimize an attack. In individuals with a known trigger that extends over a period of time (e.g., skiing or beach vacation), prophylactic short-term use of an antiviral (acyclovir, 400 mg twice daily; valacyclovir, 1 g daily; or famciclovir, 250 mg twice daily) has been shown to reduce the prevalence and severity of recurrences.

Long-term suppressive therapy with an antiviral medication typically is reserved for patients with more than six recurrences per year, HSV-triggered erythema multiforme, or an immunocompromised status. Over the past several decades, acyclovir-resistant strains of HSV have emerged, mainly among immunocompromised patients receiving long-term treatment or prophylaxis. In immunocompromised patients, the viral load tends to be high and replication is not suppressed completely by antiviral therapy, creating a favorable environment for generating drug-resistant mutants. Although resistance is seen primarily in immunocompromised patients, cavalier use of antiviral medications for mild cases of recurrent herpes infection probably is inappropriate.

For the management of recurrent herpes labialis, some clinical trials suggest that low-level laser therapy may aid in decreasing pain and the recurrence rate. However, further studies are needed. Also, laser ablation of active lesions occasionally may cause worsening, and, thus, it may be advisable to limit the use of low-level laser therapy to areas in which lesions already have healed in an attempt to prevent additional recurrences.

The pain associated with intraoral secondary herpes usually is not intense, and many patients do not require treatment. Some studies have shown chlorhexidine to exert antiviral effects. In addition, acyclovir appears to function synergistically with chlorhexidine. Extensive clinical trials have not been performed, but chlorhexidine alone or in combination with acyclovir suspension may be beneficial for patients who desire or require therapy.

During dental treatment, precautions should be taken to prevent HSV transmission between patients and oral healthcare providers. Such precautions include wearing standard personal protective equipment, avoiding manipulation of tissues with clinically evident infection, minimizing aerosol production around HSV lesions, and refraining from application of petrolatum products to active, fluid-producing lesions (i.e., prior to the scab stage). In general, it is prudent to defer dental treatment until an HSV lesion is scabbed or completely healed.

Immunocompromised hosts with HSV infection often require intravenous (IV) antiviral medications. Furthermore, severely immunosuppressed individuals, such as bone marrow transplant patients and those with AIDS, often need prophylactic oral acyclovir, valacyclovir, or famciclovir. Herpes lesions that do not respond to appropriate therapy within 5–10 days most likely are the result of resistant strains. At this point, the initial antiviral therapy should be repeated at an elevated dose. If this intervention fails, additional alternatives include IV trisodium phosphonoformate hexahydrate (foscarnet) and IV cidofovir. Ulcerations that reveal coinfection with HSV and CMV respond well to ganciclovir, with foscarnet used in refractory cases. Research for a potential HSV vaccine is ongoing.

◆ VARICELLA (CHICKENPOX)

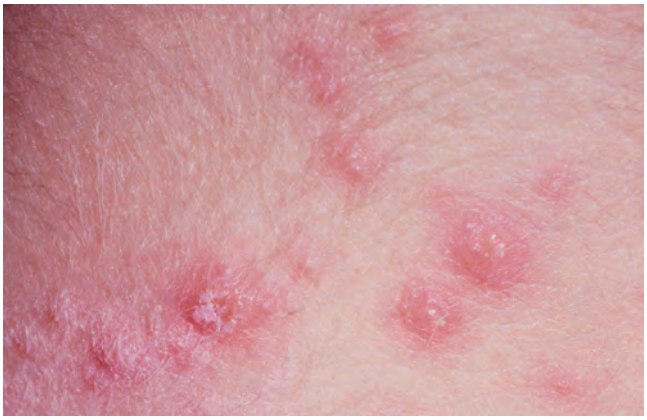
Varicella (chickenpox) represents primary infection with the varicella-zoster virus (VZV or HHV-3). Subsequently, latency ensues, and recurrence is possible as **herpes zoster** (see page 238), often after many decades. The virus may be spread through air droplets or direct contact with active lesions. In contrast to primary HSV infection, most cases

dentlearn.ir

of primary VZV infection are symptomatic. The incubation period is 10–21 days, with an average of 15 days.

In the prevaccine era, the annual incidence of chickenpox in the United States was approximately 4 million, with most cases arising in children younger than 10 years of age. However, since the introduction of universal varicella immunization in the United States in 1995, the incidence has declined across all age groups, and the age range of peak incidence has shifted to between 10 and 14 years. In surveillance areas with high vaccine coverage, the incidence of varicella decreased from 1995 to 2005 by approximately 90%; even further declines have occurred since 2006, when a two-dose vaccine regimen became routine. It is estimated that each year varicella vaccination prevents more than 3.5 million cases of chickenpox, 9000 hospitalizations, and 100 deaths in the United States.

Clinical Features

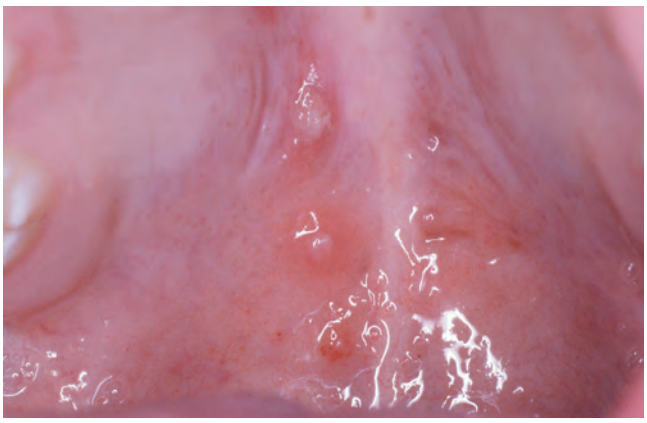


Because of high varicella vaccination rates in the United States, the majority of new varicella cases now represent **breakthrough infection** (i.e., infection with wild-type virus in a previously immunized patient). A maculopapular, cutaneous rash with only a small number of lesions, few or no vesicles, low or no fever, and a shortened disease course of approximately 4–6 days are characteristic findings. The atypical presentation of breakthrough disease may be difficult to recognize, with some cases mistaken for insect bites or poison ivy. Patients are contagious until no new lesions appear within a 24-hour period, although transmission is less frequent with mild breakthrough infection compared with symptomatic infection in unimmunized individuals.

Among unimmunized individuals, the symptomatic phase of primary VZV infection usually begins with malaise, pharyngitis, and rhinitis. In older children and adults, additional symptoms (e.g., headache, myalgia, nausea, anorexia, and vomiting) occasionally are seen. This is followed by a characteristic, intensely pruritic exanthem. The rash begins on the face and trunk and spreads to the extremities. Each lesion rapidly progresses through stages of erythema, vesicle, pustule, and hardened crust (Figs. 7.14 and 7.15). The vesicular stage is the classic presentation. Each vesicle is surrounded by a zone of erythema and has been described as "a dewdrop on a rose petal." In contrast to herpes simplex, the lesions typically continue to erupt for 4 or more days. Old crusted lesions intermixed with newly formed, intact vesicles are commonplace. Affected individuals are contagious from 2 days before the exanthem until all the lesions crust. Fever usually is present during the active phase of the exanthem.

Perioral and oral manifestations are fairly common and may precede the skin lesions. The vermilion border and palate are involved most often, followed by the buccal mucosa. Occasionally, gingival lesions resemble those noted in primary HSV infection, but distinguishing between the two is not difficult because the lesions of varicella tend to be relatively painless. The lesions begin as 3- to 4-mm, white,

• **Fig. 7.14 Varicella.** Infant with diffuse erythematous and vesicular rash. (Courtesy of Dr. Sherry Parlanti.)



• **Fig. 7.15 Varicella.** Numerous vesicles with surrounding erythema and early crusting.

opaque vesicles that rupture to form 1- to 3-mm ulcerations (Fig. 7.16). The prevalence and number of oral lesions correlate with the severity of extraoral infection. In mild cases, oral lesions are present in about one-third of affected individuals; often there are only one or two oral ulcers that heal within 1–3 days. On the other hand, patients with severe infections almost always have oral ulcerations, often numbering up to 30 and persisting for 5–10 days.

Infants, adults, and immunocompromised individuals are at increased risk for severe disease and complications. In

dentlearn.ir

• **Fig. 7.16 Varicella.** White opaque vesicles on the hard palate. (Courtesy of Tristan Neville.)

addition, household members who become secondarily infected often suffer more severe disease than those initially infected.

In childhood, the most frequent complications of varicella are secondary skin infections, followed by encephalitis and pneumonia. In particular, secondary skin infection with group A, β-hemolytic streptococci may progress to necrotizing fasciitis, septicemia, toxic shock syndrome, or other life-threatening conditions. With enhanced public education and decreased use of aspirin in children, Reye syndrome (a potentially fatal condition characterized by acute encephalopathy, liver failure, and other major organ damage) is now rare.

The prevalence of complications in adults exceeds that in children. The most common and serious complication is pneumonitis, characterized by dry cough, tachypnea, dyspnea, hemoptysis, chest pain, and cyanosis. Other potential complications include pneumonia, encephalitis, gastrointestinal disturbance, and hematologic events (i.e., thrombocytopenia, pancytopenia, hemolytic anemia, sickle cell crisis). Central nervous system (CNS) involvement typically produces ataxia but also may result in headaches, drowsiness, convulsions, or coma. The risk of death is reported to be 15 times greater in adults compared with children, mostly because of an increased prevalence of encephalitis.

Infection during pregnancy can produce congenital or neonatal chickenpox. Involvement early in pregnancy can result in spontaneous abortion or congenital defects. When infection occurs before 20 weeks of gestation, the prevalence of congenital varicella syndrome is approximately 1%–2%. In addition, infection of the mother close to delivery can result in severe neonatal infection caused by a lack of maternal antibodies.

Infection in immunocompromised patients also can be severe. Cutaneous involvement typically is extensive and may be associated with secondary bacterial infection, high fever, hepatitis, pneumonitis, pancreatitis, gastrointestinal obstruction, and encephalitis. Before effective antiviral therapy, the mortality rate in immunocompromised individuals was approximately 7%.

Histopathologic Features

The cytologic alterations are virtually identical to those described for HSV. The virus causes acantholysis, with formation of numerous free-floating Tzanck cells, which exhibit nuclear margination of chromatin and occasional multinucleation.

Diagnosis

Since the institution of universal vaccination in the United States, the annual incidence of typical varicella disease has decreased, whereas the incidence of atypical breakthrough disease has increased; consequently, the need for laboratory confirmation has grown. Confirmation can be obtained through demonstration of viral cytopathologic effects present within epithelial cells harvested from vesicular fluid. These cytologic changes are identical to those found in HSV infection, although correlation with the clinical findings may aid in distinguishing between HSV and VZV infection. The most definitive method for diagnosis is PCR performed on vesicular fluid, cells from the base of a lesion, or a scab from a resolving skin lesion. During the acute phase, infection also may be detected by PCR assay of saliva or buccal swabs. PCR is preferred over viral isolation in cell culture and direct fluorescent antibody assay, because it is more sensitive and allows for distinction between wild-type and vaccine strains of VZV. In addition, a diagnosis can be made retrospectively in immunocompetent hosts by demonstrating a fourfold or greater increase in VZV antibody titers between acute and convalescent serum samples; however, in vaccinated persons an increase of this magnitude may not be evident.

Treatment and Prognosis

Before antiviral medications became available, the treatment of varicella primarily was symptomatic. Warm baths with soap, baking soda, or colloidal oatmeal; application of calamine lotion; and systemic diphenhydramine still are used to relieve pruritus. Diphenhydramine lotions are not recommended because of reports of toxicity secondary to percutaneous absorption. Acetaminophen is the preferred antipyretic for childhood cases. In this age group, aspirin should be avoided because of the risk of Reye syndrome, and NSAIDs are discouraged because they have been associated with an increased risk for severe skin and soft tissue complications.

Peroral antiviral medications (such as, acyclovir, valacyclovir, and famciclovir) have been shown to reduce the duration and severity of infection if administered within 24 hours of the rash. Routine use of antiviral medications is not recommended in immunocompetent children with uncomplicated chickenpox. Instead, such therapy is reserved for those at risk for more severe disease, such as unvaccinated individuals over 12 years of age, patients with chronic cutaneous or pulmonary disease, patients receiving long-term salicylate therapy, and those receiving short or intermittent courses of corticosteroids. In addition, some experts

dentlearn.ir

recommend antiviral therapy for individuals who contract the disease from a household member, because secondary household cases often are more severe than corresponding index cases. IV formulations are used in immunosuppressed patients or those exhibiting progressive, severe infection.

In patients who lack evidence of immunity and become exposed to VZV, postexposure immunization or purified varicella-zoster immune globulin (VariZIG) administration may be considered. Postexposure vaccination is appropriate for nonimmune individuals 12 months or older. Ideally it should be administered within 3 days, although it may be given up to 5 days after exposure in order to prevent or modify disease. A second dose of vaccine should be administered at the age-appropriate interval following the first dose. Alternatively, VariZIG can be given postexposure to nonimmune individuals at high risk for severe disease or complications and for whom vaccination is contraindicated. Individuals at elevated risk include immunocompromised patients, pregnant women without evidence of immunity, premature infants, and neonates of nonimmune mothers. VariZIG ideally should be administered as soon as possible, with the FDA approving administration up to 10 days postexposure.

In the United States, the FDA has approved a monovalent varicella virus vaccine (Varivax) as well as a quadrivalent measles, mumps, rubella, and varicella virus (MMRV) vaccine (ProQuad). The first dose of varicella-containing vaccine is recommended for children 12 through 15 months of age and a second dose for those 4 through 6 years. Either MMRV vaccine or separate injections of measles, mumps, and rubella (MMR) vaccine and monovalent varicella vaccine may be administered to toddlers receiving their first dose; the latter method minimizes the generally small risk of vaccine-related febrile seizures in this age group. For the second dose, MMRV is preferred over separate injections of MMR and varicella virus vaccines. In addition, the monovalent varicella vaccine is licensed for routine use in individuals 13 years or older without evidence of immunity; in this age group, two doses separated by at least 28 days are recommended. Children, adolescents, and adults who have received only one dose of varicella virus vaccine as per past recommendations should receive a second "catch-up" dose.

The varicella virus vaccine is a live, attenuated virus that can be spread to individuals in close contact. Therefore, vaccine recipients who develop a rash should avoid contact with those at risk, such as immunocompromised or pregnant individuals.

◆ HERPES ZOSTER (SHINGLES)

After primary infection with VZV (chickenpox), the virus is transported up the sensory nerves and establishes latency in corresponding dorsal root, cranial nerve, or autonomic ganglia. Clinically evident herpes zoster develops after reactivation of the virus, with involvement of the distribution of the affected sensory nerve. Unlike HSV, single rather than multiple recurrences are the rule. Herpes zoster occurs during the lifetime of approximately one in three individuals, and it is estimated that 1 million new episodes of herpes zoster occur annually in the United States. The prevalence of attacks increases with age, apparently due to age-related decline in cell-mediated immunity. The incidence is low among young people but increases dramatically after 50 years of age, with studies suggesting that as many as 50% of individuals who live to 85 years of age will be affected at some time. Immunosuppression, HIV infection, treatment with cytotoxic or immunosuppressive drugs, radiation, malignancy, old age, alcohol abuse, stress (emotional or physical), and dental manipulation are additional predisposing factors for reactivation.

The long-term impact of varicella virus vaccination on herpes zoster prevalence is controversial and presently under evaluation. Interestingly, it is possible to develop herpes zoster by reactivation of either the wild-type or vaccine-strain virus, although the risk for vaccine-strain zoster seems to be much lower than that for wild-type zoster.

Clinical Features

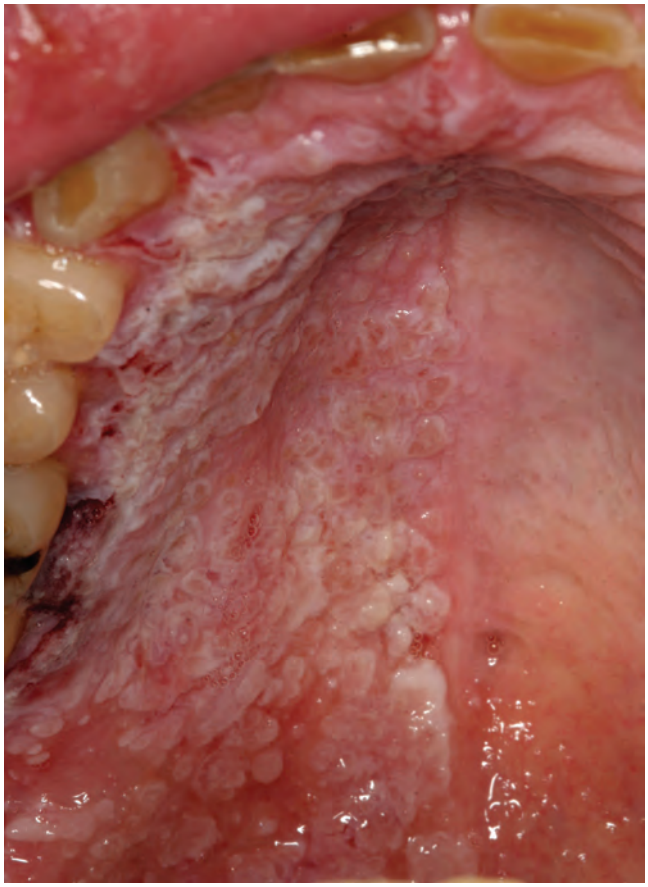
The clinical features of herpes zoster can be grouped into three phases: prodrome, acute, and chronic. During initial viral replication, ganglionitis develops with resultant neuronal necrosis and severe neuralgia. This inflammatory reaction is responsible for the prodromal pain present in more than 90% of cases. As the virus travels down the nerve, the pain intensifies and has been described as burning, tingling, itching, boring, prickly, or knifelike. The pain develops in the area of epithelium innervated by the affected sensory nerve (dermatome) and may be accompanied by fever, malaise, and headache. Typically, one dermatome is affected, but involvement of two or more can occur. The thoracic dermatomes are affected in about two-thirds of cases. This prodromal pain normally precedes the acute phase rash by 1–4 days and, depending on which dermatome is affected, may masquerade as sensitive teeth, otitis media, migraine headache, myocardial infarction, or appendicitis.

The acute phase begins as the involved skin develops clusters of vesicles set on an erythematous base (Fig. 7.17). The

• **Fig. 7.17 Herpes Zoster.** Cluster of vesicles with surrounding erythema of the skin.

dentlearn.ir

• **Fig. 7.18 Herpes Zoster.** Numerous crusting facial vesicles that extend to the midline.



lesions tend to follow the path of the affected nerve and terminate at the midline (Fig. 7.18). Within 3–4 days, the vesicles become pustular and ulcerate, with crusts developing after 7–10 days. The lesions are contagious until they crust, although the rate of VZV transmission from herpes zoster lesions is lower than that from varicella lesions. The exanthem typically resolves within 2–3 weeks in otherwise healthy individuals. On healing, scarring with hypopigmentation or hyperpigmentation is not unusual. Infrequently, there is dermatomal pain without development of a rash; this pattern is called **zoster sine herpete** (zoster without rash).

Oral lesions occur with trigeminal nerve involvement and may be present on the movable or bound mucosa (Figs. 7.19 and 7.20). The lesions often extend to the midline and frequently are accompanied by involvement of the skin overlying the affected quadrant. Like varicella, the individual lesions manifest as 1- to 4-mm vesicles or pustules that rupture to form shallow ulcerations. The teeth in affected areas may develop pulpitis, pulpal necrosis, pulpal calcification, or root resorption. In addition, several reports have documented significant bone necrosis with tooth loss. It is postulated that gnathic osteonecrosis may be secondary to extension of inflammation from affected nerves to adjacent blood vessels, leading to ischemic necrosis. The osteonecrosis may develop either during or following the exanthem, with reported lag periods as long as 150 days.

Ocular involvement is present in approximately 10%–25% of cases and can cause significant morbidity, including permanent blindness. The ocular manifestations are highly

• **Fig. 7.19 Herpes Zoster.** Numerous white opaque vesicles on the right buccal mucosa of the same patient depicted in Fig. 7.18.

• **Fig. 7.20 Herpes Zoster.** White opaque to focally clear vesicles on the right palatal mucosa with extension to the midline. (Courtesy of Dr. Molly Rosebush.)

variable and may arise from direct viral-mediated epithelial damage, neuropathy, immune-mediated damage, or secondary vasculopathy. Lesions on the tip of the nose (Hutchinson sign) indicate involvement of the nasociliary branch of the trigeminal nerve and an increased risk for severe ocular infection. In these cases, referral to an ophthalmologist is mandatory.

dentlearn.ir

Reactivation of VZV in the geniculate ganglion may cause **Ramsay Hunt syndrome,** which is characterized by cutaneous lesions of the external auditory canal and involvement of the ipsilateral facial and auditory nerves. Affected individuals may exhibit facial paralysis as well as hearing deficits, vertigo, and other auditory and vestibular symptoms. In addition, some patients may develop loss of taste in the anterior two-thirds of the tongue. By using PCR or serology, investigators have detected active VZV infection in approximately 30% of patients thought to have Bell palsy (see page 861). Similar associations also have been demonstrated with HSV and EBV. These findings suggest an underlying viral cause for many cases of "idiopathic" facial paralysis.

Approximately 15% of patients progress to the chronic phase of herpes zoster (termed **postherpetic neuralgia**), which is characterized by persistent pain after resolution of the rash. In defining postherpetic neuralgia, there is a lack of consensus regarding the duration of pain persistence following the rash, although many investigators consider a minimum period of 1–3 months. Risk factors include female gender, older age, history of prodromal pain, moderate to severe rash and/or pain during the acute phase, and ophthalmic involvement. The pain is described as burning, throbbing, aching, itching, or stabbing, often with flares caused by light stroking or contact with clothing. Most of these neuralgias resolve within 1 year, with half of patients experiencing resolution after 2 months. Rare cases may last up to 20 years, and patients have been known to commit suicide because of the extreme pain. Although the cause is unknown, some investigators believe chronic VZV ganglionitis is responsible.

In rare cases, a potentially fatal ischemic stroke syndrome, termed **granulomatous angiitis,** may develop weeks to months after resolution of a zoster rash involving the trigeminal nerve distribution. This condition appears to result from direct extension of VZV and associated inflammation from the trigeminal ganglion to the internal carotid artery.

In immunocompromised individuals, herpes zoster is often severe, with an overall increased risk for complications. The cutaneous rash may become disseminated as a result of VZV viremia; in some cases, viremia may occur even without skin involvement. Potentially life-threatening complications include pneumonia, hepatitis, disseminated intravascular coagulopathy, meningitis, and encephalitis. However, immunocompromised status does not appear to increase the risk for developing postherpetic neuralgia significantly.

Histopathologic Features

The active vesicles of herpes zoster are microscopically identical to those seen in the primary infection, varicella. For more information, see the previous sections regarding the histopathologic features of varicella and herpes simplex.

Diagnosis

Herpes zoster often is diagnosed from the clinical presentation, but laboratory testing may be necessary for atypical cases or exclusion of zosteriform recurrent HSV infection. Viral culture can provide confirmation. However, the results take at least 24 hours, and false negatives often occur because it is difficult to recover viable virus from cutaneous lesions. Cytologic smears demonstrate viral cytopathologic effects, as seen in varicella and HSV infection. A rapid diagnosis can be obtained by direct staining of cytologic smears with fluorescent monoclonal VZV antibodies. Molecular techniques, such as dot-blot hybridization and PCR, also can be used to detect VZV.

Treatment and Prognosis

Supportive therapy for herpes zoster may include antipruritics, such as diphenhydramine, and nonaspirin antipyretics. Skin lesions should be kept dry, clean, and, if possible, covered to prevent secondary infection; antibiotics may be administered to treat such secondary infections.

Prompt therapy with antiviral medications, such as acyclovir, valacyclovir, and famciclovir, has been found to accelerate healing of mucocutaneous lesions and reduce pain during the acute phase. These medications are most effective if initiated within 72 hours after development of the first vesicle. Supplementation of antiviral agents with analgesics (such as, acetaminophen, NSAIDs, tramadol, and opioids), tricyclic antidepressants, antiepileptics (including gabapentin and pregabalin), or systemic corticosteroids may provide additional pain control.

Investigations regarding whether antiviral treatment administered alone or in combination with gabapentin during the acute phase may prevent or lessen the severity of postherpetic neuralgia have yielded variable results. Similarly, combination therapy with antivirals and corticosteroids may be helpful in the treatment of acute herpes zoster but does not appear to prevent postherpetic neuralgia.

In postherpetic neuralgia, tricyclic antidepressants, anticonvulsants (including gabapentin and pregabalin), and opioids may reduce pain. In addition, the FDA has approved the lidocaine patch, capsaicin patch, and capsaicin cream for the treatment of postherpetic neuralgia. However, the evidence in support of these topical therapies is of limited quality. Also, capsaicin—which is derived from peppers—may cause significant burning or stinging of the skin as a side effect. Non-pharmacologic treatments include nerve blocks and percutaneous electrical nerve stimulation, but there are few well-controlled studies to support these alternatives. Because postherpetic neuralgia often is difficult to treat, emphasis should be placed on herpes zoster prevention.

A recombinant, adjuvanted herpes zoster vaccine (Shingrix) has been approved by the FDA for use in adults 50 years and older. This vaccine consists of two doses administered 2–6 months apart. The recombinant vaccine is preferred by the Advisory Committee on Immunization

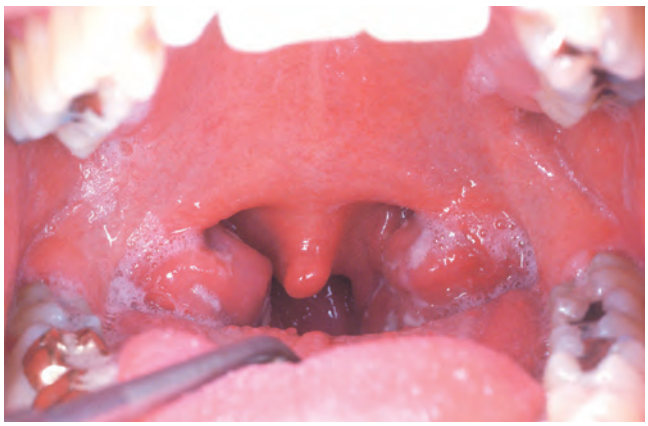
dentlearn.ir

Practices over the live zoster vaccine (Zostavax) because it confers greater protection against herpes zoster and postherpetic neuralgia.

◆ INFECTIOUS MONONUCLEOSIS (MONO; GLANDULAR FEVER; "KISSING DISEASE")

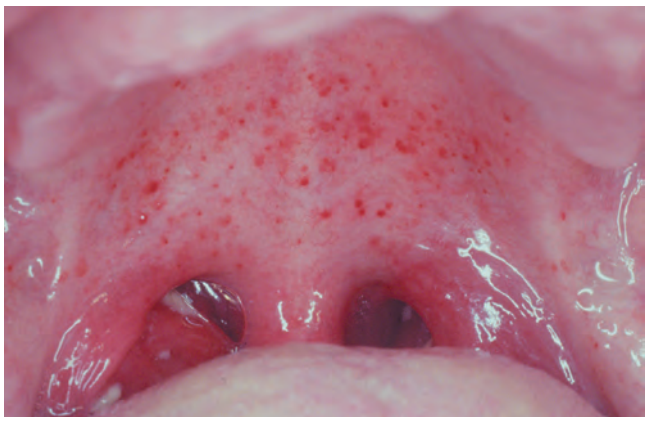
Infectious mononucleosis is a symptomatic disease resulting from exposure to Epstein–Barr virus (EBV or HHV-4). The infection usually occurs by intimate contact. Intrafamilial spread is common, and once a person is exposed, EBV remains in the host for life. Children usually become infected through contaminated saliva on fingers, toys, or other objects. Adults usually contract the virus through direct salivary transfer, such as shared straws or kissing, hence, the nickname "kissing disease." In developing nations, exposure usually occurs by age 3 and is universal by adolescence. In contrast, in developed nations, EBV infection rates have been declining among children, and introduction to the virus often is delayed. According to some studies in the United States, approximately 50% of college students lack previous exposure. Infected children are typically asymptomatic, whereas adolescents and young adults who become infected are at greatest risk for symptomatic disease. Similar mononucleosis syndromes may be produced by other pathogens, including CMV (see page 242), HIV-1 (see page 250), and *Toxoplasma gondii* (see page 222).

Besides infectious mononucleosis, EBV is associated with **oral hairy leukoplakia (OHL)** (see page 253), various lymphomas (most notably Burkitt lymphoma [see page 606]) and lymphoproliferative disorders (such as the **EBV-positive mucocutaneous ulcer** [see page 601]), nasopharyngeal carcinoma (see page 428), salivary lymphoepithelial carcinoma, some gastric carcinomas, and occasional smooth muscle tumors.



Clinical Features

The clinical presentation varies by age. Most EBV infections in children are asymptomatic. In symptomatic children younger than 4 years, typical findings include fever, lymphadenopathy, pharyngitis, hepatosplenomegaly, and rhinitis or cough. Children 4 years and older are affected similarly but exhibit a much lower prevalence of hepatosplenomegaly, rhinitis, and cough. Most young adults experience fever, lymphadenopathy, pharyngitis, and tonsillitis. In adults older than 40 years, fever and pharyngitis are the predominant findings.



Complications are uncommon at any age but most frequently arise in children. Possible significant complications include splenic rupture, thrombocytopenia, autoimmune hemolytic anemia, aplastic anemia, neurologic problems, myocarditis, and hemophagocytic lymphohistiocytosis. The latter appears to be caused by massive activation of T lymphocytes and histiocytes and is often fatal without prompt treatment.

In classic infectious mononucleosis in a young adult, prodromal fatigue, malaise, and anorexia occur up to 2 weeks before the development of pyrexia. Fever may reach 104 °F and last from 2 to 14 days. Prominent lymphadenopathy is noted in more than 90% of cases and typically appears as symmetrically enlarged and tender nodes, with frequent involvement of the posterior and anterior cervical chains. Enlargement of parotid lymphoid tissue rarely has been reported and can be associated with facial nerve palsy. More than 80% of affected young adults have oropharyngeal tonsillar enlargement, sometimes with diffuse surface exudates and secondary abscesses (Fig. 7.21). The lingual tonsils, which are located on the base of the tongue and extend from the circumvallate papillae to the epiglottis, can become hyperplastic and compromise the airway. Rare fatalities have been reported from respiratory difficulties secondary to tonsillar hyperplasia, arytenoid hypertrophy, pharyngeal edema, and epiglottal swelling.

Oral lesions other than lymphoid enlargement also may be seen. Petechiae on the hard or soft palate are present in about 25% of patients (Fig. 7.22). The petechiae usually disappear within 24–48 hours. **Necrotizing gingivitis** (see page 151) also is fairly common. Necrotizing gingivitis-like pericoronitis (see page 165) and necrotizing mucositis (see page 152) occur less frequently. Cases of necrotizing gingivitis that

• **Fig. 7.21 Infectious Mononucleosis.** Hyperplastic pharyngeal tonsils with yellowish crypt exudates. (Courtesy of Dr. George Blozis.)

• **Fig. 7.22 Infectious Mononucleosis.** Numerous petechiae of the soft palate. (Courtesy of Dr. George Blozis.)

dentlearn.ir

are refractory to conventional therapy should be evaluated to rule out the possibility of EBV infection.

In less than 10% of classic infectious mononucleosis cases, patients experience fatigue persisting for several weeks to months. However, active EBV infection beyond 4 months is rare. Several investigators have attempted to associate EBV with a controversial symptom complex called **chronic fatigue syndrome** (myalgic encephalomyelitis, systemic exertion intolerance disease), characterized by profound fatigue lasting more than 6 months, pharyngitis, myalgias, arthralgias, headaches, lymphadenopathy, postexertional malaise, unrestful sleep, and cognitive impairment. Nevertheless, current evidence does not support EBV as a specific cause of this condition, which likely may be triggered by a variety of illnesses or conditions.

Furthermore, some studies suggest that infectious mononucleosis increases the risk for developing multiple sclerosis later in life. However, it is uncertain whether EBV is a direct or indirect cause of multiple sclerosis versus an innocent bystander.

Diagnosis

The diagnosis of infectious mononucleosis commonly is based upon the clinical presentation combined with the presence of greater than 10% atypical lymphocytes on a peripheral blood smear and a positive heterophile antibody test. Heterophile antibodies are IgM antibodies that are directed against viral antigens and cross-react with sheep and horse erythrocytes. The Monospot test is a widely available assay for rapid detection of heterophile antibodies. However, false negative results are possible, especially during the first week of infection or among infected children younger than 4 years.

In suspected cases of EBV infection for which heterophile antibody testing is negative, EBV-specific antibody testing may be required. Immunoassays can be performed during various stages of infection and resolution in order to quantify antibodies directed against viral capsid antigens (VCA) and EBV nuclear antigens (EBNA).

Treatment and Prognosis

In most cases, infectious mononucleosis resolves within 4–6 weeks. NSAIDs can be used to minimize the most common symptoms. Adequate fluid intake and nutrition also are important. Patients with significant enlargement of the spleen should avoid contact sports to prevent the rare possibility of splenic rupture.

Tonsillar involvement may resemble streptococcal pharyngitis or tonsillitis (see page 174). However, ampicillin, amoxicillin, or other penicillins should be avoided because these antibiotics commonly cause nonallergic morbilliform skin rashes in patients with infectious mononucleosis.

Some clinicians advocate short-term corticosteroid administration in order to minimize acute symptoms. However, there is insufficient evidence from clinical studies to support the routine use of corticosteroid treatment for infectious mononucleosis. In addition, there is concern regarding an increased risk for complications, including encephalitis and myocarditis. In practice, most clinicians reserve corticosteroid treatment for management of severe complications, such as impending airway obstruction, hemolytic anemia, thrombocytopenia, or hemophagocytic lymphohistiocytosis. The latter also typically requires treatment with cyclosporine or etoposide.

Although antiviral medications, such as acyclovir, valacyclovir, and famciclovir, have been used successfully for temporary resolution of oral hairy leukoplakia (OHL), these medications do not demonstrate clinically obvious benefit for patients with infectious mononucleosis. These agents may block viral replication; however, the main clinical manifestations of infectious mononucleosis appear to be secondary to the immune response to EBV-infected B lymphocytes and are not altered by this intervention.

◆ CYTOMEGALOVIRUS

Similar to other human herpesviruses, **cytomegalovirus** (CMV or HHV-5) may establish latency after initial infection and reactivate under certain conditions. CMV can reside latently in salivary gland cells, endothelium, macrophages, and lymphocytes. The virus can be found in most bodily fluids, including saliva, blood, urine, tears, respiratory secretions, genital secretions, and breast milk. Most clinically evident disease is found in neonates or immunosuppressed adults. In infants, the virus is contracted through the placenta, during delivery, or during breast-feeding. The next peak of transmission occurs during adolescence, predominantly from sexual contact. Transmission also has been documented through blood transfusion and organ transplantation. Global CMV seroprevalence is estimated to be 83% in the general population. In the United States, seroprevalence is approximately 20% for children 1–5 years of age, 50% for individuals 6–49 years of age, and greater than 90% for those older than 80 years. In addition to increasing age, other risk factors for CMV seropositivity include female gender, low socioeconomic status, household crowding, and foreign birthplace.

Clinical Features

At any age, almost 90% of CMV infections are asymptomatic. In clinically evident congenital and neonatal infection, typical features include jaundice, hepatosplenomegaly, cutaneous erythropoiesis, and thrombocytopenia (often with associated petechiae and purpura). CNS involvement may cause microcephaly, seizures, and mental and motor impairment. In addition, CMV infection represents the most common cause of nonhereditary sensorineural hearing loss, with infected infants often developing hearing loss at birth or later in childhood.

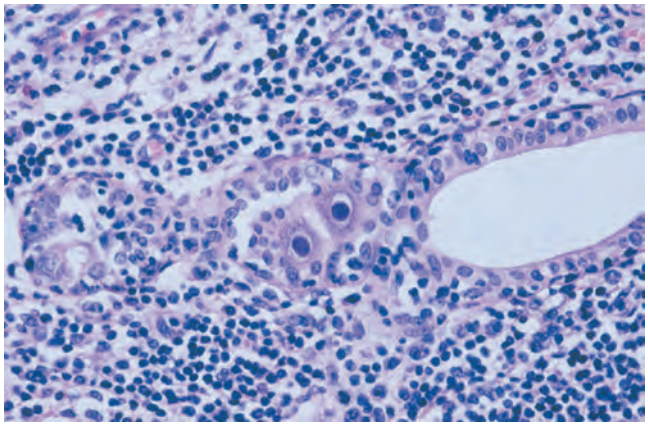
Among immunocompetent individuals, symptomatic acute CMV infection is rare and exhibits nonspecific features, ranging from an infectious mononucleosis-like presentation to lethal multiorgan involvement. CMV

dentlearn.ir

mononucleosis typically is characterized by fever, chills, sore throat, headache, and fatigue. Compared with classic EBV mononucleosis, this condition is much less commonly associated with exudative pharyngitis, lymphadenopathy, and hepatosplenomegaly. Other possible findings in symptomatic CMV infection include joint and muscle pain, abdominal pain, nonproductive cough, maculopapular rash, and diarrhea. Persistent fever of unknown origin may be the primary finding in some cases. Rarely, immunocompetent patients may develop acute sialadenitis diffusely involving the major and minor salivary glands. In such cases, xerostomia often is noted, and the affected glands are painful and enlarged. Unusual complications include myocarditis, pericarditis, pneumonitis, anterior uveitis, and meningitis.

Clinically evident CMV involvement frequently arises in immunocompromised transplant patients. In some cases a temporary, mild fever is the only finding; in others, the infection becomes aggressive and is characterized by hepatitis, leukopenia, pneumonitis, gastroenteritis, and, more rarely, a progressive wasting syndrome.

Patients with AIDS (see page 250) also are at increased risk for symptomatic CMV disease, although a decrease in prevalence has been reported with the introduction of effective antiretroviral therapy (ART). The two most common manifestations of CMV infection in patients with AIDS are chorioretinitis and gastrointestinal involvement. The former may result in blindness, and the latter may cause bloody diarrhea or odynophagia.



Chronic oral ulcerations caused by CMV infection have been documented in association with HIV infection as well as other immunosuppressive conditions. Occasionally, such lesions may harbor coinfection with additional viruses, such as HSV and EBV. In addition, neonatal CMV infection can produce developmental tooth defects. In a study of 118 people with a history of neonatal CMV infection, examination revealed tooth defects in 40% of those with symptomatic infections and slightly more than 5% of those with asymptomatic infections. The teeth exhibited diffuse enamel hypoplasia, significant attrition, enamel hypomaturation, and yellow coloration from the underlying dentin.

Histopathologic Features

Biopsy specimens of intraoral CMV lesions may demonstrate changes within vascular endothelial cells or salivary duct epithelial cells (Fig. 7.23). Scattered infected cells are extremely swollen, showing both intracytoplasmic and intranuclear inclusions and prominent nucleoli. These enlarged cells have been called "owl eye" cells. Grocott-Gomori methenamine silver and periodic acid-Schiff (PAS) stains demonstrate the cytoplasmic inclusions but not the intranuclear changes.

Diagnosis

The diagnosis of CMV infection is based upon the clinical features combined with laboratory findings. Tissue biopsy may demonstrate cells with viral inclusions suggestive of CMV infection; however, these inclusions may be scant and difficult to demonstrate on routine light microscopy. More sensitive and specific methods for confirmation of CMV infection in biopsy specimens include immunohistochemistry and in situ hybridization. Because specific treatments exist for CMV infection in immunocompromised patients, biopsy is recommended for chronic ulcerations refractory to conservative therapy. In addition, in such cases HSV coinfection should be excluded.

• **Fig. 7.23 Cytomegalovirus (CMV) Infection.** Salivary ductal epithelium exhibiting distinctive "owl eye" alterations.

Additional CMV detection methods include serology, viral culture, and PCR. Serologic testing by enzyme-linked immunosorbent assay (ELISA) is commonly available and relatively inexpensive. IgG seroconversion constitutes clear evidence of recent primary CMV infection but requires paired serum samples taken 1–3 months apart. Alternatively, recent primary infection may be diagnosed by positive IgM in combination with low IgG avidity (IgG antibodies with low binding strength to CMV). In transplant patients and other immunocompromised individuals, plasma viral load—determined by real-time quantitative PCR—may be monitored in order to assess the need for CMV treatment or response to CMV therapy.

In CMV mononucleosis, peripheral blood typically shows a 50% or greater relative lymphocytosis, with at least 10% atypical lymphocytes. Unlike EBV mononucleosis, this condition usually is heterophile antibody-negative.

Treatment and Prognosis

Although most CMV infections resolve spontaneously, therapy often is required in the immunosuppressed patient. Intravenous ganciclovir and oral valganciclovir are the most commonly used antiviral agents for CMV disease treatment and prevention in immunocompromised individuals. However, resistance to these agents has been reported; other effective treatments include foscarnet, cidofovir, combination antiviral therapy, and hyperimmune globulin. Nevertheless, the best preventive and interventional therapy in immunocompromised patients remains improvement of immune

dentlearn.ir

status, such as that achieved with antiretroviral therapy (ART) for HIV infection (see page 264).

Immunocompetent patients with clinically evident CMV infection usually are treated symptomatically with NSAIDs. Corticosteroids or IV gamma globulins have been used in patients with hemolytic anemia or severe thrombocytopenia. Use of antiviral agents in immunocompetent patients typically is reserved for severe disease because of the risk of drug-related toxicity.

No licensed vaccine is currently available for prevention of CMV infection; however, several vaccines are under investigation and may be used in the future to protect women of reproductive age and children.

◆ ENTEROVIRUSES

Human **enteroviruses** (family Picornaviridae, genus *Enterovirus*) traditionally have been classified into echoviruses, coxsackieviruses A and B, and polioviruses, with numerical designations for individual serotypes (e.g., Coxsackie virus A1). Beginning in the 1960s, newly discovered enterovirus serotypes have been designated numerically without being placed into one of the traditional groups (e.g., enterovirus 71). Current classification, based upon molecular and biologic features, divides the human enteroviruses into four species (A through D) but maintains the traditional names for individual serotypes. More than 100 serotypes have been identified. Also, a few enteroviruses (echoviruses 22 and 23) have been reclassified into the distinct *Parechovirus* genus. Polioviruses largely have been eradicated in developed countries by vaccination. However, the nonpolio enteroviruses continue to cause disease worldwide.

Most enterovirus infections are asymptomatic or subclinical. Among symptomatic cases, the clinical presentation is variable and may range from a minor febrile illness to a severe and potentially fatal infection. Death may be caused by neurologic or cardiopulmonary complications. In addition, more than 30 enteroviral subtypes are associated with skin rashes.

The estimated annual incidence of enterovirus infections in the United States is 10–15 million, with most cases affecting infants and young children. In many countries, epidemics occur every 2–3 years and primarily affect children 1–4 years old. The timing of the epidemics appears to correlate with the accumulation of a new population of susceptible young children.

The present discussion focuses upon the following clinical patterns of enteroviral infection: **herpangina, hand-foot-and-mouth disease,** and **acute lymphonodular pharyngitis.** These conditions are closely related and should not be considered entirely separate. In epidemics involving the same viral strain, the clinical presentations often vary and may include both herpangina and hand-foot-and-mouth disease. Also, many authorities regard acute lymphonodular pharyngitis as a variant of herpangina rather than a distinct entity.

Herpangina usually is produced by coxsackievirus A1 to A6, A8, A10, or A22. However, it also may represent infection by coxsackievirus A7, A9, or A16; coxsackievirus B2 to B6; echovirus 9, 16, or 17; or enterovirus 71. Hand-foot-and-mouth disease usually is caused by coxsackievirus A16 or enterovirus 71. In particular, in the Asia-Pacific region over the past few decades, enterovirus 71 has caused several large outbreaks of hand-foot-and-mouth disease, often associated with major neurologic complications. In addition, coxsackievirus A6 has emerged as a major cause of hand-foot-and-mouth disease in recent outbreaks in the United States and abroad. Other causative pathogens include coxsackievirus A5, A9, or A10 and echovirus 11. Acute lymphonodular pharyngitis is less recognized, and coxsackievirus A10 has been found in the few reported cases.

In nontropical areas, most cases arise in the summer or early fall, with crowding and poor hygiene aiding their spread. The fecal-oral route is the major mode of transmission, and frequent hand washing is important to diminish spread during epidemics. The incubation period is 4–7 days. During the acute phase, the virus also can be transmitted through saliva or respiratory droplets. Infection confers immunity against reinfection by a particular strain. Over time an individual may develop immunity against numerous enterovirus types but still remain susceptible to additional strains.

Clinical Features

In all three clinical patterns, the severity varies by strain. Most strains produce a self-limiting disease that requires no therapy, but some strains can produce epidemics with significant complications and occasional fatalities. Potential complications include pneumonia, pulmonary edema and hemorrhage, carditis, encephalitis, meningitis, and acute flaccid myelitis. In particular, the latter has been associated with several recent enterovirus outbreaks around the world and represents a severe neurologic illness characterized by profound muscle weakness, spinal cord gray matter abnormalities, and a predilection for children. In addition, infection with coxsackievirus B during pregnancy has been associated with fetal and neonatal death, whereas cardiac anomalies have been noted in infants who survive the initial infection.

Herpangina

Herpangina begins with an acute onset of sore throat, dysphagia, and fever, occasionally accompanied by cough, rhinorrhea, anorexia, vomiting, diarrhea, myalgia, and headache. Most cases, however, are mild or subclinical. Typically a small number of lesions (usually two to six) develop on the soft palate or tonsillar pillars (Fig. 7.24). The lesions begin as red macules, which form fragile vesicles that rapidly ulcerate. The ulcerations average 2–4 mm in diameter. The systemic symptoms resolve within a few days; the ulcerations usually take 7–10 days to heal.

Hand-Foot-and-Mouth Disease

Hand-foot-and-mouth disease is the best-known presentation of enterovirus infection. The name fairly well describes the location of the lesions. The oral lesions arise without

dentlearn.ir

• **Fig. 7.24 Herpangina.** Numerous aphthous-like ulcerations of the soft palate.

• **Fig. 7.26 Hand-foot-and-mouth Disease.** Numerous cutaneous vesicles on the sides of the fingers.

• **Fig. 7.25 Hand-foot-and-mouth Disease.** Multiple vesicles of the skin of the toe. (Courtesy of Dr. Samuel J. Jasper.)

• **Fig. 7.27 Hand-foot-and-mouth Disease.** Multiple aphthous-like ulcerations of the mucobuccal fold.

prodromal symptoms and precede the development of the cutaneous lesions on the hands and feet. Sore throat, dysphagia, and mild fever usually are present also. Other possible findings include cough, rhinorrhea, anorexia, vomiting, diarrhea, myalgia, and headache.

The cutaneous lesions range from a few to dozens and primarily affect the borders of the palms and soles and the ventral surfaces and sides of the fingers and toes (Fig. 7.25). Rarely other sites, especially the buttocks, external genitals, and legs, may be involved. The cutaneous lesions begin as erythematous macules that develop central vesicles and heal without crusting (Fig. 7.26). In some cases, nail loss or ridges (Beau lines) may ensue after several weeks.

The oral lesions resemble those of herpangina but may be more numerous and more frequently involve anterior regions of the mouth. The number of lesions ranges from 1 to 30. The buccal mucosa, labial mucosa, and tongue are the most common sites, but any area of the oral mucosa may be involved (Fig. 7.27). The individual lesions typically measure 2–7 mm in diameter but may be larger than 1 cm. The lesions rapidly ulcerate and then typically heal within 1 week.

Coxsackie A6 infection may cause hand-foot-and-mouth disease with atypical features. Such cases occur over an unusually broad age range, including children as well as adults. Compared to those with conventional disease, affected patients may exhibit a higher fever; more severe and widespread skin lesions (including vesicles, bullae, erosions, ulcers, and hemorrhagic lesions); and a longer disease course (approximately 2 weeks). Also, after recovery some patients exhibit delayed-onset palmar and plantar desquamation, nail loss, and Beau lines.

Acute Lymphonodular Pharyngitis

Acute lymphonodular pharyngitis is characterized by sore throat, fever, and mild headache, which may last from 4 to 14 days. Low numbers (one to five) of yellow to dark-pink nodules develop on the soft palate or tonsillar pillars (Fig. 7.28). The nodules represent hyperplastic lymphoid aggregates and resolve within 10 days without vesiculation or ulceration.

Histopathologic Features

In patients with herpangina and hand-foot-and-mouth disease, the affected epithelium exhibits intracellular and intercellular edema, which lead to the formation of an

dentlearn.ir

• **Fig. 7.28 Acute Lymphonodular Pharyngitis.** Numerous dark-pink and yellow lymphoid aggregates. (Courtesy of Dr. George Blozis.)

intraepithelial vesicle. The vesicle enlarges and ruptures through the epithelial basal cell layer, with formation of a subepithelial vesicle. Epithelial necrosis and ulceration soon follow. Inclusion bodies and multinucleated epithelial cells are absent.

Diagnosis

Herpangina, hand-foot-and-mouth disease, and acute lymphonodular pharyngitis usually are diagnosed based upon the clinical manifestations. In patients with atypical presentations, laboratory confirmation appears prudent. Reverse transcription polymerase chain reaction (RT-PCR) is preferred over viral culture because of its higher sensitivity. Testing can be performed on various specimen types, including throat swabs, rectal swabs, stool samples, and cutaneous vesicular fluid.

Treatment and Prognosis

In most instances, enterovirus infections are self-limiting and without significant complications. Therapy is directed toward symptomatic relief; nonaspirin antipyretics and topical anesthetics, such as dyclonine hydrochloride, often are beneficial.

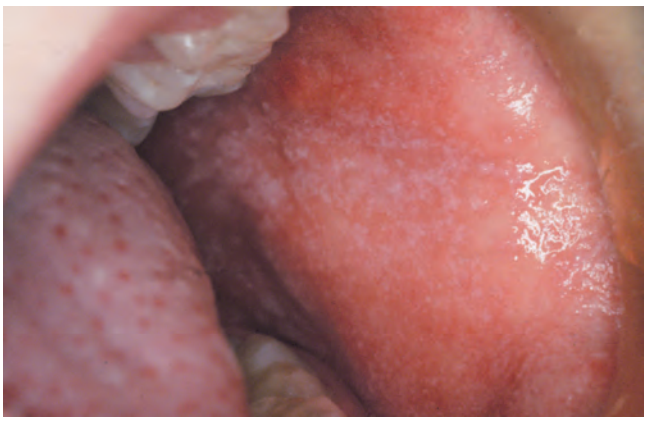
Occasionally, certain strains produce infections with a more aggressive clinical course. Body temperature above 102 °F, fever for longer than 3 days, severe vomiting, and lethargy have been associated with increased risk for serious disease complications and warrant close patient monitoring.

◆ MEASLES (RUBEOLA)

Measles (rubeola) is a highly contagious infection produced by a virus in the family Paramyxoviridae and genus *Morbillivirus*. Prior to the development of an effective measles vaccine, the disease caused millions of deaths annually worldwide. In the pre-vaccine era in the United States, greater than 90% of individuals were infected by 15 years of age, with over 500,000 measles cases and about 500 measles-related deaths reported annually. In susceptible populations, each infected person typically transmits the infection to 9–18 other individuals; there is a 90% chance that an exposed, nonimmune individual will contract the disease.

Eradication through widespread immunization is achievable yet remains a challenge. In the United States, following the introduction of universal measles vaccination in 1963, the annual incidence of measles decreased by more than 99%. A major resurgence occurred from 1989 to 1999, mainly among unvaccinated preschool-aged children. This resurgence led to the recommendation for a second vaccine dose and intensive, widespread immunization efforts. In 2000, the CDC declared that measles had been eliminated in the United States. Nevertheless, outbreaks of measles—often linked to importation of the virus from abroad with subsequent spread through undervaccinated subpopulations—continue to occur. Of particular concern, a major outbreak in 2019 represented the greatest number of reported annual cases in the United States in nearly three decades. Likewise, international efforts toward measles elimination have made progress but are ongoing. Despite an estimated 80% decrease in global measles deaths from 2000 to 2017, the disease continues to claim more than 100,000 lives per year worldwide. Political, financial, and logistical barriers as well as public complacency and concerns regarding vaccine safety have made measles control difficult.

Clinical Features



Most cases of measles arise in late winter or spring and are spread through respiratory droplets or aerosolized particles. The average incubation period is 10–14 days, and affected individuals are infectious from 4 days before until 4 days after appearance of the associated rash. The virus is associated with significant lymphoid hyperplasia that often involves the lymph nodes, tonsils, adenoids, and Peyer patches.

There are three stages of infection, with each stage lasting 3 days—hence the designation 9-day measles. The first 3 days are dominated by the "3 Cs": coryza (runny nose), cough (typically brassy and uncomfortable), and conjunctivitis (red, watery, and photophobic eyes). Fever typically accompanies these symptoms. During this initial stage, the most distinctive oral manifestation, **Koplik spots**, is seen. These lesions represent foci of epithelial necrosis and appear as numerous small, blue-white macules (or "grains of salt") surrounded by erythema (Fig. 7.29). Typical sites of involvement include the buccal and labial mucosa, and less often the soft palate.

As the second stage begins, the fever continues, the Koplik spots fade, and a maculopapular and erythematous (morbilliform) rash begins. The face is involved first, with eventual downward spread to the trunk and extremities. Ultimately, a diffuse erythematous eruption is formed, which tends to blanch on pressure (Fig. 7.30). Abdominal pain secondary to lymphatic involvement is not rare.

In the third stage, the fever ends. The rash begins to fade, with downward progression and replacement by brown

dentlearn.ir

pigmentation. Ultimately, desquamation of the skin is noted in areas previously affected by the rash.

Complications affect approximately 30% of patients, especially those who are younger than 5 years, older than 20 years, malnourished, or immunocompromised. Common complications in young children are otitis media, pneumonia, laryngotracheobronchitis (croup), and diarrhea. Another fairly common sequela is keratoconjunctivitis, which tends to affect children with vitamin A deficiency and may cause blindness. Acute appendicitis occasionally is seen secondary to vascular obstruction created by the swelling of Peyer patches. Encephalitis develops in approximately 1 in 1000 cases, often resulting in death or permanent brain damage and intellectual disability. In about 1 in 10,000–100,000 cases, a delayed complication termed **subacute sclerosing panencephalitis (SSPE)** arises as late as 11 years after the initial infection. This degenerative CNS disorder leads to personality changes, seizures, coma, and death. During pregnancy, measles is associated with an increased risk for intrauterine fetal death, spontaneous abortion, low birthweight, and maternal death.

Measles in immunocompromised patients can be serious, with a high risk for complications and death. Most of these patients exhibit either an atypical rash or no exanthem. Pneumonitis is the primary complication.

• **Fig. 7.31 Rubeola.** Histopathologic section of pharyngeal tonsil demonstrating lymphoid hyperplasia with scattered multinucleated giant cells. *Inset* reveals high-power magnification of Warthin-Finkeldey giant cells.

Koplik spots are not the only oral manifestation that may be associated with measles. Candidiasis, necrotizing gingivitis, and necrotizing stomatitis may occur if significant malnutrition also is present. Severe measles in early childhood can cause pitted enamel hypoplasia of the developing permanent teeth. Enlargement of accessory lymphoid tissues, such as the lingual and pharyngeal tonsils, also may be noted.

Histopathologic Features

Because of the reduced prevalence of measles and the transient nature of Koplik spots, few oral and maxillofacial pathologists have had the opportunity to view these lesions microscopically. Initially, Koplik spots represent areas of hyperparakeratotic epithelium with spongiosis, dyskeratosis, and epithelial syncytial giant cells. The number of nuclei within these giant cells ranges from 3 to more than 25. Close examination of the epithelial cells often reveals pink-staining inclusions in the nuclei or, less commonly, cytoplasm. Electron microscopy has shown that the inclusions represent microtubular aggregates characteristic of paramyxovirus infection. As the spot ages, the epithelium exhibits heavy neutrophilic exocytosis leading to microabscess formation, epithelial necrosis, and, ultimately, ulceration. Frequently, examination of the epithelium adjacent to the ulceration reveals the suggestive syncytial giant cells.

Examination of hyperplastic lymphoid tissue during the prodromal stage of measles often reveals a similar alteration. In 1931, Warthin and Finkeldey, in two separate publications, reported an unusual finding in patients who had their tonsils removed within 1–5 days of the clinical appearance of measles. Within the hyperplastic lymphoid tissue, there were numerous multinucleated giant lymphocytes (Fig. 7.31). These multinucleated cells subsequently have been termed **Warthin-Finkeldey giant cells** and once were thought to be specific for measles. However, similar cells have been

dentlearn.ir

noted in a variety of conditions, such as lymphoma, Kimura disease, AIDS-related lymphoproliferative disease, and lupus erythematosus.

Diagnosis

The diagnosis of measles in an epidemic setting usually is based on the clinical features and history. Laboratory confirmation can be of value in isolated or atypical cases. The most commonly used method is IgM antibody assay performed on a single serum sample. The antibodies usually appear within 72 hours after onset of the exanthem and persist for 1–2 months. Confirmation by rising IgG titers, viral culture, and RT-PCR also are possible.

Treatment and Prognosis

Primary prevention is essential for reducing measles-associated morbidity and mortality. The measles vaccine is a live, attenuated virus, which is included in the widely used MMR (measles, mumps, and rubella) and MMRV (measles, mumps, rubella, and varicella) vaccines. Routine childhood measles vaccination is recommended, with the first dose administered between the ages of 12 and 15 months and a second dose between the ages of 4 and 6 years. The vaccine is highly effective, with over 99% of individuals developing long-term immunity after receiving two doses. In a given population, measles eradication typically is attained with 95% vaccine coverage. Despite controversy regarding vaccine safety, adverse reactions from measles vaccination are rare and typically mild or transient. Extensive research shows no increased risk of permanent neurologic sequelae, and no scientific evidence supports an increased risk for autism or inflammatory bowel disease.

In otherwise healthy patients with measles, fluids and nonaspirin antipyretics are recommended for symptomatic relief. Antibiotics may be prescribed for bacterial superinfections, such as bacterial otitis media or pneumonia. Children with measles also should receive vitamin A supplementation. For immunocompromised patients, ribavirin and interferon may be administered.

In developed nations, less than 1% of measles cases result in death, whereas in developing countries, the case-fatality rate is usually about 3% to 6%. However, mortality can be as high as 30% among displaced or isolated populations with poor vaccine coverage and approximately 50% among HIV-infected children. The most common causes of death are pneumonia and acute encephalitis.

◆ RUBELLA (GERMAN MEASLES)

Rubella is a mild illness caused by a virus in the family Togaviridae and genus *Rubivirus.* The greatest importance of this infection lies not in its effects on those who contract the acute illness but in its capacity to induce birth defects in the developing fetus. The infection occurs primarily in late winter and early spring. It is contracted through respiratory droplets, with nearly 100% transmission among individuals in close living conditions. The incubation time is from 12 to 23 days, and infected patients are contagious from 1 week before to 1 week after onset of the exanthem. Infants with congenital infection may release the virus for up to 1 year and, in some cases, may continue to harbor intraocular virus for decades.

In the past, this infection occurred in cycles, with localized epidemics every 6–9 years and pandemics every 10–30 years. The last pandemic occurred from 1962 to 1964. In 1964 and 1965, the United States alone had more than 12.5 million cases, which resulted in more than 11,000 spontaneous or therapeutic abortions, 2100 neonatal deaths, and 20,000 infants born with **congenital rubella syndrome (CRS)**.

An effective vaccine, first released in 1969, has dramatically affected the epidemiology of the infection and broken the cycle of occurrences. In the United States, during the two decades immediately following introduction of the vaccine, the number of rubella and CRS cases reported annually decreased 99% and 97%, respectively. Like rubeola, rubella exhibited a slight resurgence from 1989 to 1990, primarily due to a lack of vaccination diligence; this resurgence prompted intensification of vaccination efforts and a new two-dose schedule. These measures resulted in an overall decline in rubella cases but a shift in epidemiology. During the early 1990s, children younger than 15 years mainly were affected; however, since the mid-1990s, most reported rubella cases have occurred in patients 15 years and older, especially among Hispanic and foreign-born individuals. Notwithstanding, since 2001, the overall annual incidence has remained low (less than 1 per 10,000,000 population). In 2004, a panel of experts declared that rubella elimination (i.e., absence of endemic transmission) had been achieved in the United States. However, rubella remains endemic in several parts of the world, with more than 100,000 infants with CRS born annually worldwide.

Clinical Features

A large percentage of infections are asymptomatic; the frequency of symptoms is greater in adolescents and adults. Prodromal symptoms may be seen 1–5 days before the exanthem and include fever, headache, malaise, anorexia, myalgia, mild conjunctivitis, coryza, pharyngitis, cough, and lymphadenopathy. The lymphadenopathy may persist for weeks and is noted primarily in the suboccipital, postauricular, and cervical chains. The most common complication is arthritis, which increases in frequency with age and usually arises subsequent to the rash. Rare complications include encephalitis and thrombocytopenia.

The rash is often the first sign of the infection and begins on the face and neck, with spread to the entire body within 1–3 days. The exanthem forms discrete pink macules, then papules, and finally fades with flaky desquamation. Facial involvement often clears before the rash completes its spread into the lower body areas. Generally, the rash completely resolves by day 3—hence the designation 3-day measles.

dentlearn.ir

Oral lesions, known as **Forchheimer sign,** have been reported in about 20% of cases. These lesions consist of small, discrete, dark-red papules that develop on the soft palate and may extend onto the hard palate. This enanthem arises simultaneously with the rash, becoming evident in about 6 hours after the first symptoms and not lasting longer than 12–14 hours. Palatal petechiae also may occur.

The risk of CRS correlates with the time of infection. The risk for fetal defects is as high as 90% when the infection occurs during the first 8–10 weeks of pregnancy, with the risk declining thereafter and becoming rare after 16 weeks of gestation. The classic triad of CRS consists of sensorineural deafness, heart disease, and cataracts. Hearing loss may not become evident until 2 years of age and usually is bilateral. Other frequently reported findings include microcephaly, microphthalmia, and hepatosplenomegaly. Among those who survive the neonatal period, there is an increased risk for developmental difficulties, such as autism. Less common, late-emerging complications include diabetes mellitus, thyroiditis, and progressive encephalopathy.

Diagnosis

The diagnosis of rubella is contingent on laboratory tests because the clinical presentation of the acquired infection is typically subclinical, mild, or nonspecific. Serologic analysis is the mainstay of diagnosis, although viral culture and RT-PCR also are possible.

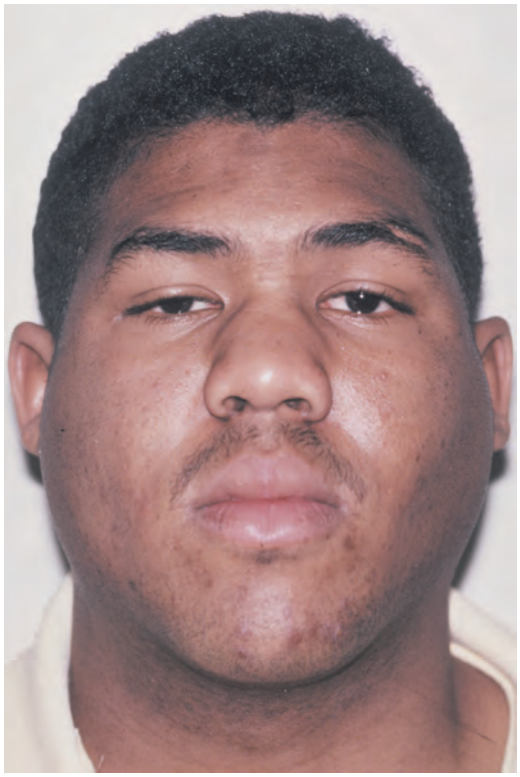
Treatment and Prognosis

Rubella is mild, and therapy usually is not required. Nonaspirin antipyretics and antipruritics may be useful in patients with significant fever or symptomatic cutaneous involvement. Passive immunity may be provided by the administration of rubella immunoglobulin. If immunoglobulin is given within a few days of exposure, it decreases the severity of the infection. This therapy typically is reserved for pregnant patients who decline abortion.

High vaccination coverage—particularly among children, women of childbearing age, and foreign-born individuals—is essential for prevention of rubella. In the United States, both the MMR (measles, mumps, and rubella) and MMRV (measles, mumps, rubella, and varicella) vaccines are licensed for rubella prevention. Routine childhood administration of either MMR or MMRV is recommended, with the first dose at 12–15 months of age and the second dose at 4–6 years of age. In addition, in the absence of evidence of rubella immunity, the following groups should receive at least one dose of MMR: adults born during or after 1957, nonpregnant women of childbearing age, and health care personnel. Evidence of immunity may include serologic testing or documentation of at least one dose of rubella-containing vaccine at 12 months of age or older; immunity also generally can be presumed in those born before 1957, as long as the individual is not a health care worker. Contraindications for the MMR and MMRV vaccines include pregnancy, immunodeficiency, allergy to any of the vaccine components, and acute febrile illness. Pregnant women lacking immunity should be vaccinated immediately postpartum.

◆ MUMPS (EPIDEMIC PAROTITIS)

Mumps is an infection caused by a virus in the family Paramyxoviridae and genus *Rubulavirus*. This infection causes diffuse swelling of the exocrine glands; although the salivary glands are the best known sites of involvement, the pancreas, choroid plexus, and mature ovaries and testes also are affected frequently. The virus can be transmitted through respiratory droplets, saliva, and urine. The incubation period usually is 16–18 days, with a range of about 2–4 weeks. Patients are contagious from 1 day before the clinical appearance of infection to 14 days after its clinical resolution. In temperate climates, mumps most commonly occurs in winter and spring.



As with measles and rubella, the epidemiology has been affected dramatically by vaccination. Before the advent of widespread vaccination, mumps epidemics developed every 2–5 years; nearly everyone was exposed with 90% of infections occurring before age 15. In the United States, the mumps vaccine was licensed in 1967, although the Advisory Committee on Immunization Practices (ACIP) did not recommend universal childhood mumps vaccination until 1977. At that time, MMR (measles, mumps, and rubella) vaccine administration became the norm for children 12–15 months of age. Subsequently, the annual incidence of mumps decreased by 98% and reached an all-time low in 1985. In 1989, the ACIP issued a two-dose recommendation for MMR vaccination, primarily in response to a resurgence of measles. Compared with the prevaccine era, the two-dose vaccination schedule has reduced the prevalence of mumps by more than 99%.

Nevertheless, several mumps resurgences have occurred over the past several decades. These resurgences often have developed among adolescents and young adults, particularly in the college setting. This shift in peak age from childhood to adolescence and young adulthood is clinically significant, because certain disease complications, such as epididymo-orchitis and oophoritis, primarily affect postpubertal patients. Although outbreaks in the mid-1980s to early 1990s were attributed to single-dose vaccine failure or a lack of vaccination, several outbreaks since the early 2000s have occurred despite high levels of two-dose vaccine coverage. The efficacy of the mumps component of the MMR vaccine is approximately 88% after two doses and is lower than that of the measles and rubella components. In 2017, the ACIP recommended a third dose of MMR vaccine for persons who have received 2 doses previously and are at increased risk for acquiring mumps during an outbreak.

Clinical Features

Approximately 30% of mumps infections are subclinical. In symptomatic cases, prodromal symptoms of low-grade fever, headache, malaise, anorexia, and myalgia develop first. These

dentlearn.ir

• **Fig. 7.32 Mumps.** Bilateral parotid enlargement. (From Neville BW, Damm DD, White DK: *Color atlas of clinical oral pathology,* ed 2, Hamilton, 1999, BC Decker.)

nonspecific findings typically are followed within a few days by significant salivary gland changes. The parotid glands are involved most often, but the sublingual and submandibular glands also can be affected. Discomfort and swelling develop in the tissues surrounding the lower half of the external ear and extending down along the posterior inferior border of the adjacent mandible (Fig. 7.32). The enlargement and pain typically peak within 2–3 days. Chewing movements of the jaw or eating saliva-stimulating foods tends to increase the pain. Enlargement of the glands usually begins on one side, followed by contralateral involvement within a few days. Unilateral involvement is seen in about 25% of patients.

The second most common finding is epididymo-orchitis, which occurs in about 25% of postpubertal males. The testicle exhibits rapid swelling, with significant pain and tenderness. The enlargement can range from a minimal swelling to a fourfold increase in size. Unilateral involvement is most common. Upon resolution of the swelling, testicular atrophy may occur; permanent sterility is rare, but subfertility develops in approximately 13% of patients with epididymyo-orchitis. Less commonly, oophoritis and mastitis can be seen in postpubertal females. In addition, spontaneous abortion occurs in approximately 25% of women who contract mumps during the first trimester of pregnancy.

Less commonly, meningoencephalitis, cerebellar ataxia, hearing loss, pancreatitis, arthritis, carditis, and decreased renal function may occur. The most common symptom associated with CNS involvement is headache, whereas involvement of the pancreas can lead to nausea and vomiting. Isolated changes, such as orchitis or meningitis, may occur in the absence of salivary gland involvement, thereby making diagnosis difficult in nonepidemic settings.

The most frequently reported oral manifestation is redness and enlargement of Wharton and Stensen salivary gland duct openings. In addition, involvement of the sublingual glands may produce bilateral enlargement of the floor of the mouth.

Diagnosis

Although the diagnosis of mumps in an epidemic setting usually can be made easily from the clinical presentation, isolated cases often require laboratory confirmation. Serologic tests include detection of either mumps-specific IgM or a fourfold rise of mumps-specific IgG titers between the acute and convalescent phases; however, false-negative results are common in previously vaccinated individuals. In addition, a swab of secretions obtained from parotid or other affected salivary gland ducts can be used for viral culture or RT-PCR.

Treatment and Prognosis

The treatment of mumps is palliative in nature. Frequently, nonaspirin analgesics and antipyretics are administered. In an attempt to minimize orchitis, bed rest is recommended for males until the fever breaks. Avoidance of sour foods and drinks helps to decrease the salivary gland discomfort. Mumps-related mortality is exceedingly rare and primarily associated with encephalitis.

As with measles and rubella, vaccination is important for controlling disease. The mumps vaccine is a live, attenuated virus, which is incorporated into the MMR and MMRV (measles, mumps, rubella, and varicella) vaccines. Monovalent mumps vaccine is no longer available in the United States. The current recommendation is for routine childhood administration of two doses of mumps-containing vaccine, with the first dose administered between the ages of 12 and 15 months and the second dose between the ages of 4 and 6 years. In addition, two doses of MMR vaccine should be administered to adults who lack immunity and fall into any of the following categories: health care workers born in or after 1957, college students, and international travelers. One dose of MMR vaccine is recommended for all other adults who lack evidence of immunity and were born in or after 1957.

◆ HUMAN IMMUNODEFICIENCY VIRUS AND ACQUIRED IMMUNODEFICIENCY SYNDROME

This section provides an overview of **human immunodeficiency virus (HIV)** and its related disease states, with an emphasis on manifestations in the oral region. For more detailed information regarding HIV infection and **acquired**

dentlearn.ir

immunodeficiency syndrome (AIDS), the reader may refer to a large body of scientific literature and entire texts dedicated to this topic.

HIV is a single-stranded RNA virus belonging to the family Retroviridae. There are two species: HIV-1 and HIV-2. The former exhibits a worldwide distribution and is responsible for the majority of cases, whereas the latter predominates in western Africa and is associated with a somewhat lower risk of transmission and slower disease progression.

In 1981, the CDC published the first scientific report of AIDS. This report detailed *Pneumocystis carinii* (since renamed *Pneumocystis jiroveci*) pneumonia in five previously healthy men from Los Angeles, California. A few years later, HIV was isolated and identified as the cause of AIDS. Since this initial description, more than 75 million individuals worldwide have become infected with HIV, and more than 32 million individuals have died of AIDS. Worldwide in 2020 alone, approximately 1.5 million new infections occurred, 38 million people were living with HIV, and 680,000 individuals died of AIDS-related illnesses. According to the most recent report by the Joint United Nations Programme on HIV/AIDS, HIV infection is most prevalent in Eastern and Southern Africa—which accounts for approximately 54% of people living with HIV worldwide and more than 40% of global AIDS deaths—followed by the Asia-Pacific region and Western and Central Africa. The toll has been devastating, although through global public health efforts and treatment advances, there has been an approximately 23% decline in the number of newly infected individuals worldwide over the past decade. Despite the considerable progress that has been made, HIV control efforts continue to be hampered by significant challenges, including socioeconomic disparities, social inequality, limited access to care, and disruption by the coronavirus disease 2019 (see page 265) pandemic.

The annual number of new HIV infections in the United States peaked in the mid-1980s at around 130,000 and subsequently sharply declined to about 50,000 in the early 1990s. In recent years, the number of new HIV infections diagnosed annually has remained relatively stable at around 36,000–38,000. Currently, it is estimated that 1.2 million individuals are living with HIV infection in the United States, and about 14% of them are unaware of their infection. At the beginning of the HIV/AIDS epidemic, the disease was nearly 100% fatal; however, since the introduction of effective antiretroviral therapy (ART) (see the Treatment and Prognosis section), there has been significant improvement in patient survival and, thus, an increased percentage of the population living with the virus.

Initially, in the United States, HIV primarily infected whites and male homosexuals. Today, male-to-male sexual contact remains the greatest risk factor; however, the epidemiology of the HIV/AIDS epidemic has shifted over time, with the highest incidence now recorded among blacks and Hispanics. In 2019, blacks represented only about 13% of the population but accounted for 44% of new HIV diagnoses. Similarly, Hispanics were disproportionately affected, with this group accounting for about 18% of the population but 30% of new HIV infections. Factors contributing to these disparities may include poverty; limited access to health care and HIV education; cultural and language barriers; lack of awareness of HIV status; high rates of other sexually transmitted infections (such as HSV-2 infection) that may increase the risk of contracting HIV; and avoidance of testing and treatment for fear of discrimination. Among newly diagnosed cases of HIV in adults and adolescents in the United States in 2019, approximately 79% were male, 19% were female, and 2% were transgender. The latter group comprised a very small proportion of cases but recently exhibited a sharply increasing trend. With respect to age, the greatest incidence was noted among individuals 20 through 29 years old.

In infected individuals, the virus can be found in most bodily fluids, including serum, blood, saliva, semen, tears, urine, breast milk, ear secretions, and vaginal secretions. In the United States, the most frequent mode of transmission is male-to-male sexual contact (accounting for approximately two-thirds of HIV infections diagnosed annually), followed by heterosexual contact and injection drug use. Perinatal exposure and transfusion of blood or blood products account for a very small proportion (1% and less than 0.5%, respectively) of current cases; these modes of transmission have become rare due to improvements in perinatal testing, prophylactic use of antivirals, blood-screening methods, and availability of recombinant clotting factors. Infection by artificial insemination, breast-feeding from infected mothers, and organ transplantation also has been documented rarely.

Transmission by oral fluids is somewhat controversial and has been reported only anecdotally. In rare instances, transmission has occurred during breast-feeding from the oral fluids of postpartum infected infants to their previously noninfected mothers. Unusual cases of transmission from bites, oral cunnilingus, or repeated passionate kissing have been described as well. Saliva contains a number of HIV inhibitory factors, which appear to reduce the ability of the virus to infect its target cells. However, the presence of erosions, ulcerations, and hemorrhagic inflammatory pathoses (e.g., gingivitis, periodontitis) may predispose an individual to oral transmission. In summary, the best precaution is avoidance of all body fluids of infected patients.

The primary target cell of HIV is the CD4+ helper T lymphocyte, although other CD4+ cells (such as, macrophages and dendritic cells) may be infected as well. The virus binds to CD4 and additional cell surface molecules in order to gain entry, upon which the viral RNA genome is reverse transcribed into complementary DNA. This complementary DNA may become incorporated into the host cell DNA. Upon transmission, the virus initially takes hold in the mucosa, within days spreads to the lymphoid tissues, and by around day 10 becomes detectable within blood. Viremia usually peaks around a month after transmission; however, the incubation period is variable, and it may take anywhere from several weeks to months before antibodies are demonstrable. In people with HIV infection, antibodies against the

dentlearn.ir

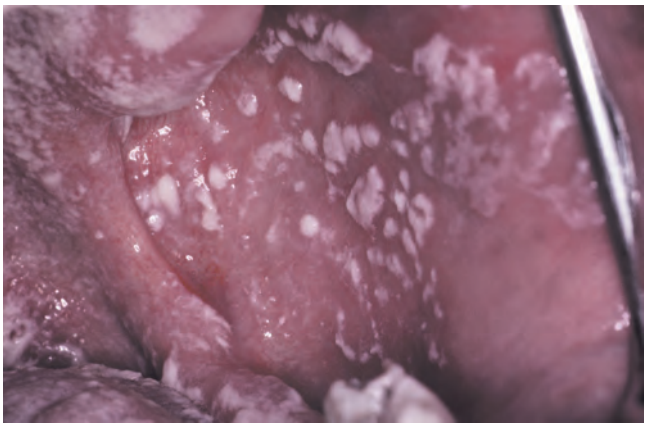
virus are developed but are not protective. The virus then enters a latency period, during which replication may stabilize at a relatively low level but nevertheless continues. During this period, many patients are asymptomatic. The mean clinical latency among untreated individuals is 10 years; however, the duration is variable and typically can be maintained for much longer time periods by administration of ART. Among untreated individuals or those for whom therapy does not control the virus, there is a progressive loss of T-helper cells with resultant immunodeficiency. The normal response to viruses, fungi, and encapsulated bacteria is diminished. In addition, infection of macrophages and microglia in the CNS may lead to neurologic disease manifestations.

Clinical Features

The clinical stages of HIV infection include an acute phase, a chronic phase (or latency period), and AIDS. During the acute phase, the patient may be asymptomatic or exhibit a self-limited **acute retroviral syndrome.** This syndrome typically develops around 3–6 weeks after exposure in 50%–70% of infected patients. The symptoms resemble those of infectious mononucleosis (e.g., generalized lymphadenopathy, sore throat, fever, malaise, lethargy, maculopapular rash, headache, myalgia, arthralgia, diarrhea, photophobia, and peripheral neuropathies). Meningitis and encephalitis also are possible. Oral changes may include mucosal erythema and focal ulcerations. During this initial phase, HIV infection often is not considered or investigated, and HIV antibodies are not yet detectable. Nevertheless, during this period, patients exhibit high levels of viremia and are extremely infectious.

After infection is established, an immune response is developed, viremia declines, and the patient enters a clinical latency period. During this time, most patients are asymptomatic, but some exhibit persistent generalized lymphadenopathy (PGL). Without treatment, the immune system fails to control the virus, and the CD4+ cell count declines at an average rate of 50 per microliter per year. When the CD4+ cell count falls below a critical level (200 per microliter for individuals 6 years and older), there is severe immunodeficiency, resulting in the development of AIDS. During this stage, patients are at high risk for opportunistic infections or neoplasms. Such infections include *Pneumocystis jiroveci* pneumonia, disseminated cytomegalovirus infection, severe herpes simplex virus infection, atypical mycobacterial infection, cryptococcal meningitis, and CNS toxoplasmosis. In addition, persistent diarrhea is commonplace and may be bacterial or protozoal in origin. Neoplasms considered to be AIDS-defining conditions include Kaposi sarcoma, non-Hodgkin lymphoma, and invasive cancer of the uterine cervix. Furthermore, clinically significant neurologic dysfunction may result from a form of progressive encephalopathy known as HIV-associated dementia (AIDS-dementia complex).

Since the widespread use of effective ART and guidelines for the prevention of opportunistic infections, the spectrum of HIV disease has evolved. Opportunistic infections have become much less common compared to the early days of the HIV epidemic. Also, with increased longevity among the HIV-infected population, there have been shifts in cancer burden. The risk for AIDS-defining cancers has decreased—especially for Kaposi sarcoma and non-Hodgkin lymphoma—apparently because improvement of immune function with ART suppresses the viruses associated with these malignancies. In contrast, the risk for various non-AIDS-defining cancers as well as cardiovascular, renal, and hepatic disease has increased.



Oral manifestations of HIV disease also have been altered dramatically by the introduction of potent ART. In particular, there have been significant reductions in the frequency of oral candidiasis, OHL, and oral Kaposi sarcoma. In contrast, an increased prevalence of periodontitis has been reported, although this finding may be explained by aging of the patient population. Some researchers also have reported an increased prevalence of benign human papillomavirus (HPV)-induced pathoses and HIV-associated salivary gland disease, but other investigators have not confirmed these findings.

Importantly, the detection of oral manifestations may suggest possible HIV infection in an undiagnosed individual. In addition, the discovery of oral manifestations in a patient with known HIV infection may signal HIV disease progression and the need for initiation or adjustment of ART.

The following discussion of oral manifestations concentrates primarily on the clinical presentations and special treatment considerations for HIV-infected patients. (For more detailed information regarding these conditions in the general patient population, see the discussion of each disease elsewhere in this text.) Oral conditions most strongly associated with HIV infection are presented first, followed by a selection of less frequently encountered conditions.

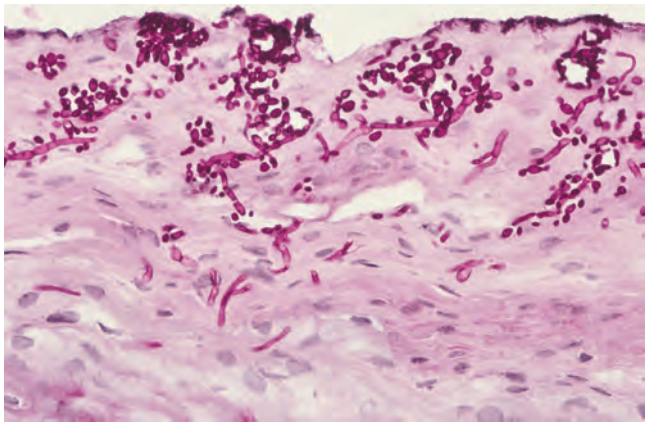
Candidiasis

Candidiasis is the most common intraoral manifestation of HIV infection and often is the presenting sign that leads to the initial diagnosis (Fig. 7.33). Among studies performed

• **Fig. 7.33 HIV-associated Candidiasis.** Extensive removable white plaques of the left buccal mucosa.

dentlearn.ir

in recent decades, the reported prevalence of oral candidiasis in HIV-infected individuals ranges from about 20% to 80%. The prevalence is lower in patients receiving ART compared to those not receiving such treatment. In particular, HIV protease inhibitors used in ART have been associated with reduced frequency and recurrence of oral candidiasis. For HIV-positive patients not receiving ART, the presence of oral candidiasis is predictive of progression to full-blown AIDS within 2 years. Compared to individuals with other types of immunocompromised status, those with HIV infection have a greater prevalence of oral candidiasis, suggesting that HIV may play a role in initiation of candidal infection. In addition, among HIV-infected groups in resource-limited settings, investigators have noted a strong association between oral candidiasis and tuberculosis—a leading cause of mortality in HIV-positive patients. The most common candidal species isolated from the oral mucosa of HIV-positive patients is *Candida albicans*, although various other *Candida* species may be encountered.



The following four clinical patterns are seen (see page 201):

1. Pseudomembranous candidiasis
2. Erythematous candidiasis
3. Hyperplastic candidiasis
4. Angular cheilitis

The first two variants constitute most cases. Although infrequently seen in immunocompetent patients, chronic multifocal oral involvement is common in HIV-infected patients. Erythematous candidiasis typically appears when the CD4+ lymphocyte count drops below 400 cells per microliter, whereas the pseudomembranous pattern usually develops when the count drops below 200 cells per microliter. Oral candidiasis can be painful and associated with a reduction in taste and smell, which may lead to decreased food intake and further wasting. In severe cases, patients may develop oral, oropharyngeal, and esophageal involvement; such individuals may experience retrosternal burning accompanied by odynophagia.

The diagnosis of candidiasis often is obvious from the clinical presentation but can be confirmed by cytologic smear or biopsy. Biopsy specimens of involved mucosa demonstrate the candidal organisms embedded in the superficial keratin, but the typical inflammatory reaction may be deficient (Fig. 7.34).

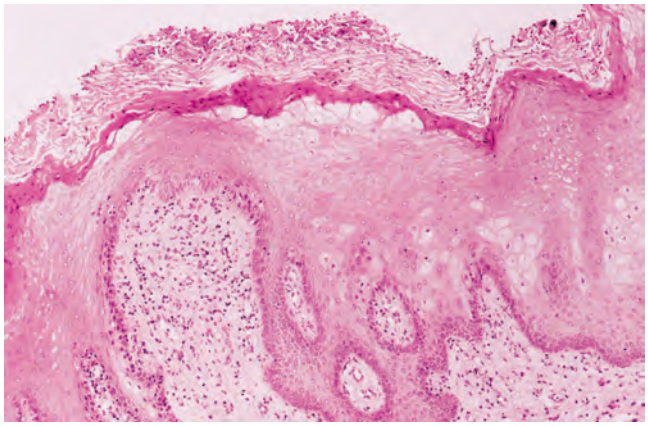
For the treatment of oral candidiasis in HIV-infected individuals, oral antifungal agents typically are preferred over topical therapy because they are more convenient, better tolerated, and associated with a lower risk for relapse. Fluconazole generally is the drug of choice and is prescribed for 1–2 weeks; for patients who also suffer from esophageal involvement, this medication is administered for 3 weeks. When there is concern regarding adverse side effects or drug interactions with systemic therapy, the patient may be treated with topical agents, such as miconazole mucoadhesive buccal tablets or clotrimazole troches. For patients with refractory disease, itraconazole oral solution, posoconazole oral suspension, amphotericin B oral solution (not available in the United States), or intravenous amphotericin B may be considered.

• **Fig. 7.34 HIV-associated Candidiasis.** Periodic acid-Schiff (PAS) stain of histopathologic section exhibiting numerous fungal organisms embedded in superficial keratin.

Routine prophylactic antifungal therapy is not recommended for patients with advanced HIV disease because acute oral candidiasis typically responds well to conventional treatment, prophylaxis is costly, and there is the potential for development of resistant candidal strains. Instead, immune reconstitution by ART is the best method for prevention of oral candidiasis in this patient population. However, for individuals with especially frequent and severe recurrences, prophylactic fluconazole may be considered.

Oral Hairy Leukoplakia

Although EBV is associated with several forms of lymphoma in HIV-infected patients, the most common EBV-related lesion in patients with AIDS is **oral hairy leukoplakia (OHL).** The prevalence of OHL among individuals with HIV has declined since the introduction of effective ART. The development of OHL may indicate HIV disease progression, a lack of compliance with ART, or antiretroviral drug resistance. Among HIV-infected individuals, OHL exhibits a predilection for males and tobacco users. OHL also has been reported in transplant recipients, steroid medication users, and aging individuals. Although the lesion occasionally occurs in relatively immunocompetent individuals, discovery of OHL in "normal" patients mandates a thorough physical evaluation to rule out immunocompromise.



OHL clinically presents as a white mucosal plaque that does not rub off. Most cases occur on the lateral border of the tongue and range in appearance from faint, white vertical streaks to thickened, furrowed areas of leukoplakia with a shaggy surface (Fig. 7.35). The lesions infrequently may extend to cover the entire dorsal and lateral surfaces of the tongue. Rarely, the buccal mucosa, soft palate, pharynx, or esophagus may be involved.

Histopathologically, OHL exhibits thickened parakeratin with surface corrugations or thin projections (Fig. 7.36). The epithelium is acanthotic and exhibits a bandlike zone of lightly stained cells with abundant cytoplasm ("balloon

dentlearn.ir

cells") in the upper spinous layer (Fig. 7.37). Close examination of the superficial epithelial cells reveals nuclear clearing and a characteristic pattern of peripheral margination of chromatin termed nuclear beading (see Fig. 7.38, *inset*), caused by extensive EBV replication that displaces the chromatin to the nuclear margin. Dysplasia is not noted. Heavy candidal infestation of the parakeratin layer may be seen, although the normal inflammatory reaction to the fungus usually is absent.

In a patient with known HIV infection, the clinical features of OHL typically are sufficient for a presumptive diagnosis. When definitive diagnosis is necessary, demonstration of EBV can be achieved by in situ hybridization, PCR, immunohistochemistry (Fig. 7.38), Southern blotting, or electron microscopy.

Treatment of OHL usually is not needed, although slight discomfort or aesthetic concerns may necessitate therapy. Systemic anti-herpesviral drugs produce rapid resolution, but recurrence is expected with discontinuation of therapy. Topical treatment with retinoids or podophyllum resin has resulted in temporary remissions. A few small-scale studies have demonstrated prolonged resolution after combined treatment with acyclovir cream and podophyllum resin. Surgical excision or cryotherapy also has been used by some.

Kaposi Sarcoma

Kaposi sarcoma (KS) is a vascular endothelial neoplasm caused by human herpesvirus 8 (HHV-8, Kaposi sarcoma–associated herpesvirus [KSHV]). Most cases in the United States have arisen in association with HIV infection. At the height of the AIDS epidemic in the early 1990s, the annual incidence of KS in the United States peaked at 4.7 cases per 100,000 population. However, since the introduction of combination ART in 1996, the annual incidence has declined substantially and currently is estimated at 0.5 cases per 100,000 population. Nevertheless, in the United States, HIV-infected individuals are 500 times more likely than the general population to be diagnosed with KS, and KS represents the second most common malignancy among people with AIDS.

In Western countries, KS has been reported primarily in HIV-infected, adult, male homosexuals and is thought to be related to sexual transmission of HHV-8. Some cases also have been reported in male homosexuals without HIV

infection. In Africa both AIDS-related and endemic types of KS frequently are seen, with no gender predilection and a significant number of children affected. Infection before sexual activity suggests alternate transmission pathways. Relatively high titers of HHV-8 have been found in saliva, and HHV-8 exhibits tropism for oral and oropharyngeal epithelial cells; these observations suggest that the oral cavity may represent an important reservoir of infectious virus and saliva may be a major transmission route.

KS mainly manifests as multiple lesions on the skin or oral mucosa, although visceral and lymph node involvement also may occur. Occasionally a solitary lesion is identified first. Among AIDS-related cases, the skin lesions exhibit a predilection for the face (Fig. 7.39) and lower extremities. The oral cavity is the initial site of involvement in 22% of patients with KS, and oral lesions are found more often in AIDS-related KS than other types of KS. Approximately 70% of individuals with AIDS-related KS demonstrate oral lesions at some point. The hard palate, gingiva, and tongue are the most frequently affected oral sites (Figs. 7.40 and 7.41). When present on the palate or gingiva, the neoplasm can invade bone and cause tooth mobility. The lesions

• **Fig. 7.43 HIV-associated Kaposi Sarcoma (KS).** Diffuse, red-blue gingival enlargement with widespread necrosis.

usually begin as erythematous blue or brown macules that do not blanch with pressure. Nonpigmented lesions have been reported very rarely. With time, the macules typically develop into plaques or nodules (Fig. 7.42), which may coalesce into a diffuse, exophytic mass (Fig. 7.43). Pain,

dentlearn.ir

bleeding, and necrosis may necessitate therapy. Uncommonly, advanced oral lesions may cause secondary lymphedema of the face and neck.

A biopsy is required for definitive diagnosis, although a presumptive clinical diagnosis sometimes is made. Other lesions can have a similar clinical appearance in HIV-infected patients, including bacillary angiomatosis (a multifocal vascular proliferation associated with the cat-scratch bacillus [see page 195]) and lymphoma.

Initiation of ART may induce regression of KS lesions, and patients who develop KS despite already receiving ART tend to have relatively mild disease without visceral involvement. Because KS typically regresses upon return of immunocompetence, many researchers question whether KS is a true sarcoma. However, in a small subset of patients, administration of ART causes immune reconstitution inflammatory syndrome (see Treatment and Prognosis section), which may induce paradoxical worsening of KS. Locoregional therapy may be used for limited, asymptomatic mucocutaneous lesions nonresponsive to ART or for palliation of advanced mucocutaneous lesions. Treatment options include topical therapy (e.g., alitretinoin gel or imiquimod cream for skin lesions), intralesional injection of chemotherapeutic or immunomodulatory agents (e.g., vinblastine, vincristine, bleomycin, and interferon-alpha), radiation, surgical excision, cryotherapy (for skin lesions), sclerotherapy, and laser therapy. Radiation therapy generally is not advised for oral lesions because of the potential for severe mucositis. For advanced AIDS-related KS, systemic chemotherapy (e.g., pegylated liposomal doxorubicin, paclitaxel) or immunomodulatory therapy in conjunction with ART is indicated. In addition, some authorities have suggested systemic therapy for oral lesions of AIDS-related KS even at the early macular stage, because progression to the exophytic stage in the oral cavity is associated with a poor prognosis.

Negative prognostic indicators for AIDS-related KS include tumor-associated edema, ulceration, extensive oral disease visceral involvement, CD4+ cell count below 150 per microliter, or other HIV-related illnesses. Interestingly, KS arising in lymph nodes does not necessarily represent metastasis or a poor prognosis. In the United States, the 5-year survival rate for individuals diagnosed with KS in recent years is approximately 70%. However, survival rates are much lower in regions where treatment is not widely available.

Persistent Generalized Lymphadenopathy

After seroconversion, HIV disease often remains silent except for **persistent generalized lymphadenopathy (PGL)**. The prevalence of this early clinical sign varies; however, in several studies it approaches 70%. PGL consists of lymphadenopathy that has been present for longer than 3 months and involves two or more extrainguinal sites. The most frequently involved sites are the posterior and anterior cervical, submandibular, occipital, and axillary nodes. Nodal enlargement fluctuates, usually is larger than 1 cm, and varies from 0.5 to 5.0 cm (Fig. 7.44).

• **Fig. 7.44 HIV-associated Lymphadenopathy.** Enlarged cervical lymph nodes in a patient with persistent generalized lymphadenopathy (PGL).

Because lymphoma is known to occur in this population, a lymph node biopsy may be indicated for localized or bulky adenopathy, when cytopenia or an elevated erythrocyte sedimentation rate is present, or when requested for patient reassurance. Histopathologic examination reveals florid follicular hyperplasia. Although not as predictive as oral candidiasis or OHL, PGL does warn of progression to AIDS; almost one-third of affected and untreated patients will have diagnostic features of AIDS within 5 years.

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma (NHL) currently represents the most common malignancy among HIV-infected people in the United States, with an estimated lifetime risk of 4%. Similar to KS, NHL has become significantly less common among HIV-infected patients since the introduction of effective ART. Nevertheless, HIV-infected individuals in the United States are 12 times more likely to develop NHL compared to the general population. Factors implicated in the etiopathogenesis of these malignancies include suppressed immune surveillance, B-lymphocyte dysregulation, reactivation of oncogenic viruses (such as EBV and HHV-8), chronic antigen stimulation by viral coinfections (such as hepatitis B and hepatitis C), and possibly direct effects of HIV itself. Most cases represent high-grade, aggressive B-cell neoplasms. HIV-associated NHL can be categorized as follows:

1. Lymphomas also occurring in immunocompetent patients (most commonly Burkitt lymphoma and diffuse large B-cell lymphoma; rarely, extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue [MALT lymphoma], peripheral T-cell, and natural killer cell lymphoma)
2. Lymphomas more specifically occurring in HIV-positive patients (e.g., primary effusion lymphoma; plasmablastic lymphoma; and HHV-8-positive diffuse large B-cell lymphoma, not otherwise specified)
3. Lymphoma also occurring in other immunodeficiency states (e.g., cases resembling post-transplant lymphoproliferative disorder [PTLD]).

dentlearn.ir

• **Fig. 7.45 HIV-associated Lymphoma.** Erythematous and ulcerated soft tissue mass involving the right posterior mandibular gingiva and mucobuccal fold.

• **Fig. 7.46 HIV-associated Gingivitis.** Band of erythema involving the free gingival margin.

Lymphoma in patients with AIDS usually occurs in extranodal locations. Oral lesions are seen in approximately 4% of patients with AIDS-related NHL and most frequently involve the gingiva, palate, and tongue (Fig. 7.45). Intraosseous involvement also has been documented and may resemble diffuse progressive periodontitis with loss of periodontal attachment and loosening of teeth. In these cases, widening of the periodontal ligament and loss of lamina dura may represent radiographic clues to the diagnosis.

In order to prevent NHL in HIV-infected individuals, early and sustained ART is recommended. Treatment for HIV-associated NHL usually consists of combination chemotherapy in conjunction with ART. Early in the AIDS epidemic, people with AIDS typically suffered from severe opportunistic infections at the time of lymphoma diagnosis and, thus, could not tolerate intensive chemotherapy. However, with the introduction of ART, there has been a significant reduction in co-morbidity, thereby allowing for intensive lymphoma treatment. Current areas of investigation include immunotherapy and cellular therapies (e.g., chimeric antigen receptor T cells). Prognosis varies by specific lymphoma type. However, with the inclusion of ART, lymphoma survival for the HIV-infected population often approaches that for the general population.

HIV-Associated Periodontal Disease

Atypical patterns of periodontal disease strongly associated with poorly controlled HIV infection include linear gingival erythema, necrotizing gingivitis, and necrotizing periodontitis. These conditions also may arise in association with risk factors other than HIV infection.

Linear gingival erythema represents an unusual pattern of gingivitis, with a distinctive linear band of erythema involving the free gingival margin and extending 2–3 mm apically (Fig. 7.46). In addition, the alveolar mucosa and gingiva may demonstrate punctate or diffuse erythema in a significant percentage of cases. This diagnosis should be reserved for gingivitis that does not respond to improved plaque control and exhibits a greater degree of erythema than would be expected for the amount of plaque present. The literature related to linear gingival erythema is difficult to evaluate, because well-defined diagnostic criteria are lacking and the condition often is confused with conventional marginal gingivitis. Although some investigators believe linear gingival erythema results from an abnormal host immune response to subgingival bacteria, data suggest that this condition may represent an unusual pattern of candidiasis. Treatment may include débridement, povidone-iodine irrigation, chlorhexidine mouth rinse, and/or antifungal medication.

Necrotizing gingivitis (see page 151) and **necrotizing periodontitis** are conditions belonging to the broader category of necrotizing periodontal diseases. The microbial profile of necrotizing periodontal diseases in HIV-infected individuals includes organisms associated with disease in HIV-negative patients plus additional findings, such as *Candida albicans*, herpes viruses, and various types of bacterial superinfection. Among studies of sizeable patient cohorts with HIV/AIDS, reported prevalence is approximately 10%–11% for necrotizing gingivitis and 0.3%–9% for necrotizing periodontitis.

In necrotizing gingivitis, there is sudden onset of necrosis and ulceration involving one or more interdental papillae without periodontal attachment loss. Patients also exhibit gingival bleeding, pain, and halitosis (Fig. 7.47).

Necrotizing periodontitis is characterized by gingival necrosis and ulceration with rapidly progressing periodontal attachment loss. Although severe cases can affect all teeth, multiple isolated defects often are seen and contrast with the diffuse pattern associated with typical chronic periodontitis. Edema, severe pain, and spontaneous hemorrhage are common. Deep pocketing usually is not seen because extensive gingival necrosis typically coincides with loss of the adjacent alveolar bone (Fig. 7.48). Attachment loss may be especially rapid in patients with HIV infection, with some individuals exhibiting up to 10 mm of bone loss within a 6-month period.

HIV-infected patients also are at increased risk for developing **necrotizing stomatitis**, characterized by massive areas

dentlearn.ir

• **Fig. 7.47 HIV-associated Necrotizing Gingivitis.** Multiple punched-out interdental papillae of the mandibular gingiva. Note diffuse pseudomembranous candidiasis of the surrounding mucosa.

• **Fig. 7.48 HIV-associated Periodontitis.** Extensive loss of periodontal support without deep pocketing.

• **Fig. 7.49** HIV-associated Periodontitis with Necrotizing Stomatitis. Diffuse gingival necrosis with extension onto alveolar mucosa.

• **Fig. 7.50 HIV-associated Necrotizing Stomatitis.** Massive necrosis of soft tissue and bone of the anterior maxilla.

of tissue destruction beyond the alveolar ridges (Fig. 7.49). This process clinically resembles noma (see page 191) and may involve predominantly soft tissue or extend into the underlying bone, resulting in extensive sequestration (Fig. 7.50). Although necrotizing stomatitits often develops as an extension of necrotizing periodontitis, it also may arise in areas of the oral mucosa other than the gingiva. In the absence of gingival involvement, the clinical features of necrotizing stomatitis are nonspecific and mandate biopsy. In many instances, the areas of ulceration and necrosis demonstrate infection with one or more pathogens, such as HSV, CMV, and EBV.

Management of HIV-infected individuals with necrotizing periodontal diseases includes débridement, antimicrobial therapy, pain control, immediate follow-up care, and long-term maintenance in conjunction with ensuring that the patient is receiving appropriate ART. The initial removal of necrotic tissue typically is performed under local anesthesia and usually is combined with chlorhexidine or povidone-iodine irrigation. Additional débridement, scaling and root planning, and lavage are performed during follow-up visits. Systemic antibiotic therapy (such as metronidazole) is reserved for patients with severe involvement, because of the risk for inducing secondary fungal or viral infection. Long-term maintenance considerations include oral hygiene reinforcement, chlorhexidine mouth rinse, nutritional counseling, and frequent recall visits.

In addition to linear gingival erythema and necrotizing periodontal diseases, HIV-infected patients may demonstrate conventional gingivitis, chronic periodontitis, and progressive nonnecrotizing periodontitis. Studies have shown that periodontal attachment loss can be combated successfully with regular professional scaling and root planing, plus optimization of oral hygiene. Recent evidence suggests that management of chronic periodontitis is important for reduction of systemic inflammatory mediators that may stimulate HIV activation.

Mycobacterial Infection

The best known mycobacterial infection is **tuberculosis (TB),** which is caused mainly by *Mycobacterium tuberculosis* (see page 185). Less common TB-causing mycobacteria include *M. bovis, M. africanum, M. canetti,* and *M. microti.* In addition, atypical mycobacterial infection with *Mycobacterium avium* and *Mycobacterium intracellulare* (*Mycobacterium*

dentlearn.ir

avium-intracellulare complex) can cause clinically evident disease, particularly in advanced stages of AIDS.

Approximately one-quarter of the world's population is infected with TB. Each year about 10 million people fall ill with TB worldwide, of which 9% represent HIV-positive individuals. Coinfection with HIV is associated with an increased risk for TB activation, and TB represents the leading cause of death in HIV-infected persons. Among 1.5 million TB deaths reported annually, approximately 250,000 occur in association with HIV. In the United States, HIV-related TB case rates are low, due in part to the widespread use of ART. Nevertheless, even with the beneficial effects of ART, HIV-infected individuals remain at increased risk for developing TB compared to the general population.

There is an unusual predilection for extrapulmonary involvement among HIV-infected individuals with TB. Nevertheless, oral lesions are uncommon and occur in less than 5% of all individuals with active TB. The tongue is the most frequently involved oral site, but lesions also can develop on the buccal mucosa, gingiva, floor of mouth, lips, and palate. The affected areas present as chronic ulcerations, granular leukoplakias, exophytic proliferative masses, or fissures. Jaw involvement also is possible and may present as tuberculous osteomyelitis, a periapical lesion, or an infected dental extraction socket.

Confirming TB often is difficult in AIDS patients, because tuberculin skin tests, microscopic examination of sputum smears for acid-fast bacilli, and chest radiographs lack sensitivity in this patient population. Liquid cultures, nucleic acid amplification tests, or urine lipoarabinomannan assay may facilitate diagnosis. In resource-limited settings, screening for a history of cough, fever, and/or night sweats is useful for identification of HIV-infected patients requiring diagnostic testing for TB.

In conjunction with ART, a regimen consisting of isoniazid, a rifamycin, pyrazinamide, and ethambutol for 2 months followed by isoniazid and a rifamycin for 4 months typically is effective for TB disease in HIV-infected adults. There is the potential for drug interactions between rifampin and some protease inhibitors or nonnucleoside reverse transcriptase inhibitors. Therefore, other rifamycins, such as rifabutin, may be selected.

Hyperpigmentation

Hyperpigmentation of the skin, nails, and mucosa has been reported in HIV-infected patients. The changes are similar microscopically to focal melanosis, with increased melanin pigmentation observed in the basal cell layer of the affected epithelium. Several medications taken by AIDS patients (e.g., ketoconazole, clofazimine, pyrimethamine, zidovudine, and emtricitabine) may cause increased melanin pigmentation. Adrenocortical destruction from several AIDS-associated opportunistic infections has been reported, resulting in an Addisonian pattern of pigmentation. Finally, some investigators have theorized that HIV-induced cytokine dysregulation may play a role in development of hyperpigmentation.

HIV-Associated Salivary Gland Disease

HIV-associated salivary gland disease can arise anytime during HIV infection. The condition is characterized by at least one of the following: (1) salivary hypofunction or subjective xerostomia, (2) diffuse enlargement of one or more major salivary glands. Irreversible salivary gland damage may result. The exact etiopathogenesis is unknown but has been linked to reactivation of BK polyomavirus (BKPyV) infection. Males are affected more often than females, and the disease occurs in both children and adults. Salivary gland enlargement most often affects the parotid. Bilateral involvement is seen in about 60% of cases and often is associated with cervical lymphadenopathy. Microscopic changes within the affected glands may include lymphocytic infiltration, hyperplasia of intraparotid lymph nodes, and lymphoepithelial cyst formation. Pathologic examination is important to rule out lymphoma.

Patients with mild HIV-associated salivary gland disease may require no specific treatment other than periodic monitoring. For more severe cases, management options include ART, aspiration, sclerotherapy, low-dose radiation therapy, and surgery. Some investigators have noted regression after initiation of ART, whereas others have reported increased prevalence with ART, possibly due to immune reconstitution inflammatory syndrome (see Treatment and Prognosis section).

Salivary gland enlargement within the setting of HIV infection also may be caused by **diffuse infiltrative lymphocytosis syndrome (DILS)** (also referred to as HIV-related sicca complex). This condition occurs in about 3%–8% of persons with HIV infection, although its frequency has declined since the introduction of effective ART. This syndrome mainly occurs in adults and is characterized by CD8+ lymphocytosis with diffuse lymphocytic infiltration of various sites, such as the major or minor salivary glands, lacrimal glands, lungs, kidneys, muscle, nerve, and liver. In particular, there may be massive parotid gland enlargement, which is more often bilateral than unilateral. Many patients also develop xerostomia, dry eyes, cervical lymphadenopathy, and interstitial pneumonia. There is an association between DILS and certain human leukocyte antigen (HLA) types. Labial salivary gland biopsy typically shows periductal CD8+ T-lymphocytic infiltration, acinar atrophy, ductal dilatation, and fibrosis. The most widely accepted treatments for DILS are ART and corticosteroids. DILS is associated with a relatively favorable HIV disease prognosis but also an increased risk for lymphoma; therefore, some authors recommend periodic monitoring for lymphoma development by fine-needle aspiration.

Interestingly, a few authors have reported ranulas (see page 462) and sialoliths (see page 465) in HIV-infected patients. However, the significance of these findings is uncertain, and a definitive association with HIV disease has not been established.

Thrombocytopenia

Thrombocytopenia (see page 590) is often an early manifestation of HIV infection but may occur at any time during the course of HIV disease. Among patients with untreated HIV infection, thrombocytopenia develops in approximately 3%

dentlearn.ir

of those with CD4+ T cell counts at or above 400 per microliter and 10% of those with CD4+ T cell counts below 400 per microliter. The underlying mechanisms may include direct infection of platelet progenitor cells, platelet destruction by anti-HIV antibodies that cross-react with platelet glycoproteins, platelet destruction by nonspecific binding of immune complexes, and defective modulation of hematopoiesis by HIV-infected T lymphocytes. In addition, thrombocytopenia may develop secondary to medications, concurrent infections, or malignancy. Cutaneous lesions are present in most cases, but oral lesions also may occur; typical findings include petechiae, ecchymosis, and spontaneous gingival hemorrhage.

ART is considered first-line treatment for thrombocytopenia in HIV-infected patients. For severe or refractory cases, additional treatment options may include interferon-alpha, intravenous immunoglobulin (IVIG), IV anti-Rho immunoglobulin (anti-D), rituximab, platelet transfusion, and splenectomy.

Herpes Simplex Virus

The prevalence of oral recurrent HSV infection among HIV-infected individuals increases significantly once the CD4+ cell count drops below 50 per microliter. Within the setting of HIV infection, recurrent herpetic lesions may be widespread, occur in an atypical pattern, and persist for months (Fig. 7.51). Herpes labialis may extend to the facial skin and exhibit extensive lateral spread. Persistence of active HSV infection for more than 1 month in a patient infected with HIV is one accepted definition of AIDS. The clinical presentation and management of recurrent HSV infection in immunocompromised patients are discussed in the section on HSV (see page 235). Evaluation of persistent oral ulcerations in HIV-infected individuals should be performed in order to rule out HSV infection (at times combined with infection by CMV, EBV, or other viruses), deep fungal infection, neoplasia, or other processes.

• **Fig. 7.51 HIV-associated Recurrent Herpetic Infection.** Mucosal erosion of the anterior dorsal surface of the tongue on the left side. Note the yellowish circinate border.

Varicella-Zoster Virus

During the ART era, the prevalence of recurrent varicella-zoster virus (VZV) infection **(herpes zoster)** in HIV-infected patients has decreased significantly but still remains greater than that in the general population. Some patients paradoxically develop herpes zoster shortly after initiating ART, as a result of immune reconstitution inflammatory syndrome (see Treatment and Prognosis section). Among patients with HIV infection, herpes zoster is often severe, with increased morbidity and mortality rates. Many of these patients are younger than 40 years, in contrast to immunocompetent patients who typically develop herpes zoster later in life. In patients with well-controlled HIV disease, herpes zoster usually is confined to a single dermatome but persists longer than usual. In full-blown AIDS, dissemination to multiple dermatomes is not unusual. Severe intraoral involvement may lead to bone sequestration and loss of teeth; these sequelae may be delayed a month or more after the initial onset of herpes zoster. Associated pain typically is intense.

For HIV-infected patients with acute, localized herpes zoster, treatment with oral valacyclovir, famciclovir, or acyclovir should be instituted as soon as possible. If there is more extensive disease, then IV acyclovir is indicated. Routine zoster vaccination for HIV-infected patients is not recommended currently; however, according to some experts, zoster vaccination may be considered for those with well-controlled HIV disease and CD4+ cell counts greater than 200 per microliter.

Human Papillomavirus

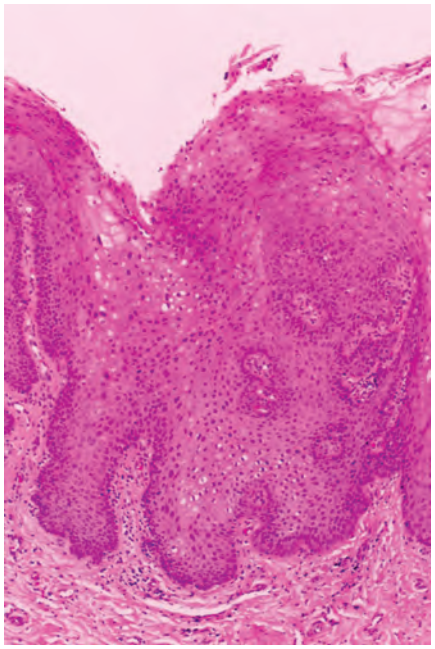
Among HIV-infected individuals, most human papillomavirus (HPV) lesions arise in the anogenital region, although oral involvement also is possible. Benign oral lesions caused by HPV (commonly referred to as "oral warts") include **oral squamous papilloma** (see page 355), **verruca vulgaris** (see page 357), **condyloma acuminatum** (see page 358), and **multifocal epithelial hyperplasia** (see page 360). The reported prevalence of these benign oral HPV lesions in various HIV-infected cohorts ranges from approximately 0.5% to 7%, and the prevalence is greater among HIV-positive individuals compared to the general population. Unusual HPV types (such as, HPV-7 [associated with butcher's warts], HPV-13, and HPV-32 [associated with multifocal epithelial hyperplasia]) frequently are identified in oral HPV lesions arising in HIV-infected patients.

A few retrospective studies have reported an increase in the frequency of benign oral lesions caused by HPV since the introduction of ART, and one prospective study noted an increase in oral HPV DNA among HIV-infected adults several months after initiation of ART. The reason for this apparent increase is unclear, although some authors have hypothesized that immune reconstitution by ART may lead to an inflammatory response that stimulates HPV activation (i.e., immune reconstitution inflammatory syndrome [see the Treatment and Prognosis section]). Also, some investigators have reported a positive correlation between oral HPV lesions, age, and duration of ART. Based on these findings,

dentlearn.ir

researchers have proposed that ART may extend patient survival without full restoration of HPV-specific immunity or that extended survival may allow increased cumulative risk for HPV infection acquisition over time despite restoration of immune function.

The oral lesions usually are multiple and may be located on any mucosal surface, with the labial mucosa, tongue, buccal mucosa, and gingiva most frequently involved. The lesions may exhibit a cluster of white, spikelike projections, pink cauliflower-like growths, or slightly elevated sessile papules (Fig. 7.52).



Histopathologically, the lesions may be sessile or papillary and covered by acanthotic or hyperplastic stratified squamous epithelium (Fig. 7.53). The affected epithelium often demonstrates vacuolization of numerous epithelial cells (i.e., koilocytosis) and occasionally may exhibit mild variation in nuclear size (Fig. 7.54). Immunohistochemistry or DNA in situ hybridization may be used to confirm the presence and type of HPV within histopathologic specimens (Fig. 7.55).

Surgical excision is the most commonly used treatment for benign oral HPV lesions; additional surgical options include cryosurgery, electrocautery, and laser ablation. However, all of these surgical methods are associated with frequent recurrence, and the latter two methods may expose the surgical team and patient to a plume containing

dentlearn.ir

infectious HPV. Alternative treatments with anecdotal evidence of efficacy include topical cidofovir, intralesional or systemic interferon-alpha, oral cimetidine, and topical podophyllin.

Dysplasia has been noted within HPV-related lesions in patients with AIDS and mandates close observation for development of squamous cell carcinoma. See the section below (page 263) for a discussion of oral and oropharyngeal squamous cell carcinoma within the setting of HIV infection.

Histoplasmosis

Histoplasmosis, the most common endemic respiratory fungal infection in the United States, is produced by *Histoplasma capsulatum* (see page 212). In healthy patients the infection typically is subclinical and self-limiting, but clinically evident infections often occur in immunocompromised individuals. Although a number of deep fungal infections are possible in patients with AIDS, histoplasmosis is the most common. In areas where the fungus is endemic, disseminated histoplasmosis affects approximately 2%–25% of HIV/AIDS patients and represents the initial AIDS-defining infection in as many as 50%–75% of these patients. Histoplasmosis also has been documented in nonendemic areas, possibly from reactivation of a previous subclinical infection.

The signs and symptoms associated with dissemination are nonspecific and include fever, weight loss, splenomegaly, and pulmonary infiltrates. Oral lesions are not uncommon and usually are caused by bloodborne organisms or spread from pulmonary involvement. On occasion, the initial diagnosis is made from the oral changes, with some patients demonstrating involvement isolated to the oral cavity. Although intrabony infection of the jaws has been reported, the most common oral presentation is a chronic, indurated mucosal ulceration with a raised border (Fig. 7.56). The oral lesions may be single or multiple and may involve any area of the mucosa.

First-line agents for progressive disseminated histoplasmosis in HIV-infected patients include IV liposomal amphotericin B and oral itraconazole. It is also important to ensure that these patients are receiving appropriate ART. Primary prophylaxis with itraconazole should be considered for HIV-infected patients who have CD4+ cell counts less than 150 per microliter and live in endemic areas with an especially high incidence of histoplasmosis.

Aphthous Stomatitis

Lesions that are clinically similar to **aphthous stomatitis** (see page 321) occur with increased frequency in patients infected with HIV. All three forms (minor, major, and herpetiform) are seen; surprisingly, however, almost two-thirds of affected patients have the usually uncommon herpetiform and major variants (Fig. 7.57). As immunosuppression becomes more profound, major aphthae demonstrate an increased prevalence.

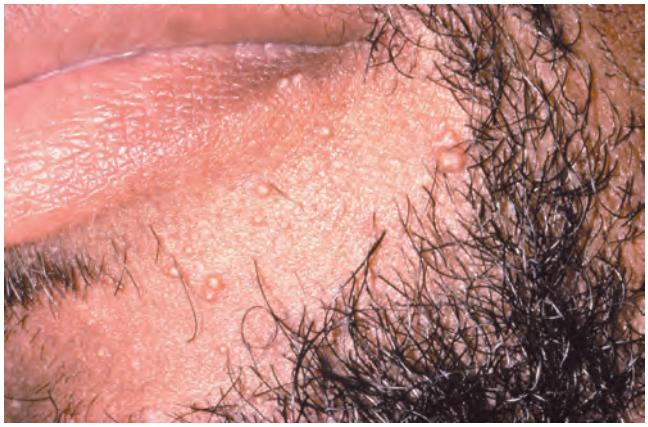
Initiation of ART is important for inducing remission and limiting recurrences of aphthae. In addition, treatment with potent topical or intralesional corticosteroids has been successful in many patients. However, not all lesions respond, and recurrences are common. Systemic corticosteroid drugs also may prove beneficial but typically are avoided in order to prevent further immunosuppression. Secondary candidiasis may be a complication of topical or systemic corticosteroid therapy. For lesions nonresponsive to topical corticosteroids, thalidomide may be effective. However, thalidomide must be used cautiously because of its association with increased viral load and potentially serious adverse effects, including peripheral neuropathy, neutropenia, and thrombosis.

Biopsy of any chronic mucosal ulceration clinically diagnosed as an aphthous ulceration should be considered if the lesion is atypical clinically or does not respond to therapy (Fig. 7.58). In such cases, biopsy often reveals another cause, such as HSV, CMV, deep fungal infection, or neoplasia.

Molluscum Contagiosum

Molluscum contagiosum (see page 364) is an infection caused by the molluscum contagiosum virus (MCV), which is a member of the poxvirus family. The lesions classically appear on the skin and genitals as small, waxy, dome-shaped papules with central umbilication. In immunocompetent individuals, the lesions are usually localized and self-limiting. However, in patients with AIDS, the lesions may be

• **Fig. 7.56 HIV-associated Histoplasmosis.** Indurated ulceration with a rolled border on the dorsal surface of the tongue on the right side.



• **Fig. 7.57 HIV-associated Aphthous Ulceration.** Large superficial ulceration of the posterior soft palate.

dentlearn.ir

• **Fig. 7.58 HIV-associated Ulceration.** Atypical mucosal ulceration that mandates biopsy and may be attributable to a variety of causes.

• **Fig. 7.59** HIV-associated Molluscum Contagiosum. Numerous perioral papules.

widespread, persistent, more numerous, and larger in size. Approximately 5% to 18% of HIV-infected patients are affected, and the facial skin commonly is involved (Fig. 7.59). Rare intraoral cases have been described as erythematous, white, or pink papules on either keratinized or nonkeratinized mucosa.

The most effective treatment for molluscum contagiosum in HIV-infected patients is ART. Paradoxical worsening of lesions shortly after initiation of ART due to immune reconstitution inflammatory syndrome (see Treatment and Prognosis section) is possible but typically is transient. For lesions that persist despite ART, there is limited evidence for treatment with topical imiquimod, topical or IV cidofovir, or intralesional interferon-alpha. Because MCV may be present in perilesional skin of HIV-infected patients, conventional local therapy (e.g., curettage, cryosurgery, cautery, or topical podophyllotoxin) often is associated with recurrence.

Oral and Oropharyngeal Squamous Cell Carcinoma

Relative to the general population, HIV-infected individuals are at modestly increased risk for developing squamous cell carcinoma of the oral cavity, pharynx, and other head and neck sites. In developed countries, this increase in risk has been estimated to be 1.5- to 4-fold for head and neck cancers as a whole, with a similar increase in risk reported for oropharyngeal cancers in particular. A high prevalence of known risk factors (e.g., tobacco use and HPV infection) for oral and oropharyngeal cancers has been noted among various HIV/AIDS cohorts. In addition, an inverse relationship has been demonstrated between oral cavity/pharyngeal cancer risk and CD4+ cell count, and underlying immune dysfunction may account for an increased tendency for persistent oral HPV infection among HIV-infected individuals. Thus, investigators hypothesize that conventional risk factors as well as HIV-related immunosuppression may contribute to elevated cancer risk. However, one large-scale study based in California found no significant difference in the risk for oral cavity/pharyngeal cancer between HIV-positive and HIV-negative individuals after controlling for tobacco use, alcohol abuse, and other potential confounding factors.

• **Fig. 7.60 HIV-associated Squamous Cell Carcinoma.** Ulcerated mass with raised, indurated borders on the ventrolateral tongue.

Clinical presentation (Fig. 7.60) and treatment options for oral and oropharyngeal squamous cell carcinoma are similar among those with and without HIV infection. Although underlying immunosuppression is associated with aggressive behavior and poor patient outcomes for many cancer types, registry data in the United States for oral cavity/pharyngeal cancer show no significant difference in stage at diagnosis among HIV-infected individuals compared to the general population after adjusting for age, gender, and race. In addition, among individuals with HPV-positive head and neck cancers, one recent multi-center study did not find HIV infection to represent an adverse prognostic factor.

Screening and Diagnosis

The Centers for Disease Control and Prevention recommend that individuals between 13 and 64 years of age receive HIV testing as part of routine health care at least once and individuals with known HIV risk factors be tested at least annually. The standard screening tool is HIV antibody testing by enzyme immunoassay (EIA); in addition, there is a

dentlearn.ir

combination immunoassay for detection of both HIV antibodies and p24 antigen. False-positive antibody test results are possible, and a positive or indeterminate result should be confirmed by repeat EIA and a more specific assay, such as Western blot or plasma HIV RNA level. Seroconversion generally takes 3–12 weeks following infection; thus, repeat testing may be considered after a negative result, if there is a strong reason to suspect recent HIV infection. HIV home testing kits also are available. These kits allow the user to send a sample into a laboratory for antibody testing; however, positive results still need to be confirmed by standard assays. For patients suspected of having acute retroviral syndrome, p24 antigen capture assay may be performed to detect the virus before the development of antibodies. Tests used to measure plasma HIV RNA levels include RT-PCR, branched DNA assay, transcription-mediated amplification, and nucleic acid sequence–based amplification. Although these tests may be performed for diagnosis, they more commonly are used to monitor response to therapy among patients already diagnosed.

AIDS is diagnosed based on the presence of any of the following criteria:

1. CD4+ T-lymphocyte count:
   - less than 200 per microliter for individuals 6 years or older
   - less than 500 per microliter for individuals 1–5 years of age
   - less than 750 per microliter for individuals less than 1 year old
2. Diagnosis of an AIDS-defining opportunistic illness (Box 7.1)

• BOX 7.1 AIDS-Defining Opportunistic Illnesses

1. Bacterial infections, multiple or recurrent*
2. Candidiasis of bronchi, trachea, or lungs
3. Candidiasis of esophagus
4. Cervical cancer, invasive†
5. Coccidioidomycosis, disseminated or extrapulmonary
6. Cryptococcosis, extrapulmonary
7. Cryptosporidiosis, chronic intestinal (more than 1 month duration)
8. CMV disease (other than liver, spleen, or nodes), onset at age of more than 1 month
9. CMV retinitis (with loss of vision)
10. Encephalopathy attributed to HIV
11. Herpes simplex: Chronic ulcer or ulcers (more than 1 month duration) or bronchitis, pneumonitis, or esophagitis (onset at age of more than 1 month)
12. Histoplasmosis, disseminated or extrapulmonary
13. Isosporiasis, chronic intestinal (more than 1 month duration)
14. Kaposi sarcoma (KS)
15. Lymphoma, Burkitt (or equivalent term)
16. Lymphoma, immunoblastic (or equivalent term)
17. Lymphoma, primary, of brain
18. *Mycobacterium avium* complex or *Mycobacterium kansasii,* disseminated or extrapulmonary
19. *Mycobacterium tuberculosis* of any site, pulmonary,† disseminated, or extrapulmonary
20. *Mycobacterium*, other species or unidentified species, disseminated, or extrapulmonary
21. *Pneumocystis jiroveci* pneumonia
22. Pneumonia, recurrent
23. Progressive multifocal leukoencephalopathy
24. *Salmonella* septicemia, recurrent
25. Toxoplasmosis of brain, onset at age of more than 1 month
26. Wasting syndrome attributed to HIV

*Only among children less than 6 years old.
†Only among adults, adolescents, and children aged 6 years or older.

Treatment and Prognosis

Current guidelines recommend initiation of ART as soon as possible after HIV diagnosis regardless of CD4+ cell count—an approach known as "test and treat." There is strong evidence that early treatment reduces the risk for serious AIDS-related events (including AIDS-related cancer and opportunistic infection) as well as serious non-AIDS-related events (including non-AIDS-related cancer and major cardiovascular, renal, and liver disease). With appropriate ART, a person newly diagnosed with HIV infection in North America is expected to have a nearly normal life expectancy. Furthermore, early treatment is important to reduce the risk for viral transmission.

A wide variety of antiretroviral agents is available and continues to expand. These agents are administered in combination in order to reduce the emergence of viral resistance. Although numerous combinations are possible, ART often consists of two nucleoside reverse transcriptase inhibitors combined with a nonnucleoside reverse transcriptase inhibitor, boosted protease inhibitor, or integrase inhibitor (2 NRTI + NNRTI/PI/II). With such treatment, viremia typically declines to undetectable levels, and there is clinically significant immune reconstitution. Although ART works well for most patients, downsides of such therapy include cost, toxicity, adverse reactions, and difficulty with compliance. Some patients who receive ART during advanced stages of disease develop a paradoxical worsening of their condition—termed **immune reconstitution inflammatory syndrome**—despite decreasing viral load and increasing CD4+ cell counts. The underlying mechanism may be related to a hyper-inflammatory response to pathogens and pathogenic antigens present at the time of rapid immune reconstitution. ART is unable to cure HIV infection, apparently because of persistence of viral reservoirs in the peripheral blood and lymphoid tissues. Therefore, lifelong treatment is necessary—discontinuation typically results in rebound of the virus within weeks.

Some health professionals have been concerned about the risk of occupational transmission of HIV. However, the risk appears to be very low, with only a paucity of confirmed cases of occupational transmission in the United States since the

dentlearn.ir

late 1990s. In the event of occupational exposure, postexposure prophylaxis with antiretroviral medications should be initiated as soon as possible (preferably within hours of the event) and continued for 4 weeks. Basic postexposure prophylaxis consists of a regimen containing three or more antiretroviral drugs. Because of the complexity of choosing and administering HIV postexposure prophylaxis, involvement of an infectious disease specialist or other physician experienced in ART is recommended.

◆ CORONAVIRUS DISEASE 2019

The emergence of the coronavirus disease 2019 (COVID-19) pandemic has created a massive global health challenge. As of this writing, hundreds of millions of individuals have been infected worldwide, with a rising death toll and widespread socioeconomic devastation. Our knowledge regarding this disease has evolved rapidly with intensive research efforts and the emergence of new variants of the virus; the discussion below represents a brief overview based on current knowledge, although the reader is encouraged to access additional resources for the most up-to-date information.

COVID-19 is caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which is a member of the family *Coronaviridae* and the genus *Betacoronavirus*. The virus is transmitted mainly by inhalation of contaminated respiratory droplets or aerosols; deposition of respiratory droplets or particles onto oral, nasal, or ocular mucous membranes; or touching mucous membranes with hands that have come into contact with respiratory fluids or contaminated surfaces. The incubation period ranges from about 2 to 14 days. The virus enters host cells by interaction between its spike protein and the host receptor, angiotensin-converting enzyme 2 (ACE2). Tissue types that highly express ACE2 include the lungs (particularly type II alveolar cells), myocardium, intestinal lining, renal proximal tubules, and tongue epithelium. Although the respiratory tract is the primary site of infection, various other tissue types may exhibit disease manifestations as well.

Clinical Features

The clinical presentation of individuals infected with SARS-CoV-2 is variable, ranging from no or minimal symptoms to severe, life-threatening illness. Clinical findings may include the following: fever, chills, cough, dyspnea, hypoxia, pneumonia, fatigue, myalgia, headache, sore throat, runny nose or nasal congestion, nausea, vomiting, and diarrhea. Critically ill patients may develop respiratory failure/acute respiratory distress syndrome, cardiac arrhythmia, acute cardiac injury, acute kidney injury, coagulopathy, septic shock, and multiple organ failure.

Interestingly, various skin eruptions also have been described in patients with COVID-19, although it is not entirely clear whether such lesions represent direct effects of the virus and/or adverse drug reactions. Reported skin findings include maculopapular rash, urticaria, vesicular eruption, petechiae, purpura, livedoid (reticular red-blue)/necrotic lesions, erythema multiforme-like lesions, and chilblain-like lesions (red to violaceous macules, plaques, and nodules at the distal aspects of toes and fingers with a pattern mimicking injury from cold temperatures). Such findings have been noted in patients with severe COVID-19 as well as those with no to mild symptoms.

A rare manifestation of COVID-19 is multisystem inflammatory disease in children (MIS-C). This condition bears some resemblance to Kawasaki disease (an acute-onset systemic vasculitis and febrile illness of unknown etiology). MIS-C typically develops 2–6 weeks after a SARS-CoV-2 infection that may be mild or asymptomatic. Characteristic features include age under 21 years; fever of 38°C or higher for at least 24 hours; laboratory evidence of inflammation (e.g., C-reactive protein, erythrocyte sedimentation rate, D-dimer); severe illness requiring hospitalization; and involvement of 2 or more organ systems. Reported oral manifestations of MIS-C include mucosal erythema, strawberry tongue (erythematous tongue with enlarged papillae), and cracked or swollen lips.

Among oral manifestations of COVID-19, taste disturbance is the most salient finding, with an overall prevalence of approximately 38% among reported patients according to a comprehensive systematic review of the literature. Hypogeusia and dysgeusia have been described more frequently than ageusia. In some cases, gustatory dysfunction is accompanied by olfactory dysfunction. Such taste and smell abnormalities exhibit a female predilection and may develop early in the course of mild to moderate disease—at times even in the absence of other signs or symptoms. Therefore, screening for new-onset smell and/or taste dysfunction may aid in the identification of patients with COVID-19. The underlying mechanism for COVID-19-related taste disturbance is uncertain, although it has been hypothesized that expression of ACE2 and transmembrane protease serine 2 (TMPRSS2) by taste bud cells facilitates viral entry and disruption of gustatory function. Furthermore, expression of these viral entry molecules by acinar and ductal epithelial cells within salivary glands has been proposed to explain reports of xerostomia, which has been noted in approximately 40% of patients and could contribute to taste disturbance as well.

Information regarding other potential oral manifestations of COVID-19 is limited. Anecdotal reports or series of patients with confirmed SARS-CoV-2 infection have noted various oral conditions, such as ulceration (including aphthous-like, herpes-like, necrotic, or nonspecific ulceration); tongue findings (including lingual papillitis or depapillated tongue); hemorrhagic lesions (such as petechiae, ecchymosis, spontaneous hemorrhage, and angina bullosa); vesiculobullous eruption; desquamative gingivitis; halitosis; orofacial pain; salivary gland abnormalities (including sialadenitis or ectasia); and erythematous plaques or macules (Fig. 7.61). However, it is uncertain whether such findings represent actual manifestations of COVID-19 versus secondary or incidental phenomena. Oral coinfections (e.g.,

dentlearn.ir

• **Fig. 7.61 Coronavirus Disease 2019.** Erythematous macules on the lower labial mucosa. (Courtesy of Dr. Bea Venturi.)

candidiasis/angular cheilitis, herpes simplex virus infection, mucormycosis) also have been reported in COVID-19 patients. Further studies are needed to determine the significance of such observations.

Histopathologic Features

Information regarding microscopic findings in oral mucosal lesions sampled from COVID-19 patients is limited. However, some investigators have noted paranuclear vacuolization in keratinocytes within the spinous cell layer of the surface epithelium, which may correlate with SARS-CoV-2 spike protein expression demonstrated by immunhistochemistry. Within the lamina propria, there may be inflammation (more often lymphohistiocytic than neutrophilic), thrombosis of small arteries or capillaries, and hemorrhage. Fibrinoid necrosis may be evident in patients with extensive ecchymosis.

Diagnosis

Current SARS-CoV-2 infection can be detected by antigen or nucleic acid amplification tests. Antigen tests are relatively easy to perform and typically can be used for at-home or point-of-care applications with rapid results. However, antigen tests have lower sensitivity than laboratory-based nuclei acid antigen tests (such as RT-PCR). Depending on test type, samples may be obtained from the nasopharynx, nasal cavity, oropharynx, saliva, or sputum.

Other laboratory test findings in patients with COVID-19 may include lymphopenia, prolonged prothrombin time, elevated lactate dehydrogenase, hypoalbuminemia, and elevated C-reactive protein. In patients with pneumonia, computed tomography (CT) typically exhibits bilateral ground-glass opacities of the lungs. In addition, this pattern has been documented in some asymptomatic patients with SARS-CoV-2 infection.

Treatment and Prognosis

Individuals with mild COVID-19 can be managed by home isolation and supportive care (i.e., acetaminophen, fluids, antibiotics for secondary infection, and supplemental oxygen). Drugs for nonhospitalized patients with mild to moderate disease and high risk of progression to serious disease represent an active area of investigation, and recommendations for various agents (e.g., oral antivirals, anti-SARS-CoV-2 monoclonal antibodies) have changed with the emergence of new variants of the virus. Patients with severe or critical disease require hospitalization for management of complications. Treatment may include antiviral agents (e.g., remdesivir), dexamethasone, IL-6 blockers, Janus kinase (JAK) inhibitors, respiratory support, and anticoagulants. MIS-C typically is treated by intravenous immunoglobulin with or without corticosteroids. Even with optimal care, fatality is >10% among hospitalized COVID-19 patients. Risk factors for severe disease and death include male gender, age over 60 years, hypertension, cardiovascular disease, diabetes, and obesity.

Several vaccines have been developed. Additional practices for disease prevention and mitigation include testing, isolation, contact tracing, and quarantine procedures; wearing face coverings; environmental disinfection and ventilation; frequent hand hygiene; and physical distancing from others.

8 Physical and Chemical Injuries

LINEA ALBA

Linea alba ("white line") is a common alteration of the buccal mucosa that most likely is associated with pressure, frictional irritation, or sucking trauma from the facial surfaces of the teeth. No other associated problem, such as insufficient horizontal overlap or rough restorations of the teeth, is necessary for the development of linea alba.

Clinical Features

As the name implies, the alteration consists of a white line that usually is bilateral. It may be scalloped and is located on the buccal mucosa at the level of the occlusal plane of the adjacent teeth (Fig. 8.1). The line varies in prominence and usually extends from the corner of mouth posteriorly toward the pterygomandibular raphe with the alteration stopping adjacent to the most posterior teeth in occlusion. It often is more pronounced adjacent to the posterior teeth. In clinical surveys of oral alterations, linea alba appears to be one of the more common oral conditions. Several studies have reported a female predominance.

Histopathologic Features

Biopsy is rarely indicated. If a biopsy is performed, hyperkeratosis is seen overlying otherwise normal oral mucosa. On occasion, intracellular edema of the epithelium and mild chronic inflammation of the underlying connective tissue may be noted.

Treatment and Prognosis

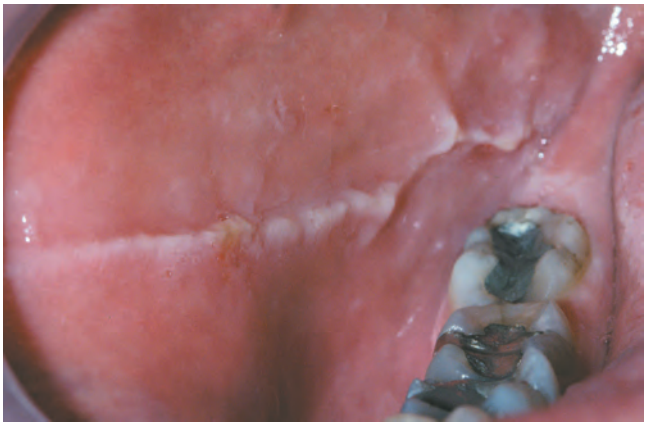
No treatment is required for patients with linea alba, and no difficulties are documented because of its development. Spontaneous regression may occur.

MORSICATIO MUCOSAE ORIS (CHRONIC MUCOSAL CHEWING)

Morsicatio mucosae oris is a classic example of medical terminology gone astray; it is the scientific term for chronic chewing of the oral mucosa. *Morsicatio* comes from the Latin word *morsus,* or *bite*. Chronic nibbling produces lesions that are located most frequently on the buccal mucosa **(morsicatio buccarum);** however, the labial mucosa **(morsicatio labiorum)** and the lateral border of the tongue **(morsicatio linguarum)** also may be involved. Similar changes have been seen because of suction and in glassblowers whose technique produces chronic irritation of the buccal mucosa.

Chronic cheek chewing is considered a body-focused repetitive behavior (BFRB) along with skin picking, hair pulling, and nail biting. When one of these behaviors is noted, the individual also has a greater chance to demonstrate anxiety, depression, obsessive-compulsive disorder, body dysmorphic disorder (BDD), or fear of negative evaluation. Chronic cheek biting also can be seen in patients with a mass in their cheek or in individuals whose anatomy has been altered during oncologic surgery. Most patients are aware of their habit, although many deny the self-inflicted injury or perform the act subconsciously. An increased prevalence has been noted in women and in patients older than 35 years.

Clinical Features



Most frequently, the lesions in patients with morsicatio are found bilaterally on the anterior buccal mucosa. They also may be unilateral, combined with lesions of the lips or the tongue, or isolated to the lips or tongue. Thickened, shredded, white areas may be combined with intervening zones of erythema, erosion, or focal traumatic ulceration (Figs. 8.2 and 8.3). The areas of white mucosa demonstrate an irregular ragged surface, and the patient may describe being able to remove shreds of white material from the involved area. Although dysplastic leukoplakias tend to have more sharply demarcated borders, the periphery of morsicatio-related lesions gradually blends with the adjacent mucosa.

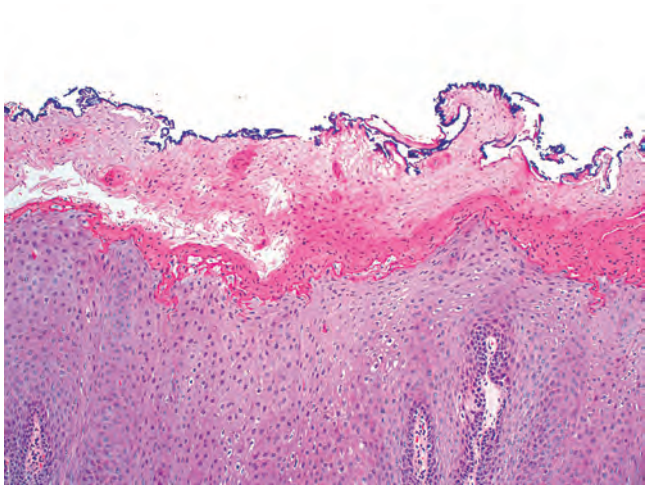
The altered mucosa typically is in the midportion of the anterior buccal mucosa along the occlusal plane. Large lesions may extend some distance above or below the occlusal plane in patients whose habit involves pushing the cheek between the teeth with a finger.

Histopathologic Features

Biopsy reveals extensive hyperparakeratosis that often results in an extremely ragged surface with numerous projections of keratin. Surface bacterial colonization is typical (Fig. 8.4). On occasion, clusters of vacuolated cells are present in the

dentlearn.ir

• **Fig. 8.1 Linea Alba.** White line of hyperkeratosis on the right buccal mucosa at the level of the occlusal plane.



• **Fig. 8.2 Morsicatio Buccarum.** Thickened, shredded areas of white hyperkeratosis of the left buccal mucosa.

• **Fig. 8.3 Morsicatio Linguarum.** Thickened, rough areas of white hyperkeratosis of the lateral border of the tongue on the left side.

superficial portion of the prickle cell layer. This histopathologic pattern is not pathognomonic of morsicatio and may bear a striking resemblance to **oral hairy leukoplakia (OHL),** a lesion that can be seen in a wide variety conditions associated with local and systemic immunosuppression (most notably patients infected with the **human immunodeficiency virus (HIV)** (see page 253), or to **uremic stomatitis** (see page 852). In contrast to OHL, the superficial epithelial cells will not demonstrate the characteristic nuclear beading associated with infection with Epstein-Barr virus. Lesions in patients who chronically chew betel quid (**betel chewer's mucosa;** see page 393) may resemble morsicatio microscopically. Similarities with linea alba and leukoedema also may be seen.

• **Fig. 8.4 Morsicatio Buccarum.** Oral mucosa exhibiting greatly thickened layer of parakeratin with ragged surface colonized by bacteria.

Diagnosis

In most cases, the clinical presentation of morsicatio is sufficient for a strong presumptive diagnosis, and clinicians familiar with these alterations rarely perform biopsy. Some cases of morsicatio may not be diagnostic from the clinical presentation, and biopsy may be necessary.

Treatment and Prognosis

No treatment of the oral lesions is required, and no long-term difficulties arise from the presence of the mucosal changes. For patients desiring either confirmation of the cause or preventive therapy, construction and use of acrylic shields to separate the teeth from the adjacent mucosa can provide quick resolution of the lesions. Alternatively, a maxillary splint with a facial cheek bumper can be constructed to increase the distance between the teeth and the adjacent buccal mucosa.

◆ TRAUMATIC ULCERATIONS

Acute and chronic injuries of the oral mucosa are common and may be associated with surface ulcerations. The ulcerations may remain for extended periods of time but most usually heal within days. A histopathologically unique type of chronic traumatic ulceration of the oral mucosa is the **eosinophilic ulceration (traumatic granuloma; traumatic ulcerative granuloma with stromal eosinophilia [TUGSE];**

dentlearn.ir

eosinophilic granuloma of the tongue), which exhibits a deep pseudoinvasive inflammatory reaction and typically is slow to resolve. Interestingly, many of these traumatic granulomas undergo resolution after incisional biopsy. Lesions microscopically similar to eosinophilic ulceration have been reproduced in rat tongues after repeated crushing trauma and in traumatic lesions noted in patients with familial dysautonomia, a disorder characterized by indifference to pain. In addition, similar sublingual ulcerations may occur in infants because of chronic mucosal trauma from adjacent anterior primary teeth, often associated with nursing. An Italian physician, Antonio Riga, initially described the clinical presentation of the ulcerations in 1881, and Fede followed with a description of the associated histopathology in 1890. Accordingly, these distinctive ulcerations of infancy have been termed **Riga-Fede disease** and should be considered a variation of the traumatic eosinophilic ulceration.

In rare subsets of eosinophilic ulcerations, the lesion does not appear to be associated with trauma, and sheets of large, atypical cells intermixed with numerous eosinophils are seen histopathologically. The atypical cells have been shown to represent T lymphocytes with a strong immunoperoxidase reactivity for CD30. When T-cell clonality is demonstrated, many believe these cases represent the oral counterpart of the **primary cutaneous CD30+ lymphoproliferative disorder,** which also exhibits sequential ulceration, necrosis, and occasional self-regression. In these cases, a thorough physical evaluation appears prudent to rule out the possibility of a systemic lymphoproliferative process.

In most cases of traumatic ulceration, there is an adjacent source of irritation, although this is not present invariably. The clinical presentation often suggests the cause, but many cases resemble early ulcerative squamous cell carcinoma; biopsy is performed to rule out that possibility.

Clinical Features

As would be expected, simple chronic traumatic ulcerations occur most often on the tongue, lips, and buccal mucosa—sites that may be injured by the dentition (Fig. 8.5). Lesions of the gingiva, palate, and mucobuccal fold may occur from other sources of irritation. The individual lesions appear as areas of erythema surrounding a central removable, yellow fibrinopurulent membrane. In many instances, the lesion develops a rolled white border of hyperkeratosis immediately adjacent to the area of ulceration (Fig. 8.6).

Eosinophilic ulcerations are not uncommon but frequently are not reported. The lesions occur in people of all ages, with a significant male predominance. Most have been reported on the tongue, although cases have been seen on the gingiva, buccal mucosa, floor of mouth, palate, and lip. The lesion may last from 1 week to 8 months. The ulcerations appear very similar to the simple traumatic ulcerations; however, on occasion, underlying proliferative granulation tissue can result in a raised lesion similar to a pyogenic granuloma (see page 525) (Fig. 8.7).

Riga-Fede disease typically appears between 1 week and 1 year of age. The condition often develops in association with natal teeth (see page 79). The anterior ventral surface of the tongue is the most common site of involvement, although the dorsal surface also may be affected (Fig. 8.8). Ventral lesions contact the adjacent mandibular anterior

incisors; lesions on the dorsal surface are associated with the maxillary incisors. A presentation similar to Riga-Fede disease can be the initial finding in a variety of neurologic conditions related to self-mutilation, such as familial dysautonomia (Riley-Day syndrome), congenital indifference to pain, Lesch-Nyhan syndrome, Gaucher disease, cerebral palsy, or Tourette syndrome.

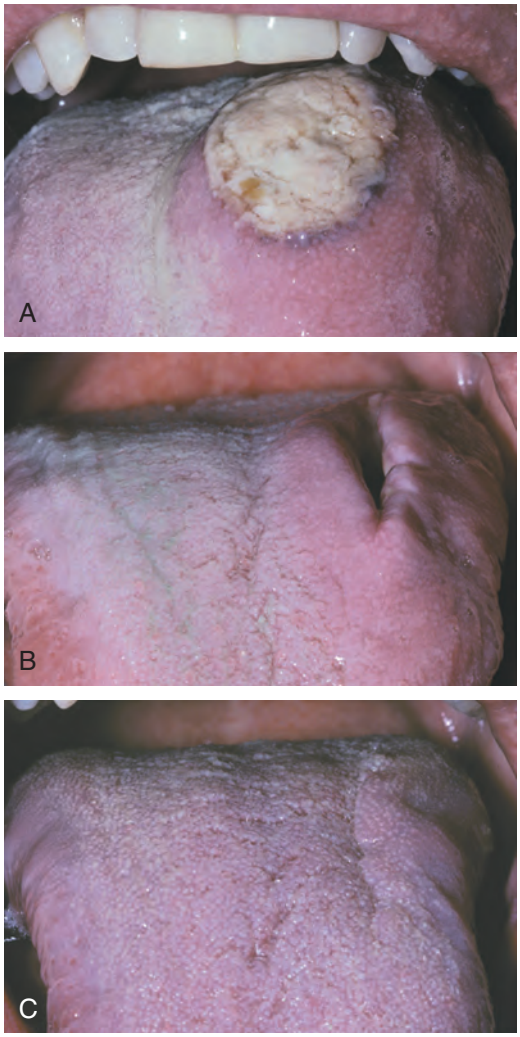
The atypical eosinophilic ulceration occurs in older adults, with most cases developing in patients older than age 40. Surface ulceration is present, and an underlying tumefaction also is seen. The tongue is the most common site, although the gingiva, alveolar mucosa, mucobuccal fold, buccal mucosa, and lip may be affected (Fig. 8.9).

Histopathologic Features

Simple traumatic ulcerations are covered by a fibrinopurulent membrane that consists of fibrin intermixed with neutrophils. The membrane is of variable thickness, and the adjacent surface epithelium may be normal or may demonstrate slight hyperplasia with or without hyperkeratosis. The ulcer bed consists of granulation tissue that supports a mixed inflammatory infiltrate of lymphocytes, histiocytes, neutrophils, and, occasionally, plasma cells. In patients with eosinophilic ulcerations, the pattern is very similar; however, the inflammatory infiltrate extends into the deeper tissues and exhibits sheets of lymphocytes and histiocytes intermixed with eosinophils. In addition, the vascular connective tissue deep to the ulceration may become hyperplastic and cause surface elevation.

Atypical eosinophilic ulcerations exhibit numerous features of the traumatic eosinophilic ulceration, but the deeper tissues are replaced by a highly cellular proliferation of large lymphoreticular cells. The infiltrate is pleomorphic, and mitotic features are somewhat common. Intermixed with the large atypical cells are mature lymphocytes and numerous eosinophils. Although an associated immunohistochemical profile rarely has been reported, several investigators have shown the large cells to be T lymphocytes, the majority of which react with CD30 (Ki-1). In many instances, molecular studies for T-cell clonality by polymerase chain reaction (PCR) have been performed on the CD30+ cells and demonstrated monoclonal rearrangement. Despite the clonality noted in many cases, the lymphoproliferative disorder typically demonstrates negative reactivity with anaplastic lymphoma kinase protein, a marker associated with large cell CD30+ lymphoma.

Treatment and Prognosis



For traumatic ulcerations that have an obvious source of injury, the irritating cause should be removed. A topical anesthetic or protective film can be applied for temporary pain relief. If the cause is not obvious, or if a patient does not respond to therapy, then biopsy is indicated. Rapid healing after a biopsy is typical even with large eosinophilic ulcerations (Fig. 8.10). Recurrence is not expected.

The use of corticosteroids in the management of traumatic ulcerations is controversial. Some clinicians have suggested that use of such medications may delay healing. Despite this, other investigators have reported success using corticosteroids to treat chronic traumatic ulcerations.

Although extraction of the anterior primary teeth is not recommended, this procedure has resolved the ulcerations in Riga-Fede disease. The teeth should be retained if they are stable. Grinding the incisal mamelons, coverage of the teeth with a light-cured composite or cellulose film, construction of a protective shield, or discontinuation of nursing have been tried with variable success.

In patients demonstrating histopathologic similarities to the cutaneous CD30+ lymphoproliferative disorder, a thorough evaluation for systemic lymphoma is mandatory, along with lifelong follow-up. Although recurrence frequently is seen, the ulcerations typically heal spontaneously, and most patients do not demonstrate dissemination of the process. Further documentation is critical to define more fully this poorly understood process.

◆ ELECTRICAL AND THERMAL BURNS

Electrical burns to the oral cavity are fairly common, constituting approximately 5% of all burn admissions to hospitals. Two types of electrical burns can be seen: (1) **contact** and (2) **arc.**

Contact burns require a good ground and involve electrical current passing through the body from the point of contact to the ground site. The electric current can cause cardiopulmonary arrest and may be fatal. Most electrical burns affecting the oral cavity are the arc type, in which the saliva acts as a conducting medium and an electrical arc flows between the electrical source and the mouth. Extreme heat, up to 3000°C, is possible with resultant significant tissue destruction. Most cases result from chewing on the female end of an extension cord or from biting through a live wire.

Most **thermal burns** of the oral cavity arise from ingestion of hot foods or beverages. Microwave ovens have been associated with an increased frequency of thermal burns because of their ability to cook food that is cool on the exterior but extremely hot in the interior.

Since the early 2000s, a rash of thermal burns have been noted in association with use of electronic cigarettes (e-cigarettes). These devices were introduced in 2003 with availability in the United States and Europe beginning in 2007. E-cigarettes consist of a cartridge tank containing the vapor fluid, a heating element to vaporize the solution, and a lithium-ion battery to power the system. The heating systems can be triggered when the user inhales deeply or manually depresses a button on the side of the unit. The heating element can create temperatures up to 100–250°C (212–482°F). Over 450 brands exist and are largely unregulated because the devices are not required by law to undergo safety testing. During a two-year period in England, 105 house fires were linked to failures of e-cigarettes. Due to the risk of fire, electronic cigarettes are banned in checked baggage aboard aircraft.

Several different patterns of burns have been associated with use of e-cigarettes. Thermal burns with or without flames may be seen from thermal runaway of the lithium battery or overheating of the vaporizing system. In some cases of overheating, the battery seal at the ends of the device can fail and result in an explosive blast that launches the internal battery like a missile out of its case, combining physical injury with thermal burns. The e-cigarette also can release electrolyte solution, resulting in a chemical alkali burn.

Clinical Features

The hands are the most common site of electrical burns in adults. In contrast, the oral cavity is the most affected location in children, with 90% of these accidents occurring before age 4. The lips are affected most frequently, and the commissure commonly is involved. Initially, the burn appears as a painless, charred, yellow area that exhibits little to no bleeding (Fig. 8.11). Significant edema often develops within a few hours and may persist up to 12 days. Starting on the fourth day, the affected area becomes necrotic and begins to slough. Bleeding may develop during this period from exposure of the underlying vital vasculature, and the presence of this complication should be monitored closely. The adjacent mucobuccal fold, the tongue, or both also may be involved. On occasion, adjacent teeth may become nonvital, with or without necrosis of the surrounding alveolar bone. Malformation of developing teeth also has been documented. In patients receiving high-voltage electrical injury, resultant facial nerve paralysis is reported infrequently and typically resolves over several weeks to months. Focal enamel cavitation, which was thought to represent a high voltage exit point, also has been reported in association with an electrocution injury.

The injuries related to thermal food burns usually appear on the palate or posterior buccal mucosa (Fig. 8.12). The lesions appear as zones of erythema and ulceration that often exhibit remnants of necrotic epithelium at the periphery. If

hot beverages are swallowed, swelling of the upper airway can occur and lead to dyspnea, which may develop several hours after the injury.

Burns related to electronic cigarettes most frequently affect the thigh, hands, face, and thorax. A significant percentage occur when the device fails while being carried in trouser pockets, resulting in significant burns of the thigh and the hands that are attempting to stop the fireball. Several oral injuries have been seen when the device explodes at the moment the user presses the heating button with the unit being held between their lips. In two surprisingly identical reports, the launching of the battery from its case into the mouth resulted in loss of the maxillary incisors with significant damage to the surrounding maxillary bone and the soft tissues of the hard palate, soft palate, lips, and tongue (Fig. 8.13).

Treatment and Prognosis

For patients with electrical burns of the oral cavity, tetanus immunization, if not current, is required. Most clinicians prescribe a prophylactic antibiotic, usually penicillin, to prevent secondary infection in severe cases. The primary problem with oral burns is contracture of the mouth opening during healing. Without intervention, significant microstomia can develop and may produce such restricted access to the mouth that hygiene and eating become impossible in severe cases. Extensive scarring and disfigurement are typical in untreated patients.

To prevent the disfigurement, a variety of microstomia prevention appliances can be used to eliminate or reduce the need for subsequent surgical reconstruction. Compliance is the most important consideration when choosing the most appropriate device. Tissue-supported appliances appear most effective for infants and young children; older, more cooperative patients usually benefit from tooth-supported devices. In most cases, splinting is maintained for 6–8 months to ensure proper scar maturation. Evaluation for possible surgical reconstruction usually is performed after a 1-year follow-up.

Most thermal burns are of little clinical consequence and resolve without treatment. When the upper airway is involved and associated with breathing difficulties, antibiotics and corticosteroids often are administered. In rare cases,

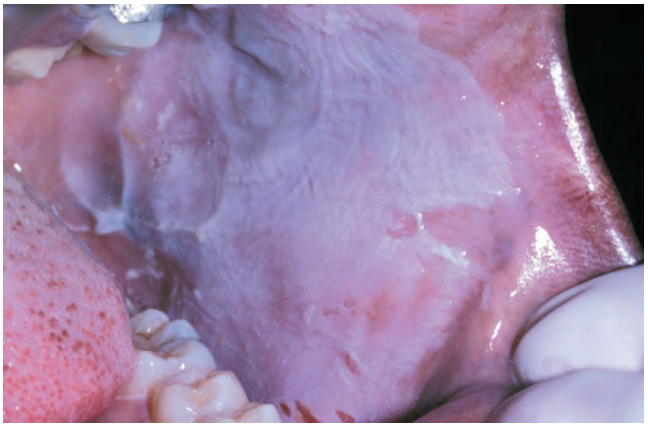
dentlearn.ir

swelling of the airway mandates intubation or tracheotomy to resolve the associated dyspnea. In these severe cases, oral intake of food often is discontinued temporarily with nutrition provided by a nasogastric tube.

In burns related to electronic cigarettes, the battery can deposit lithium cobalt oxides or lithium manganese into the damaged tissues. If irrigated with water, alkali lithium hydroxide and hydrogen gas can be generated in a vigorous exothermic reaction. For this reason, e-cigarette burns should be tested with pH paper and covered with mineral oil if an alkaline pH is confirmed; otherwise, the area can be irrigated with water, gently debrided of necrotic tissue, and treated with traditional burn therapy. Oral burns are treated with saline rinses, systemic analgesics, and a soft diet with avoidance of carbonated and alcoholic beverages. Lacerations of the oral soft tissues also may be present and must be repaired surgically. Computed tomographic imaging and radiographs are prudent to determine the degree of damage to the maxilla and inspect the oral cavity and gastrointestinal tract for foreign bodies. As expected, reconstruction of the maxillary dentition requires significant dental care, often with placement of implant prosthetics.

◆ CHEMICAL INJURIES OF THE ORAL MUCOSA

Many chemicals and drugs come into contact with the oral tissues. A percentage of these agents are caustic and can cause clinically significant damage.



Patients often can be their own worst enemies. The array of chemicals that have been placed within the mouth to resolve oral problems is amazing. Aspirin, sodium perborate, hydrogen peroxide, gasoline, turpentine, rubbing alcohol, and battery acid are just a few of the more interesting examples. In addition, mucosal damage has been documented from many of the topical medicaments sold as treatments for toothache or mouth sores. Over-the-counter products containing isopropyl alcohol, phenol, hydrogen peroxide, or eugenol have produced adverse reactions in patients. Tooth-whitening products also contain hydrogen peroxide or one of its precursors, carbamide peroxidase, which has been shown to create mucosal necrosis (Fig. 8.14). A surprising number of medications also are potentially caustic when held in the mouth long enough. Aspirin, bisphosphonates, and two psychoactive drugs, chlorpromazine and promazine, are well-documented examples.

Health care practitioners also are responsible for the use of many caustic materials. Silver nitrate, formocresol, sodium hypochlorite, paraformaldehyde, chromic acid, trichloroacetic acid, dental cavity varnishes, and acid-etch materials all can cause patient injury. Education and use of the rubber dam have reduced the frequency of such injuries.

Recreational drugs also can result in areas of mucosal necrosis. Cocaine has been applied directly to the gingiva or alveolar mucosa to judge the drug's purity and can result in areas of epithelial necrosis. Other drugs such as MDMA (methylenedioxymethamphetamine) and amphetamine in association with cocaine also have been noted to damage oral mucosa. A later section of this chapter discusses further the orofacial complications of drug abuse.

• **Fig. 8.14 Mucosal Burn From Tooth-whitening Strips.** Sharply demarcated zone of epithelial necrosis on the maxillary facial gingiva, which developed from the use of tooth-whitening strips. Less severe involvement also is present on the mandibular gingiva.

• **Fig. 8.15 Aspirin Burn.** Extensive area of white epithelial necrosis of the left buccal mucosa caused by aspirin placement in an attempt to alleviate dental pain.

The improper use of aspirin, hydrogen peroxide, silver nitrate, phenol, and certain endodontic materials deserves further discussion because of their frequency of misuse, the severity of related damage, and the lack of adequate documentation of these materials as harmful agents.

Aspirin

Mucosal necrosis from aspirin being held in the mouth is not rare (Fig. 8.15). Aspirin is available not only in the well-known tablets but also as powder.

Hydrogen Peroxide

Hydrogen peroxide became a popular intraoral medication for prevention of periodontitis in the late 1970s. Since that time, mucosal damage has been seen more frequently because of this application. Concentrations at 3% or greater are associated

dentlearn.ir

most often with adverse reactions. Epithelial necrosis has been noted with dilutions as low as 1%, and many over-the-counter oral medications exceed this concentration (Fig. 8.16).

Silver Nitrate

Silver nitrate remains a popular treatment for aphthous ulcerations because the chemical cautery brings about rapid pain relief by destroying nerve endings. Despite this, its use should be strongly discouraged. In all cases, the extent of mucosal damage is increased by its use. In some patients, an abnormal reaction is seen, with resultant significant damage and enhanced pain. In addition, rare reports have documented irreversible systemic argyria secondary to habitual intraoral use of topical silver nitrate after recommendation by a dentist (see page 304).

Phenol

Occasionally, phenol has been used in dentistry as a cavity-sterilizing agent and cauterizing material. It is extremely caustic, and judicious use is required. Over-the-counter agents advertised as "canker sore" treatments may contain low concentrations of phenol, often combined with high levels of alcohol. Extensive mucosal necrosis and rarely underlying bone loss have been seen in patients who placed this material (phenol concentration 0.5%) in attempts to resolve minor mucosal sore spots (Fig. 8.17).

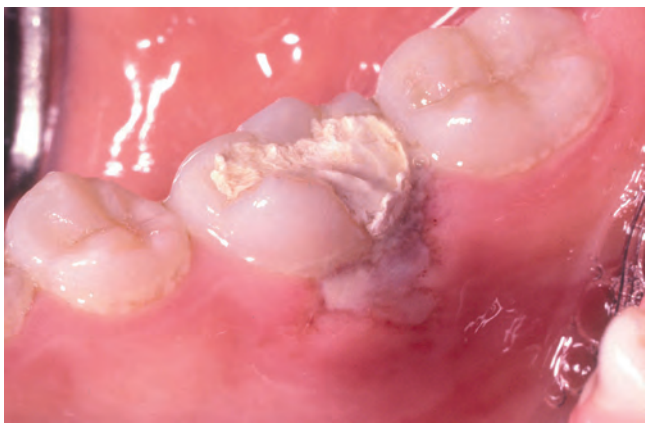
A prescription therapy containing 50% sulfuric acid, 4% sulfonated phenol, and 24% sulfonated phenolic agents is being marketed heavily to dentists for treatment of aphthous ulcerations. Because extensive necrosis has been seen from use of medicaments containing 0.5% phenol, this product must be used with great care.

Endodontic Materials

Because of the past difficulty of obtaining profound anesthesia in some patients undergoing root canal therapy, some clinicians have used arsenical paste or paraformaldehyde formulations to devitalize the inflamed pulp. Gingival and bone necrosis have been documented because of leakage of this material from the pulp chamber into the surrounding tissues. Endodontic irrigants, such as formocresol (Fig. 8.18) or sodium hypochlorite, produce similar necrosis if the material leaks into the surrounding supporting tissues or is injected past the apex, leading some to suggest chlorhexidine as a safer irrigant. Because chlorhexidine lacks the tissue-dissolving properties of sodium hypochlorite, some clinicians have suggested alternating between chlorhexidine and sodium hypochlorite. Others have warned that contact of these two compounds results in formation of a precipitate, para-chloroaniline, which is thought to be potentially toxic and carcinogenic.

The following can reduce the chances of tissue damage during irrigation with sodium hypochlorite:

- Using a rubber dam
- Avoiding excessive pressure during application
- Keeping the syringe needle away from the apex



In some countries, clinicians have used recycled anesthetic cartridges to keep solutions of sodium hypochlorite for

• **Fig. 8.17 Phenol Burn.** Extensive epithelial necrosis of the mandibular alveolar mucosa on the left side. Damage resulted from placement of an over-the-counter, phenol-containing, antiseptic and anesthetic gel under a denture. (Courtesy of Dr. Dean K. White.)

• **Fig. 8.16 Hydrogen Peroxide Burn.** Extensive epithelial necrosis of the anterior maxillary gingiva secondary to interproximal placement of hydrogen peroxide with cotton swabs.

• **Fig. 8.18 Formocresol Burn.** Tissue necrosis secondary to leakage of endodontic material between a rubber dam clamp and the tooth.

dentlearn.ir

endodontic irrigation. Several reports have documented massive necrosis from inadvertent injection of sodium hypochlorite into soft tissue when these cartridges were mistaken for a local anesthetic.

For almost 100 years, calcium hydroxide has been utilized in the chemomechanical debridement of root canals due to its antimicrobial activity and its ability to dissolve uninstrumented fragments of pulpal tissue within the canal. The material is highly alkaline and overfill of the material can be toxic to periapical tissues. Numerous examples of chronic pain, numbness, or burning pain have been reported in patients in which calcium hydroxide escaped from the roots of lower molars and infiltrated the neurovascular canal.

Clinical Features

The previously discussed caustic agents produce similar damage. With short exposure, the affected mucosa exhibits a superficial white, wrinkled appearance. As the duration of exposure increases, the necrosis proceeds, and the affected epithelium becomes separated from the underlying tissue and can be desquamated easily. Removal of the necrotic epithelium reveals red, bleeding connective tissue that subsequently will be covered by a yellowish, fibrinopurulent membrane. Mucosa bound to bone is keratinized and more resistant to damage, whereas the nonkeratinized movable mucosa is destroyed more quickly. In addition to mucosal necrosis, significant tooth erosion has been seen in patients who chronically chew aspirin or hold the medication in their teeth as it dissolves.

The use of the rubber dam can dramatically reduce iatrogenic mucosal burns. When cotton rolls are used for moisture control during dental procedures, two problems may occur. On occasion, caustic materials can leak into the cotton roll and be held in place against the mucosa for an extended period, with mucosal injury resulting from the chemical absorbed by the cotton. In addition, oral mucosa can adhere to dry cotton rolls, and rapid removal of the rolls from the mouth often can cause stripping of the epithelium in the area. The latter pattern of mucosal injury has been termed **cotton roll burn (cotton roll stomatitis)** (Fig. 8.19).

Caustic materials injected into bone during endodontic procedures can result in significant bone necrosis, pain, and perforation into soft tissue. Necrotic surface ulceration and edema with underlying areas of soft tissue necrosis may occur adjacent to the site of perforation.

Histopathologic Features

Microscopic examination of the white slough removed from areas of mucosal chemical burns reveals coagulative necrosis of the epithelium, with only the outline of the individual epithelial cells and nuclei remaining. The necrosis begins on the surface and moves basally. The amount of epithelium affected depends on the duration of contact and the concentration of the offending agent. The underlying connective tissue contains a mixture of acute and chronic inflammatory cells.

• **Fig. 8.19 Cotton Roll Burn.** Zone of white epithelial necrosis and erythema of the maxillary alveolar mucosa.

Treatment and Prognosis

The best treatment of chemical injuries is prevention of exposure of the oral mucosa to caustic materials. When prescribing potentially caustic drugs, the clinician must instruct the patient to swallow the medication and not allow it to remain in the oral cavity for any significant length of time. Children should not use chewable aspirin immediately before bedtime, and they should rinse after use.

Superficial areas of necrosis typically resolve completely without scarring within 10–14 days after discontinuation of the offending agent. For temporary protection, some clinicians have recommended coverage with a protective emollient paste or a hydroxypropyl cellulose film. Topical anesthetics also may be used to provide temporary pain relief. When large areas of necrosis are present, surgical débridement and antibiotic coverage often are required to promote healing and prevent spread of the necrosis.

In patients who report pain, numbness, or dysesthesia in association with a calcium hydroxide overfill into the inferior alveolar canal, referral to an oral surgeon or endodontist is recommended for possible surgical intervention with debridement to remove the material from the injured neurovascular tissue. The success of the surgical intervention is higher if performed within 72 hours of the injury.

◆ NONINFECTIOUS ORAL COMPLICATIONS OF ANTINEOPLASTIC THERAPY

No systemic anticancer therapy currently available can destroy tumor cells without causing the death of at least some normal cells, and tissues with rapid turnover (e.g., oral epithelium) are especially susceptible. The mouth is a common site (and one of the most visible areas) for complications related to cancer therapy. Both radiation therapy and systemic chemotherapy may cause significant oral problems—the more potent the treatment, the greater the risk of complications. Severe therapy-associated mucositis may require a decrease in dosage of the chemotherapy regimen or a break in the schedule of

dentlearn.ir

radiation treatment, both of which can negatively impact the long-term prognosis.

Clinical Features

A variety of noninfectious oral complications are seen regularly because of both radiation and chemotherapy. Two acute changes, **mucositis** and **hemorrhage,** are the predominant problems associated with chemotherapy, especially in cancers, such as leukemia, that involve high treatment doses.

Painful acute mucositis and dermatitis are the most frequently encountered side effects of radiation, but several chronic alterations continue to plague patients long after their courses of therapy are completed. Depending on the fields of radiation, the radiation dose, and the age of the patient, the following outcomes are possible:

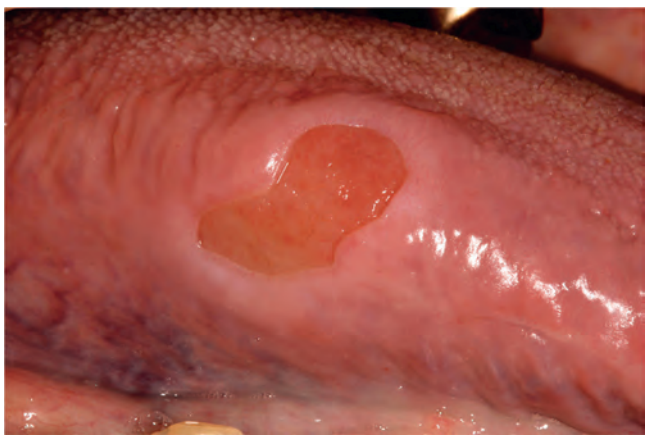
- Xerostomia
- Loss of taste (hypogeusia)
- Osteoradionecrosis
- Trismus
- Chronic dermatitis
- Developmental abnormalities

Hemorrhage

Intraoral **hemorrhage** is typically secondary to thrombocytopenia, which develops from bone marrow suppression. Intestinal or hepatic damage, however, may cause lower vitamin K–dependent clotting factors, with resultant increased coagulation times. Conversely, tissue damage related to therapy may cause release of tissue thromboplastin at levels capable of producing potentially devastating disseminated intravascular coagulation (DIC). Oral petechiae and ecchymosis secondary to minor trauma are the most common presentations. Any mucosal site may be affected, but the labial mucosa, tongue, and gingiva are involved most frequently.

Mucositis

Oral mucositis has been shown to be the single most debilitating complication of high-dose chemotherapy and radiation therapy to the head and neck. In addition to significant local discomfort, the mucositis may be associated with an increased need for total parenteral nutrition, prolonged hospital stays, and most importantly, systemic bacteremia and sepsis.



Oral mucositis is seen in 20%–40% of patients receiving systemic chemotherapy, 80% of patients receiving high-dose chemotherapy, and almost all patients receiving radiation therapy to the head and neck for deeply seated neoplasms. The prevalence associated with chemotherapy is variable, depending on the regimen being used. Agents strongly associated with oral mucositis include methotrexate, 5-fluorouracil, etoposide, irinotecan, cytarabine, 6-mercaptopurine, 6-thioguanine, busulfan, melphalan, cyclophosphamide, idarubicin, doxorubicin (Adriamycin), daunorubicin, dactinomycin, bleomycin, and vinblastine. Beyond the direct effects of the antineoplastic agent, additional risk factors include young age, female gender, poor oral hygiene, oral foci of infection, poor nutrition, impaired salivary function, tobacco use, and alcohol consumption.

Cases of oral **mucositis** related to radiation or chemotherapy are similar in their clinical presentations. The manifestations of chemotherapy develop after a few days of treatment; radiation mucositis may begin to appear during the second week of therapy. Both chemotherapy and radiation-induced mucositis resolve slowly 2–3 weeks after cessation of treatment. Oral mucositis associated with chemotherapy typically involves the nonkeratinized surfaces (i.e., buccal mucosa, ventrolateral tongue, soft palate, and floor of the mouth), whereas radiation therapy primarily affects the mucosal surfaces within the direct portals of radiation.

The earliest manifestation is development of a whitish discoloration from a lack of sufficient desquamation of keratin. This is soon followed by loss of this layer with replacement by atrophic mucosa, which is edematous, erythematous, and friable. Subsequently, areas of ulceration develop with formation of a removable yellowish, fibrinopurulent surface membrane (Figs. 8.20–8.22). Pain, burning, and discomfort are significant and can be worsened by eating and oral hygiene procedures.

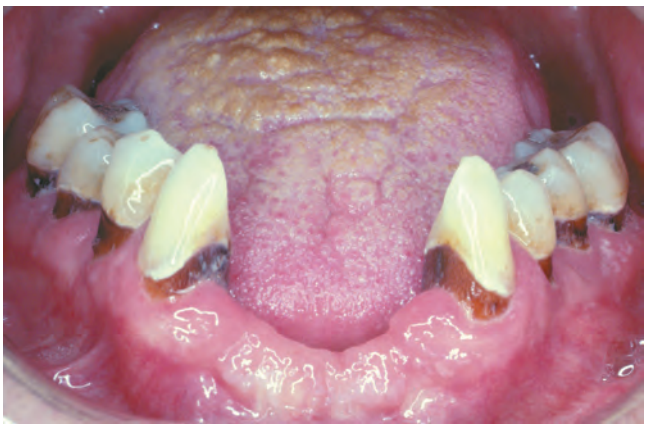
Note resolution of the tumor and the radiation mucositis.

Dermatitis

Acute **dermatitis** of the skin in the fields of radiation is common and varies according to the intensity of the therapy. Patients with mild radiation dermatitis experience erythema, edema, burning, and pruritus. This condition resolves in 2–3 weeks after therapy and is replaced by hyperpigmentation and variable hair loss. Moderate radiation causes erythema and edema in combination with erosions and ulcerations. Within 3 months these alterations resolve, and permanent hair loss, hyperpigmentation, and scarring may ensue. Necrosis and deep ulcerations can occur in severe acute reactions. Radiation dermatitis also may become chronic and be characterized by dry, smooth, shiny, atrophic, necrotic, telangiectatic, depilated, or ulcerated areas (Fig. 8.23).

• **Fig. 8.23 Radiation Dermatitis.** Cutaneous atrophy and telangiectasia secondary to radiation therapy. (Courtesy of Dr. Terry Day.)

Xerostomia



Salivary glands are very sensitive to radiation, and **xerostomia** is a common complication. When a portion of the salivary glands is included in the fields of radiation, the remaining glands undergo compensatory hyperplasia to maintain function. The changes begin within 1 week of initiation of radiation therapy, with a dramatic decrease in salivary flow noted during the first 6 weeks of treatment. Even further decreases may be noted for up to 3 years.

Serous glands exhibit an increased radiosensitivity when compared with the mucous glands. On significant exposure, the parotid glands are affected dramatically and irreversibly. In contrast, the mucous glands partially recover and, over several months, may achieve flow that approaches 50% of preradiation levels. In addition to the discomfort of a mouth that lacks proper lubrication, diminished flow of saliva leads to a significant decrease of the bactericidal action and self-cleansing properties of saliva.

Without intervention, patients often develop symptomatic dry mouth that affects their ability to eat comfortably, wear dentures, speak, and sleep. In addition, there often is an increase in the caries index **(radiation-related caries),** regardless of the patient's past caries history (Fig. 8.24). The decay is predominantly cervical in location and often secondary to xerostomia. Radiation also causes biomechanical alterations in the teeth, resulting in reduced microhardness and decreased resistance to tensile and compressive stresses.

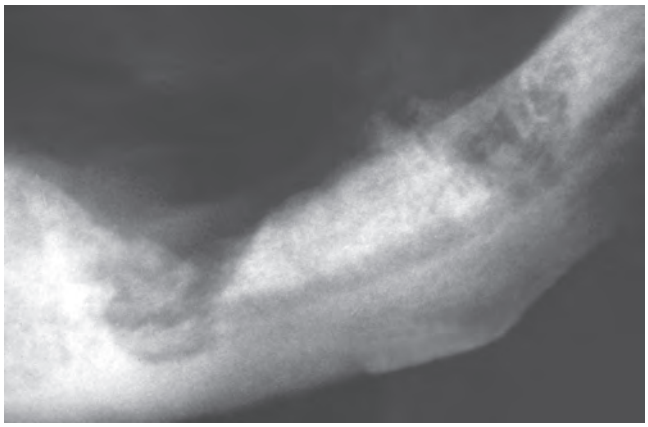
Several interventions to reduce radiation-related xerostomia have demonstrated promise. Intensity-modulated radiation therapy (IMRT) appears to be more gland-sparing than conventional radiation therapy and is emerging as the standard of care for head and neck cancer. Amifostine is a cytoprotective agent that has been shown to reduce the severity and duration of xerostomia in patients receiving radiotherapy (but not chemoradiotherapy) for head and neck cancer. On

dentlearn.ir

• **Fig. 8.24 Xerostomia-Related Caries.** Extensive cervical caries of mandibular dentition secondary to radiation-related xerostomia.

• **Fig. 8.25 Osteoradionecrosis (ORN).** Ulceration overlying left body of the mandible with exposure and sequestration of superficial alveolar bone.

the downside, this medication has significant side effects, and there are lingering concerns related to possible tumor protective effects. Surgical transfer of a single submandibular salivary gland outside of the radiation field to the submental space has proven successful in selected patients.



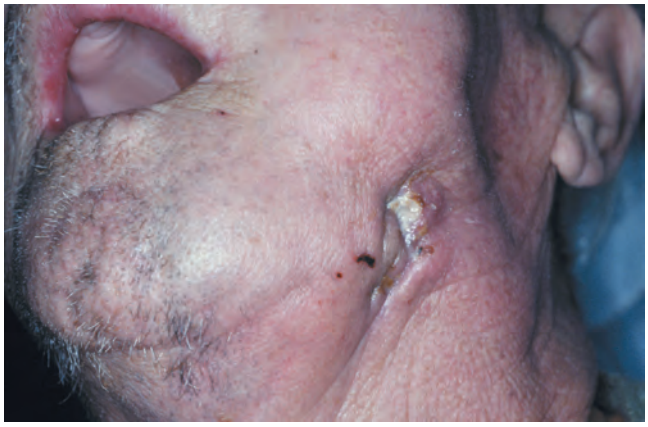
Taste Disorders

In a review of 1645 drugs, 282 were associated with **dysgeusia** (altered sense of taste) whereas 61 created **hypogeusia** (abnormally lowered sense of taste). Of these drugs, the most common group were antineoplastic medications. In addition, in patients who receive significant radiation to the oral cavity, a substantial loss of all four tastes often develops within several weeks. Although these tastes return within 4 months for most patients, some patients are left with permanent hypogeusia; others may have persistent dysgeusia (see page 869).

Osteoradionecrosis

Osteoradionecrosis (ORN) is defined as exposed nonvital irradiated bone that persists longer than 3 months in the absence of local neoplastic disease. It represents one of the most serious complications of radiation to the head and neck. In earlier studies, the prevalence approached 15%, but the risk has been reduced to less than 5% secondary to modern therapeutic advances such as intensity-modulated radiotherapy (IMRT) and three-dimensional conformal radiation therapy (3DCRT). These newer techniques can maintain therapeutic effectiveness but decrease the total maximum radiation to the jaw bones. Most cases of ORN occur in patients who have received greater than 60 Gy, with the majority of cases occurring between 4 months and 3 years after completion of radiation therapy. Although the rate of osteoradionecrosis appears to be decreasing due to advances in radiotherapy technique, the prevalence still appears to be increasing due to a greater percentage of head and neck cancer patients receiving radiation and the increasing numbers of surviving patients.

Two major etiologic theories for osteoradionecrosis remain popular. In 1983, Marx proposed that radiation



• **Fig. 8.26 Osteoradionecrosis (ORN).** Multiple ill-defined areas of radiolucency and radiopacity of the mandibular body.

produced hypovascularity, hypoxia, and hypocellularity with persistent hypoxia creating the primary disturbance leading to osteoradionecrosis. This theory laid the groundwork for use of hyperbaric oxygen in the management of affected patients. In 2002–2004, Delanian and Lefaix proposed the fibroatrophic theory that suggests radiation therapy causes activation and dysregulation of fibroblastic activity resulting in fibrotic tissue prone to breakdown. This theory has led to use of antioxidant and antifibrotic medications as a primary therapeutic approach.

Although most instances of ORN arise secondary to local trauma (such as, tooth extraction), a minority appear spontaneous. Seventy percent of osteoradionecrosis cases occur in the first three years following completion of radiation therapy, but patients remain at risk for trauma-induced ORN for the remainder of their lives. The mandible is involved 24 times more frequently than the maxilla (Fig. 8.25), and the process is three times more common in dentate patients. Affected areas of bone reveal ill-defined areas of radiolucency that may develop zones of relative radiopacity as the dead bone separates from the residual vital areas (Fig. 8.26). Intractable pain, cortical perforation, fistula formation, surface ulceration, and pathologic fracture may be present (Fig. 8.27).

dentlearn.ir

• **Fig. 8.27 Osteoradionecrosis (ORN).** Same patient as depicted in Fig. 8.26. Note fistula formation of the left submandibular area resulting from ORN of the mandibular body.

The radiation dose is the main factor associated with bone necrosis, although the proximity of the tumor to bone, the presence of remaining dentition, and the type of treatment also exert an effect. Additional factors associated with an increased prevalence include older age, male sex, poor health, or nutritional status, and continued use of tobacco or alcohol.

Prevention of bone necrosis is the best course of action. Before therapy, all unrestorable teeth and those with advanced periodontal disease should be extracted, all oral foci of infection should be eliminated, and excellent oral hygiene should be initiated and maintained. A healing time of at least 3 weeks between extensive dental procedures and the initiation of radiotherapy significantly decreases the chance of bone necrosis. Extraction of teeth or any bone trauma is strongly contraindicated during radiation therapy.

Trismus

Trismus may develop and can produce extensive difficulties concerning access for hygiene and dental treatment. Tonic muscle spasms with or without fibrosis of the muscles of mastication and the temporomandibular joint (TMJ) capsule can cause difficulties in jaw opening. When these structures are radiated heavily, jaw-opening exercises may help to decrease or prevent problems.

Developmental Abnormalities

Antineoplastic therapy during childhood can affect growth and development. The changes vary according to the age at treatment and the type and severity of therapy. Radiation can alter the facial bones and result in micrognathia, retrognathia, or malocclusion. Developing teeth are very sensitive and can exhibit several changes, such as root dwarfism, blunting of roots, dilaceration of roots, incomplete calcification, premature closure of pulp canals in deciduous teeth, enlarged canals in permanent teeth, microdontia, and hypodontia (see page 56).

Treatment and Prognosis

Optimal treatment planning involves the oral health practitioner before initiation of antineoplastic therapy. Elimination of all current or potential oral foci of infection is paramount, along with patient education about maintaining ultimate oral hygiene. Proper nutrition, cessation of tobacco use, and alcohol abstinence minimize oral complications. Once cancer therapy is initiated, efforts must be directed toward relieving pain, preventing dehydration, maintaining adequate nutrition, eliminating foci of infection, and ensuring continued appropriate oral hygiene.

Mucositis

Although therapy-related mucositis represents one of the most intensely studied toxicities related to cancer care, the current standard of care remains centered on palliative approaches combined with a small number of interventions that are available in specific situations. The best source of information originates from the Mucositis Study Group of the Multinational Association of Supportive Care in Cancer and International Society of Oral Oncology (MASCC/ISOO), with their guidelines being adopted by the European Society of Medical Oncology and the US National Comprehensive Cancer Network. As described in their most recent review, the number of interventions backed by strong science sadly is very low.

Palifermin is a keratinocyte growth factor and the only agent that has been approved by the FDA for prevention of oral mucositis. Although this agent has demonstrated significant effectiveness, its use is limited to patients receiving high-dose chemotherapy and total body irradiation prior to autologous stem cell transplantation for hematologic cancers. Concern remains that this epithelial growth factor may promote growth of tumor cells in patients with carcinoma.

Cryotherapy (placement of ice chips, ice-cold water, ice cream, or ice popsicles in the mouth 5 minutes before chemotherapy and continued for 30 minutes) has been shown to reduce significantly the prevalence and severity of oral mucositis caused by a bolus injection of 5 fluorouracil for solid cancers or high-dose melphalan before hematopoietic stem cell transplants (both are chemotherapeutic drugs with a short half-life). It has been suggested that the cold may produce local vasoconstriction leading to reduced exposure of the oral mucosa to the chemotherapeutic medications. Cryotherapy has no effect on the prevalence or severity of radiation mucositis.

Benzydamine is a nonsteroidal anti-inflammatory medication with topical analgesic and anesthetic effects. Although the medication is not marketed in the United States due to an association with hallucinations, it is available through compounding pharmacies. Benzydamine has been recommended by the MASCC/ISOO for prevention of oral mucositis in patients with head and neck cancer who are receiving radiotherapy up to 50 Gy without concomitant

dentlearn.ir

chemotherapy. Subsequently, a 2019 systematic review of anti-inflammatory agents in cancer patients suggested benzydamine also is effective in individuals receiving greater than 50 Gy and in those receiving chemoradiotherapy.

Zinc, in addition to being an antioxidant, favors the tissue repair process. In the MASCC/ISOO review, zinc supplementation demonstrated a reduction of oral mucositis in patients with oral cancer who were receiving radiation therapy or chemoradiation. Unfortunately, one study has suggested that cigarette smokers who use an antioxidant such as zinc may have a reduced therapeutic impact of their radiation therapy.

Low-level laser therapy also was associated with a decreased prevalence of oral mucositis in selected cancer patients. The strongest effect was seen in patients receiving high-dose chemotherapy prior to hematologic stem cell transplant with or without total body irradiation. In addition, a similar positive effect was seen in patients receiving head and neck radiation therapy without concomitant chemotherapy. In a systematic review and meta-analysis, prophylactic low-level laser therapy reduced the risk of severe oral mucositis; whereas its therapeutic use shortened the duration of severe oral mucositis in patients receiving chemotherapy or radiotherapy. In the most recent MASCC/ISOO guidelines, use of the mucosal coating agent sucralfate was not recommended. In addition, insufficient evidence was found to recommend use of the commonly utilized coating agent "magic mouthwash," a variable mixture of lidocaine, diphenhydramine, and milk of magnesia or kaopectate with or without an antifungal, antibiotic, or corticosteroid. Alternatively, the use of 0.5% doxepin mouthwash (tricyclic antidepressant with anesthetic and analgesic properties) or 2% morphine mouthwash has been recommended. Several additional coating agents exist but demonstrate insufficient scientific evidence of effectiveness to warrant a positive recommendation from MASCC/ISOO. If topical therapies are insufficient, patient-controlled analgesia with morphine or transdermal fentanyl is favored by the current guidelines.

One of the more effective mechanisms to reduce radiation-associated mucositis has been placement of midline radiation blocks or use of three-dimensional radiation treatment to limit the volume of irradiated mucosa. In addition, cotton rolls or custom splints have been used to cover metallic dental restorations to prevent localized enhanced scatter effect of the radiation.

Xerostomia

Xerostomic patients should be counseled to avoid all agents that may decrease salivation, especially the use of tobacco products and alcohol. To combat xerostomia-related caries, a regimen of daily topical fluoride (1.1% neutral sodium fluoride) application should be instituted.

The problem of chronic xerostomia has been approached using salivary substitutes and sialagogues. Use of liquids with a low pH or significant sugar content should be avoided as a mouth moistener. Because the mucous glands often demonstrate significant recovery after radiation, the sialagogues show promise because they stimulate the residual functional glands. Moisturizing gels and sprays, sugar-free candies, chewing gum, and various artificial salivary substitutes are available. Gums and mints containing xylitol have an added benefit of inhibition of cariogenic bacteria. Many salivary substitutes are expensive and of short duration, with patients often alternatively choosing frequent use of water. In these cases, use of unfiltered fluoridated tap water is recommended over bottled water that may not contain sufficient fluoride. In controlled clinical studies, some of the most effective and longer-lasting products are one of the systemic sialogogues, such as pilocarpine, cevimeline, bethanechol, carbocholine, or anetholtrithione. Of these, the most widely used are pilocarpine and cevimeline. Although these drugs may be beneficial for many patients, they are contraindicated in patients with asthma, gastrointestinal ulcerations, labile hypertension, glaucoma, chronic obstructive pulmonary disease, and significant cardiovascular disease. Adverse reactions are uncommon but include excess sweating, rhinitis, headache, nausea, uropoiesis, flatulence, and circulatory disorders. Bethanechol also appears effective, is not contraindicated in patients with asthma and narrow angle glaucoma, and has been associated with fewer side effects than pilocarpine.

Radiation-related caries can be minimized through regular professional care, application of fluoride varnishes, and use of remineralizing toothpastes. Restoration of active areas of decay is achieved best through use of adhesive materials such as resin composites.

Taste Disorders

Although the taste buds often regenerate within 4 months after radiation therapy, the degree of long-term impairment is highly variable. In those with continuing symptoms, zinc sulfate supplements greater than the usual recommended daily doses may be beneficial.

Osteoradionecrosis

Although prevention must be stressed, cases of ORN do occur. The therapeutic approach is determined largely by the severity of the osteoradionecrosis. Early localized disease in asymptomatic or mildly symptomatic patients usually is approached conservatively with oral hygiene optimization and systemic antibiotics. In symptomatic patients with larger areas of involvement, the antioxidant and antifibrotic drugs pentoxifylline and tocopherol often are combined with sequestrectomy or saucerization to remove the necrotic bone and obtain primary mucosal closure. A meta-analysis of pentoxifylline and tocopherol has shown that the therapy is more effective than antibiotics or hyperbaric oxygen in patients with osteoradionecrosis. In resistant cases, addition of clodronate has been shown to lead to resolution in many patients. Clodronate is a unique first generation nonnitrogenous bisphosphonate that not only decreases osteoclastic activity but also stimulates osteoblastic function and reduces inflammatory cytokine expression; sadly, this

• BOX 8.1 Medication-Related Osteonecrosis of the Jaw Case Definition

Required characteristics for diagnosis of medication-related osteonecrosis of the jaw (MRONJ):
- Current or previous treatment with antiresorptive or antiangiogenic agent
- Exposed bone in maxillofacial region for longer than 8 weeks
- No history of radiation therapy or obvious metastatic disease to the jaws

• BOX 8.2 Staging of Medication-Related Osteonecrosis of the Jaw

- Stage 0: No exposed necrotic bone but with associated clinical or radiographic changes such as unexplained odontalgia, dull bone pain, sinus pain, altered neurosensory function, unexplained loose teeth, sinus tracts or alveolar bone loss not associated with periapical or periodontal infection, patchy zones of osteosclerosis, thickening of the lamina dura, failure to remodel extraction sites.
- Stage 1: Asymptomatic exposed necrotic bone or sinus tract that probes to bone
- Stage 2: Symptomatic exposed necrotic bone or sinus tract that probes to bone associated with pain and erythema in the region with or without purulence.
- Stage 3: Symptomatic exposed necrotic bone or sinus tract that probes to bone with more than one of the following: necrotic bone beyond the alveolus (extension to inferior border or ramus of mandible, extension into the sinus or zygoma of the maxilla), pathologic fracture, extraoral sinus tract, oral antral or nasal communication.

• BOX 8.3 Antiangiogenic Agents

Tyrosine kinase inhibitors:
- Axitinib (Inlyta)
- Cabozantinib (Carbometyx, Cometriq)
- Dasatinib (Sprycell)
- Erlotinib (Tarceva)
- Imatinib (Gleevec)
- Pazopanib (Votrient)
- Sorafenib (Nexavar)
- Sunitinib (Sutent)

Monoclonal antibody inhibiting vascular endothelial growth factor:
- Aflibercept (Zaltrap, Eylea)
- Bevacizumab (Avastin, Mvasi)
- Ramuciramab (Cyramza)

medication is not commercially available in the United States. Hyperbaric oxygen is expensive with numerous contraindications and possible adverse reactions. For these reasons, many reserve its use for high-risk patients with persistent osteoradionecrosis that is resistant to other forms of therapy. Some clinicians have begun use of ultrasound in place of hyperbaric oxygen due to its low adverse reaction profile and its ability to stimulate tissue regeneration and angiogenesis. For advanced cases that demonstrate extension to the lower border of the mandible, associated sinus formation, or pathologic fracture, the primary therapy is surgical resection with immediate reconstruction. The amount of bone removed is determined by clinical judgment, with the surgery extended until brightly bleeding edges are seen.

◆ MEDICATION-RELATED OSTEONECROSIS OF THE JAW (BISPHOSPHONATE-RELATED OSTEONECROSIS; ANTIRESORPTIVE-RELATED OSTEONECROSIS)

In 2003, a pattern of gnathic osteonecrosis began to be recognized, which was difficult to treat and appeared to be associated with certain medications. This process was correlated initially to bisphosphonates, leading to the name **bisphosphonate-related osteonecrosis of the jaw (BRONJ).** In the 2011 position paper of the American Dental Association (ADA), the name was modified to **antiresorptive-related osteonecrosis of the jaw (ARONJ)** due to the discovery of an association with a monoclonal antibody designed to prevent osteoclastic maturation (denosumab). Subsequently, the 2014 position paper of the American Association of Oral and Maxillofacial Surgeons (AAOMS) changed the name again to **medication-related osteonecrosis of the jaw (MRONJ)** due to the discovery that antiangiogenic therapies also may be implicated. In this update, the position paper provided a specific definition (Box 8.1) and updated the associated staging (Box 8.2). The name, medication-related osteonecrosis, is sufficiently generic and hopefully will stand the test of time. The name, definition, and associated staging remain unchanged in most recent 2022 update.

Antiangiogenic agents are prescribed for a variety of cancers and include tyrosine kinase inhibitors and monoclonal antibodies directed against vascular endothelial growth factor (Box 8.3). This risk is increased if these agents are combined with bisphosphonates. Several additional medications also have been implicated in small series of cases including mTOR inhibitors (everolimus, temsirolimus), immunomodulators (adalimumab, infliximab, rituximab), and methotrexate; however, much more research is necessary to prove the association between these medications and MRONJ.

Currently, the medications most strongly associated with gnathic osteonecrosis include the aminobisphosphonates (nitrogen-containing bisphosphonates), denosumab, and a more recently developed medication, romosozumab. (Box 8.4). The bisphosphonates and denosumab are antiresorptives and used primarily to treat patients with osteoporosis or various cancers that involve bone (predominantly multiple myeloma, breast carcinoma, and prostate carcinoma). Less frequent uses include treatment for Paget disease, osteogenesis imperfecta, rheumatoid arthritis, and giant cell tumors of bone. Most osteonecrosis cases occur in patients receiving

dentlearn.ir

• BOX 8.4 Antiresorptive Agents and Bone Metabolism Modifiers

Aminobisphosphonate antineoplastics:
- Pamidronate disodium (Aredia)
  - Relative potency of 100
  - IV infusion every 4 weeks
- Ibandronate sodium (Boniva)
  - Relative potency of 10,000
  - IV infusion every 4 weeks
- Zoledronic acid (Zometa)
  - Relative potency of 100,000
  - IV infusion every 4 weeks

Denosumab antineoplastic:
- Denosumab (Xgeva)
  - Injection every 4 weeks

Aminobisphosphonates for osteoporosis:
- Risedronate sodium (Actonel)
  - Relative potency of 5000
  - PO weekly
- Delayed release risedronate sodium (Atelvia)
  - Relative potency of 5000
  - PO weekly
- Ibandronate sodium (Boniva)
  - Relative potency of 10,000
  - PO monthly
  - IV infusion every 3 months
- Alendronate sodium (Fosamax)
  - Relative potency of 1000
  - PO weekly
- Zoledronic acid (Reclast)
  - Relative potency of 100,000
  - IV annually

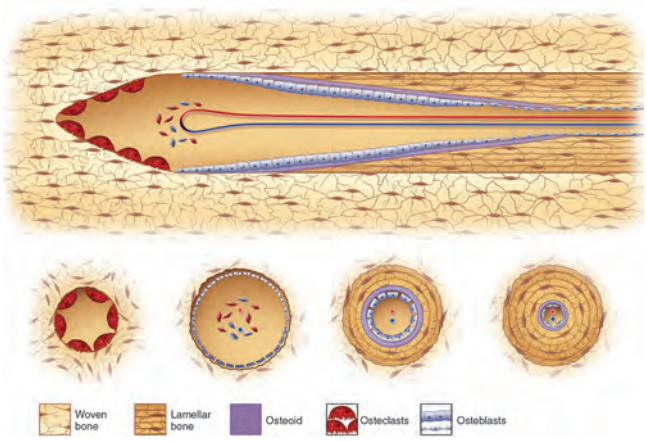
Denosumab for osteoporosis:
- Denosumab (Prolia)
  - Injection every 6 months

Romosozumab for osteoporosis:
- Romososumab (Evenity)
  - Injection monthly

IV, Intravenous; *PO,* per os (by mouth).

the medication as part of their therapy for cancer. Romosozumab is indicated primarily for patients with osteoporosis who are at high risk of fracture or have failed other osteoporosis therapy. The risk of osteonecrosis related to romosozumab use is comparable to that seen with alendronate.

Bisphosphonates, denosumab, and bevacizumab also are administered to children for a wide variety of diseases associated with childhood osteoporosis, osteogenesis imperfecta, hypercalcemia of malignancy, ectopic calcifications, chemotherapy-related osteonecrosis (such as corticosteroids), and several childhood malignancies. Despite the use of potent formulations, there have been no reports of osteonecrosis in children related to these medications. The reason for this is unclear, but investigators have speculated it may be due to the increased vascularity, high marrow cellularity, and greater bone turnover in this age group. Use of bisphosphonates in children with osteogenesis imperfecta identified a greater than 1.5-year delay in tooth eruption.



Once in the serum, 50% of bisphosphonates is cleared rapidly by the kidneys with the remainder going to bone. The medications are not distributed evenly throughout the skeleton. Osteocytes represent 85% of the cells associated with bone and do not retain the medication. In contrast, osteoclasts demonstrate an affinity eight times greater than osteocytes, but they release the drug for recycling at the end of their short 2-week life span. Osteoblasts exhibit four times the affinity of osteocytes and incorporate the medication into the bone matrix. Due to a half-life longer than 10 years, deposits of bisphosphonates can remain in place for over four decades. The effect of the medication on the bone varies with concentration. At low concentrations, the medication diminishes the ability of osteoclasts to resorb and degrade bone matrix, whereas high local concentration induces osteoclastic apoptosis. Therefore, bisphosphonates are selectively concentrated into areas of bone repair and remodeling, with potential effects over the patient's lifetime. In addition, the impact on the bone worsens as the local concentration is increased.

Denosumab is a monoclonal antibody that also reduces osteoclastic function, but it does this by inhibiting osteoclastic differentiation. Due to the short life span of osteoclasts, this medication quickly reduces osteoclastic activity by 85% with maximal reduction occurring within 1 month of an injection. The medication is not deposited in bone and has a half-life of 24.5 days, with complete clearance in 4–5 months.

Romosozumab is a monoclonal antibody that inhibits the action of the protein sclerostin. Bone cells release sclerostin which acts to decrease osteoblast-mediated bone formation and increase bone resorption. Administration of romosozumab blocks sclerostin activity, leading to increased bone formation with reduced bone resorption. The medication is administered monthly as an injection. Romosozumab use has shown rapid gains in bone mineral density with significant reductions in both vertebral and nonvertebral fractures. Serious adverse events related to its use are occasional hypersensitivity reactions and an increased frequency of serious cardiovascular events. Although rare, cases of gnathic osteonecrosis and atypical femoral fractures have been associated with its use. Less is known about this medication due to its late arrival and the reduction in its use due to the association with an increase in adverse cardiovascular events.

Any discussion of antiresorptive agents also must include information on bone healing. When a traumatic event such as an extraction occurs, the initial clot is replaced with granulation tissue and eventually woven bone. The remodeling period of this immature bone into structurally sound lamellar bone typically is 4 months but can range from 2–8 months. The final remodeling is performed by an organized synergism of osteoclasts, osteoblasts, and the local vascular supply, which work together in a cell packet known as the basic multicellular unit (BMU). This is a moving structure that requires continual replacement of participating cells at exactly the correct time and place in an ever-changing position. The osteoclasts are critical cells of the BMU and are

dentlearn.ir

• **Fig. 8.28 Basic Multicellular Unit (BMU).** Organized synergy of osteoclasts, osteoblasts, and vasculature working together to transform immature woven bone into structural sound lamellar bone.

largely responsible for the signaling necessary for the participation of the other cellular components (Fig. 8.28). Functional impairment or loss of the osteoclasts by antiresorptive drugs disrupts not only resorption but also new lamellar bone deposition and angiogenesis.

Although most osteonecrosis cases have occurred in the jaws, problems are beginning to surface elsewhere in the skeleton. Osteonecrosis of the ear has been documented following removal of an exostosis. More significantly, numerous orthopedic surgeons have reported an increased prevalence of subtrochanteric or femoral shaft fractures associated with aminobisphosphonates, leading the US Food and Drug Administration (FDA) to add this complication to the drug information.

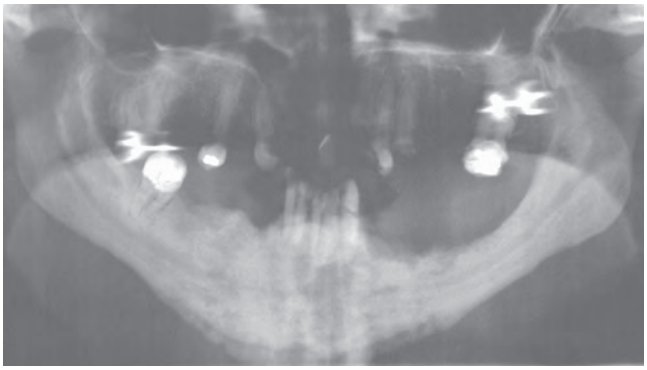
Clinical and Radiographic Features

In an excellent comprehensive review of 2408 reported cases of BRONJ, 89% were discovered in patients who were treated with the IV formulations (primarily pamidronate and zoledronic acid) for cancer, with 43% being reported in patients with multiple myeloma. In another summary review, the prevalence of osteonecrosis associated with the IV formulations in cancer patients has been estimated to be 100 cases per 10,000 patients. Unfortunately, all the information now available is based on reported cases, and such reports frequently have inherent biases. Randomized prospective trials with appropriate controls will be necessary to obtain reliable data with respect to prevalence and management.

Osteonecrosis related to use of aminobisphosphonates for osteoporosis is most uncommon. A conservative estimate by the drug industry suggested an annual incidence of 0.7 per 100,000, but a more recent review suggested 10 cases occur per 100,000 patients (100 times less frequent than that seen in cancer patients treated with antiresorptive medications). In another systematic review with meta-analysis, the prevalence of osteonecrosis reported in patient receiving antiresorptives for osteoporosis was 0.01% whereas the

• **Fig. 8.29 Medication-Related Osteonecrosis.** Bilateral necrotic exposed bone of the mandible in a patient receiving zoledronic acid for metastatic breast cancer. (Courtesy of Dr. Brent Mortenson.)

• **Fig. 8.30 Medication-Related Osteonecrosis**. Necrotic exposed bone of the left anterior maxilla in a cancer patient receiving denosumab. (Courtesy of Dr. Martin Steed).



frequency increased to 12% in patients receiving antiresorptive medications for cancer and 16% for those receiving both antiresorptives and antiangiogenics. However, well-designed prospective trials for the true frequency of this complication have yet to be performed. Additional risk factors for MRONJ include advanced patient age (older than 65 years), corticosteroid use, use of chemotherapy drugs, diabetes, smoking or alcohol use, poor oral hygiene, and duration of drug use exceeding 3 years. A predictive test for those at risk for bisphosphonate osteonecrosis has not been confirmed. Some investigators have suggested use of a serum marker for bone turnover, serum C-telopeptide (CTX), but the test has demonstrated insufficient reliability and accuracy in predicting the risk of developing of MRONJ.

In the previously mentioned comprehensive review, the mandible was involved in 65%, the maxilla in 27%, and both jaws in 8% (Fig. 8.29 and 8.30). In 67% of these patients, the necrosis followed a dental extraction, with another 26% arising spontaneously, and 7% associated with a variety of triggers such as denture pressure or minor trauma of a torus (Figs. 8.31 and 8.32). In patients with exposed bone, 16%

dentlearn.ir

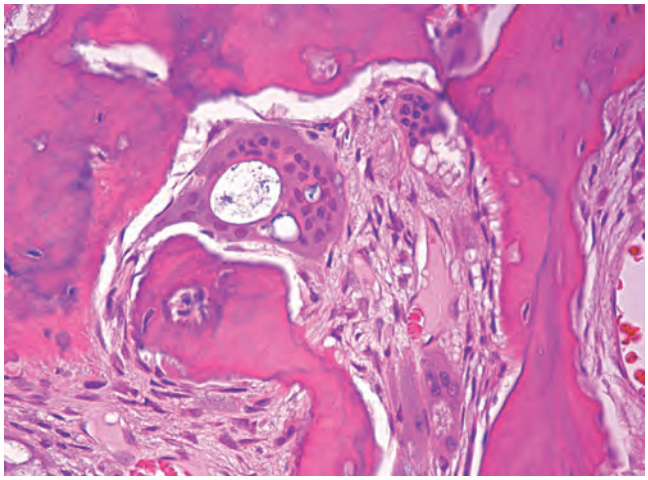
• **Fig. 8.34 Medication-Related Osteonecrosis.** Patient with multiple cutaneous sinuses associated with extensive necrosis of the left side of the mandible. The patient was taking zoledronic acid for multiple myeloma. (Courtesy of Dr. Molly Rosebush.)

were asymptomatic, 66% were painful, and another 18% demonstrated extensive involvement in which the associated pain was not responsive to antibiotics.

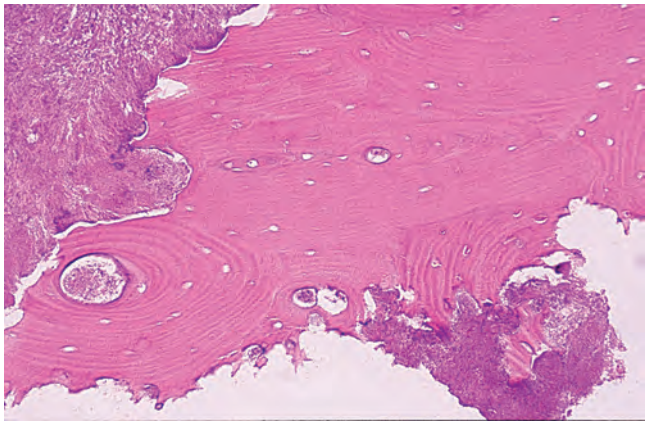
Research related to denosumab-associated osteonecrosis is in its infancy when compared to BRONJ, but reviews of cancer patients randomized to zoledronic acid or denosumab have demonstrated a similar frequency of osteonecrosis with these two medications. The frequency of MRONJ appears to range from 70 to 90 cases per 10,000 cancer patients receiving denosumab.

Investigators have suggested that bone at imminent risk for osteonecrosis often will demonstrate increased radiopacity before clinical evidence of frank necrosis. These changes typically occur predominantly in areas of increased bone remodeling, such as the alveolar ridges. Panoramic radiographs often will reveal a marked radiodensity of the crestal portions of each jaw, with a more normal appearance of the bone away from tooth-bearing portions. Periosteal hyperplasia also is not rare. In more severe cases, the osteonecrosis creates a moth-eaten and ill-defined radiolucency with or without central radiopaque sequestra (Fig. 8.33). In some cases, the necrosis can lead to development of a cutaneous sinus or pathologic fracture (Fig. 8.34).



Histopathologic Features

Biopsy of vital bone altered by aminobisphosphonates is not common. In such cases, the specimen often reveals irregular trabeculae of pagetoid bone, with adjacent enlarged and irregular osteoclasts that often demonstrate numerous intracytoplasmic vacuoles (Fig. 8.35). Specimens of active areas of MRONJ reveal trabeculae of sclerotic lamellar bone, which demonstrate loss of the osteocytes from their lacunae and frequent peripheral resorption with bacterial colonization (Fig. 8.36). Although the peripheral bacterial colonies often resemble actinomycetes, the infestation is not supportive of a diagnosis of invasive cervicofacial actinomycosis.



Treatment and Prognosis

Virtually all recommendations regarding management of patients who are taking or have been exposed to antiresorptive agents are empirical. No large, randomized, controlled studies have been done with respect to prevention or treatment of the complications of this therapy. The best therapeutic approach to MRONJ is prevention. In cancer patients evaluated before initiation of bisphosphonate

therapy, the goal is to improve dental health to prevent future procedures that disrupt bone; this includes elimination of oral foci of infection and removal of large tori or partially impacted teeth. If only noninvasive oral care is indicated, then the initiation of the medication need not be delayed. If surgical procedures need to be performed, then a month-long delay in initiation of the medication is recommended, along with prophylactic antibiotic therapy. In an 18-year review of 273 patients presenting to the dental service of Memorial Sloan Kettering Cancer Center, a premedication dental evaluation was associated with a 0.9% prevalence of MRONJ; in contrast, patients who did not receive a premedication dental evaluation experienced a 10.5% frequency of MRONJ. This represents an almost 12-fold increase in the prevalence of MRONJ in those patients who did not have a dental evaluation prior to the start of their antiresorptive medication.

For cancer patients actively being treated with antiresorptive therapy, manipulation of bone should be avoided if possible. Conventional endodontics is a better option than extraction. If a nonvital tooth is not restorable, then endodontics should be performed and followed by crown amputation. Teeth with 1+ or 2+ mobility should be splinted; those with 3+ mobility can be extracted.

Despite the desire to avoid jaw surgery during IV therapy, occasional clinical situations may make surgical intervention unavoidable. Several investigators have suggested that the likelihood of osteonecrosis can be minimized by antibiotic prophylaxis starting 1 day prior and extending 3 days after any invasive dental procedure.

For patients with MRONJ, the primary goal of therapy is to minimize pain. Aggressive removal of dead bone typically results in further bone necrosis, and hyperbaric oxygen has not been significantly beneficial. Asymptomatic patients (Stage 1) should rinse daily with chlorhexidine and be monitored closely. Any rough edges of exposed bone should be smoothed and loose sequestra can be removed carefully. If the exposed bone irritates adjacent tissues, then coverage with a soft splint may provide some relief. In symptomatic patients (Stage 2), systemic antibiotic therapy and chlorhexidine usually reduce discomfort. If the antibiotics fail to stop the pain, then hospitalization with IV antibiotic therapy can be considered. In extensive cases with necrosis beyond the confines of the alveolus (Stage 3), the dead bone is removed surgically. Such removal may require segmental resection in the mandible and a partial or total maxillectomy of the upper jaw. Mandibular resection is reconstructed with a titanium osteosynthesis plate and may include a microsurgical free tissue transfer; whereas a prosthetic appliance is used for maxillary reconstruction. Because of the long half-life of bisphosphonates, discontinuation of the drug offers no short-term benefit. In isolated anecdotal reports of recalcitrant cases, discontinuation of the medication for 6–12 months occasionally has been associated with spontaneous sequestration and resolution.

The conservative predominantly nonsurgical therapeutic approach described in the preceding paragraph has been the subject of controversy with many surgeons supporting more aggressive intervention. Proponents of surgical intervention believe that conservative management translates to *palliation*; whereas surgical removal of necrotic and infected bone translates to *cure.* Both groups agree that Stage 3 is treated best with surgical resection, with the main controversy centering around therapy of patients presenting with Stage 1 and 2. Many believe that surgery represents the gold standard for MRONJ management in all stages with nonsurgical approaches reserved for patients who refuse surgery or are ineligible for surgery due to health reasons. These opinions are supported by numerous studies in which complete healing was achieved at a significantly higher rate in patients treated surgically. In addition, a 2019 longitudinal study of 92 patients with Stage 1 MRONJ treated with a standardized conservative nonsurgical protocol revealed 80% of the patients showed progression of the lesions with an upshift

dentlearn.ir

from Stage 1 to 2 or 3. This investigation suggests surgical intervention not only resolves symptoms but also prevents progression of the bone necrosis.

In a change from previous position papers, the 2022 update of the AAOMS position paper on medication-related osteonecrosis supports the value of earlier surgical intervention. Close clinical and radiographic follow-up is recommended for all stages of MRON with early operative intervention recommended for patients who fail nonoperative therapy or demonstrate worsening disease.

When surgery is performed, several adjunctive therapies in addition to antimicrobials occasionally are employed to improve the success of the procedure. These interventions include pentoxifylline and tocopherol, teriparatide, abaloparatide, hyperbaric oxygen, platelet rich plasma, and low-level laser therapy. Insufficient documentation of these interventions currently exists to warrant definitive inclusion into the current therapeutic protocols.

To eliminate all areas of necrotic bone, intraoperative fluorescence-guided debridement has been performed on bone labeled preoperatively with doxycycline. In this technique, necrotic bone appears pale bluish-white while vital bone appears brightly fluorescent. In a similar technique, the autofluorescence properties of vital bone are noted after exposure to 400–440-nm wavelengths of light. In this situation, vital bone demonstrates green fluorescence while necrotic bone reveals pale or no fluorescence.

Prevention also represents the best approach for patients taking antiresorptive medications for osteoporosis. In the original ADA position paper, a 3-month drug holiday before and after osseous surgery was suggested for any patient using bisphosphonates longer than 3 years. In the 2011 update, the ADA removed this suggestion due to the fear of increasing the skeletally related risks of low bone mass during the drug-free period. Despite this, the 2014 AAOMS update recommended use of a drug holiday for patients using bisphosphonates longer than 4 years or patients who also are utilizing systemic corticosteroids or antiangiogenic agents. In the 2022 AAOMS update, the working group was unable to reach a consensus on the use of drug holidays and was split evenly between those recommending temporary drug cessation and others who believed the risk of potential harm related to suspension of osteoporotic therapy outweighed the benefit of a drug holiday. Due to this controversy, AAOMS removed the 2014 recommendation for support of drug holidays because the benefit associated with operative intervention of MRON has not been substantiated.

A possible alternative in osteoporotic patients to minimize the risk of osteonecrosis **without a drug holiday** has been proposed. As previously mentioned, bisphosphonates concentrate in healing or remodeling bone. Once deposited, the medications remain for decades. As the concentration increases, the impact on the bone worsens. The best method to avoid osteonecrosis is to minimize the osseous deposition of bisphosphonates by ensuring the serum is free of the medication at the time of a surgical procedure and for the subsequent healing period. This can be accomplished in patients being treated for osteoporosis by suggesting use of annual IV administration of zoledronic acid and timing all surgical procedures to occur 2 months after the annual infusion. At this time, the serum will be essentially free of bisphosphonate with an additional 10 months of healing time prior to the next infusion. This is NOT a drug holiday; it selective scheduling of invasive procedures at a time when the serum is relatively free of bisphosphonate, reducing the chance of additional drug deposition into the healing bone. Alternatively, biannual injections with denosumab could be substituted for bisphosphonate therapy with any surgical procedure planned to occur 2 months after an injection (at which time 79.9% of the medication would be degraded) with 4 months of healing time prior to the next injection. Once again, this is NOT a drug holiday but would allow surgical healing during the period of lowest drug concentration. The worst approach would be to ignore totally the dates of drug administration. Surgery occurring close to the time of bisphosphonate infusion or denosumab injection would maximize the adverse effects on healing and future bone health. Due to the frequent administration pattern of the oral bisphosphonates, none of these medications can be utilized in a manner that would prevent concentration of the drug into surgical sites.

For patients with osteoporosis, all restorative, prosthodontic, conventional endodontic, and routine periodontic procedures can be implemented as needed. Although orthodontic treatment is not contraindicated, progress should be evaluated after 2–3 months of active therapy. At that point, therapy can proceed if the tooth movement is occurring predictably with normal forces. Invasive orthodontic techniques such as orthognathic surgery, four-tooth extraction cases, and miniscrew anchorage should be avoided, if possible.

When an osseous procedure is considered, the patient should be advised of the potential complications of antiresorptive use and the risk of MRONJ. Written informed consent and documentation of a discussion of the benefits, risks, and alternative therapies are highly advised.

Osteonecrosis associated with antiresorptive therapy for osteoporosis tends to be less extensive and more responsive to conservative therapy when compared to MRONJ in cancer patients. When the antiresorptive therapy can be discontinued, many cases of MRONJ resolve without surgical intervention. This spontaneous resolution occurs slowly over many months, but reports have documented greatly reduced healing times secondary to administration of teriparatide or abaloparatide (recombinant human parathyroid hormone).

The clinical approach to patients treated with antiresorptive medications varies according to the formulation of the drug, the disease being treated, and the duration of drug use. All patients who take these medications should be warned of the risks and instructed to obtain and maintain ultimate oral hygiene. The oral bisphosphonates are extremely caustic; patients should be warned to minimize oral mucosal contact and ensure the medication is swallowed completely.

dentlearn.ir

Overall, the benefits of antiresorptive therapy for osteoporosis and metastatic cancer appear to greatly outweigh the risk of developing MRONJ. No patient should discontinue his or her medication against medical advice. An osteoporotic hip fracture is a life-altering event, with 75% of patients never fully recovering and a mortality rate of 20% in women and 30% in men. The antiresorptive medications reduce hip fractures by approximately 50%. A similar success has been seen in cancer patients where antiresorptive medications are associated with a significant reduction in skeletal-related adverse events.

Despite the obvious benefits of antiresorptive drugs, increased bone density does not correlate necessarily to good bone quality. The negative effects of oversuppression of bone metabolism must be considered. Reports are continuing to document spontaneous nontraumatic stress fractures with associated delayed healing in patients on long-term antiresorptive therapy for osteoporosis. Many physicians now believe that such therapy should be stopped after 5 years. Patients no longer osteoporotic could be removed from active therapy until bone density studies confirm redevelopment of significant osteoporosis. For those with continuing osteoporosis, alternatives such as teriparatide or raloxifene could be considered.

◆ OROFACIAL COMPLICATIONS OF DRUG ABUSE

Over the last decade, numerous reports have described significant oral manifestations of drug abuse, most commonly the illegal stimulants cocaine and methamphetamine.

After marijuana, cocaine represents one of the more commonly utilized illicit drugs with 1.4 million active (past month) users in the United States during 2011. Cocaine can be ingested by snorting, injecting, or smoking as free base or crack cocaine. Cocaine-laced *gummies* also are seen and can be associated with local oral changes. The drug is known by nicknames that include *blow, bump, C, candy, Charlie, coke, crack, flake, rock, snow,* and *toot.* Snorting is the main method of administration due to the associated euphoric high that lasts from 20 to 90 minutes. When snorted, cocaine is associated with a sympathetic-mediated vasoconstriction that can be associated with significant local ischemia combined with inflammation and ulceration secondary to the adulterants utilized to "cut" the cocaine.

Methamphetamine is a drug with stimulant effects on the central nervous system (CNS). In 1937, the drug was approved in the United States for the treatment of narcolepsy and attention deficit hyperactivity disorder. Within a few years, many began to use the drug to increase alertness, control weight, and combat depression. Because methamphetamine users perceive increased physical ability, greater energy, and euphoria, illegal use and manufacture of the drug began to develop. Because of greater control over the main ingredient, pseudoephedrine, production of homemade methamphetamine is decreasing but often being replaced by illegal importation of the finished product. Although illicit use of methamphetamine dropped in 2011 to 439,000 active users, the drug remains a serious problem in many areas of the nation. The drug is a powder that dissolves easily in liquid and can be snorted, injected, or taken orally. The powder form of the drug is known by nicknames that include *chalk*, *crank*, *crypto*, *fire*, *go fast*, *meth,* and *speed.* The powder can be purified into large crystals that can be smoked and are known as *crystal meth*, *crystal glass,* or *ice.*

Clinical Features

As mentioned, cocaine creates a feeling of euphoria and arousal. Other less desirable symptoms include aggressive behavior, blurred vision, dilated pupils, delirium, dizziness, light-headedness, restlessness, tinnitus, tremors, shivering, insomnia, and vomiting. Physical signs include tachycardia, tachypnea, hypertension, and hyperthermia. The sympathomimetic effects increase the oxygen demands of the myocardium, and the vasoconstrictive effects reduce oxygen delivery by the coronary arteries. This combination may trigger angina, myocardial infarction, or heart dysrhythmias.

One of the more common local complications to cocaine snorting is perforation of the nasal septum, a finding noted in approximately 5% of abusers. Loss of the nasal septum can lead to complete nasal collapse resulting in a saddle nose deformity. Less frequently, the necrosis can spread to the orbital wall, lateral nasal wall, or the hard palate and may cause palatal perforation that has been termed **cocaine-induced midline destructive lesion (CIMDL).** Associated findings include recurrent epistaxis, a nasal tone of voice (rhinolalia), regurgitation of food/drink, intranasal crusting, rhinitis, and sinusitis. Most of the reported palatal perforations are limited to the hard palate, followed by involvement of both the hard and soft palates. Perforation isolated to the soft palate is most uncommon. Although uncommon, similar nasal collapse and palatal perforations have been reported from intranasal abuse of narcotics, such as hydrocodone/acetaminophen or oxycodone/acetaminophen (Figs. 8.37 and 8.38). On occasion, mucosal burns of the lips may be seen in users of crack pipes (Fig. 8.39), and localized enamel erosion has been seen in habitual users of cocaine-laced gummies. Most cocaine in the United States is laced levamisole, an anthelminthic drug that is used to treat livestock. In humans, levamisole may cause scattered cutaneous hemorrhagic bullae and purpura.

The midline destructive process of CIMDL can mimic the clinical presentation of granulomatosis with polyangiitis (see page 333), and the confusion is complicated by the fact that approximately half of the CIMDL demonstrate antineutrophil cytoplasmic antibodies to PR3 (proteinase 3) and to a much lesser extent to MPO (myeloperoxidase). Although these similarities exist, granulomatosis with polyangiitis rarely perforates the hard palate and is negative for antineutrophil cytoplasmic antibodies against human neutrophil elastase, a finding often seen in CIMDL.

Although methamphetamine abuse may occur throughout society, most users are men between the ages of 19 and 40 years. The effects of the medication last up to 12 hours, and the typical abuser reports use that exceeds

• **Fig. 8.40 Methamphetamine-Related Dental Caries.** Extensive smooth-surface decay of the anterior dentition.

20 days per month, creating an almost continuous effect of the drug. The short-term effects of methamphetamine include insomnia, aggressiveness, agitation, hyperactivity, decreased appetite, tachycardia, tachypnea, hypertension, hyperthermia, vomiting, tremors, and xerostomia. Long-term effects additionally include strong psychologic addiction, violent behavior, anxiety, confusion, depression, paranoia, auditory hallucinations, delusions, mood changes, skin lesions, and several cardiovascular, CNS, hepatic, gastrointestinal, renal, and pulmonary disorders.

Many addicts develop delusions of **parasitosis** (**formication,** from the Latin word *formica,* which translates to *ant*), a neurosis that produces the sensation of snakes or insects crawling on or under the skin. This sensation causes the patient to attempt to remove the perceived parasites, usually by picking at the skin with fingernails, resulting in widespread traumatic injury. The factitial damage can alter dramatically the facial appearance in a short period of time, and these lesions have been nicknamed *speed bumps, meth mites, meth sores,* or *crank bugs.*

Rampant dental caries is another common manifestation and exhibits numerous similarities with milk-bottle caries. The carious destruction initially affects the facial smooth and interproximal surfaces, but without intervention, the coronal structure of the entire dentition can be destroyed (Fig. 8.40). Although it was theorized that the damage might have been secondary to corrosive agents in smoked crystal meth, a study of 571 meth users revealed that the tooth destruction is secondary to drug-related xerostomia combined with use of sugary soda, poor diet, infrequent toothbrushing, and lack of professional dental care. Of these, toothbrushing demonstrated the largest protective effect. Consumption of one or more sugary beverages daily was sufficient to contribute to decay; an increased number of sodas was not associated correspondingly to higher levels of caries. A similar degree of tooth destruction was noted in all forms of use: smoking, snorting, ingesting, and injecting.

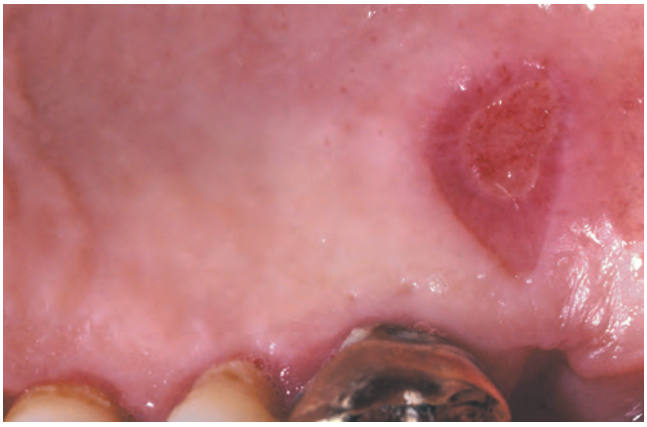
dentlearn.ir

Treatment and Prognosis

Cessation of illicit drug use is paramount in both cocaine and methamphetamine abuse. In patients with palatal perforation, complete cessation of cocaine use must be stopped 6 months prior to surgical reconstruction. If surgical reconstruction fails, a removable maxillary obturator can be constructed. Although cessation of the illicit drug use is critical, methamphetamine addicts should be encouraged during periods of xerostomia to discontinue use of highly acidic and sugar-filled soft drinks and to avoid diuretics, such as caffeine, tobacco, and alcohol. In addition, the importance of personal and oral hygiene should be stressed. Preventive measures such as topical fluorides may assist in protecting the remaining dentition.

The oral health practitioner should be alerted when an agitated, nervous adult presents with tachycardia, tachypnea, hypertension, and hyperthermia. Failure to recognize these signs can be serious. For up to 24 hours after ingestion, both cocaine and methamphetamine potentiate the effects of sympathomimetic amines. Use of local anesthetics with epinephrine or levonordefrin can lead to a hypertensive crisis, cerebrovascular accident, or myocardial infarction. Caution also should be exercised when administering sedatives, general anesthesia, nitrous oxide, or prescriptions for narcotics. A medical consultation with referral to a substance abuse center should be encouraged.

◆ ANESTHETIC NECROSIS



Administration of a local anesthetic agent can, on rare occasions, be followed by ulceration and necrosis at the site of injection. Researchers believe that this necrosis results from localized ischemia, although the exact cause is unknown and may vary from case to case. Faulty technique, such as subperiosteal injection or administration of excess solution in tissue firmly bound to bone, has been blamed. The epinephrine contained in many local anesthetics also has received attention as a possible cause of ischemia and secondary necrosis.

Clinical Features

Anesthetic necrosis usually develops several days after the procedure and most commonly appears on the hard palate (Fig. 8.41). A well-circumscribed area of ulceration develops at the site of injection.

Treatment and Prognosis

Treatment of anesthetic necrosis usually is not required unless the ulceration fails to heal. Minor trauma, such as that caused by performing a cytologic smear, has been reported to induce resolution in these chronic cases. Recurrence is unusual but has been reported in some patients in association with use of epinephrine-containing anesthetics. In these cases, the use of a local anesthetic without epinephrine is recommended.

• **Fig. 8.41 Anesthetic Necrosis.** Mucosal necrosis of the hard palate secondary to palatal injection with a local anesthetic agent containing epinephrine.

◆ EXFOLIATIVE CHEILITIS

Exfoliative cheilitis is a persistent scaling and flaking of the vermilion border, usually involving both lips. The process arises from excessive production and subsequent desquamation of superficial keratin. A significant percentage of cases appear related to chronic injury secondary to habits, such as lip licking, biting, picking, or sucking. Those cases proven to arise from chronic injury are termed **factitious cheilitis**. A similar pattern also has been seen from accumulation of dried saliva intermixed with an overabundance of topically-applied medications, which results in a crusted surface. This process has been termed *ointment pseudo-cheilitis* and usually is noted in overconcerned patients, who also report a disproportionate amount of pain.

Many patients deny chronic self-irritation of the area. The patient may be experiencing associated personality disturbances, psychologic difficulties, or stress. In a review of 48 patients with exfoliative cheilitis, 87% exhibited psychiatric conditions and 47% also demonstrated abnormal thyroid function. Evidence suggests that there may be a link between thyroid dysfunction and some psychiatric disturbances.

In other cases, no evidence of chronic injury is evident. In these patients, other causes should be ruled out (e.g., atopy, chronic candidal infection, actinic cheilitis, cheilitis glandularis, hypervitaminosis A, and photosensitivity). In a review of 165 patients with acquired immunodeficiency syndrome (AIDS), more than one-quarter had alterations that resembled exfoliative cheilitis. In this group the lip alterations appeared secondary to chronic candidal infestation. The most common presentation of bacterial or fungal infections of the lips is **angular cheilitis** (see page 204). Diffuse primary infection of the entire lip is very unusual; most diffuse cases represent a secondary candidal infection in areas of low-grade trauma of the vermilion border of the lip **(cheilocandidiasis).**

In one review of 75 patients with chronic cheilitis, a thorough evaluation revealed that more than one-third represented irritant contact dermatitis (often secondary to

dentlearn.ir

chronic lip licking). In 25% of the patients, the cheilitis was discovered to be an allergic contact mucositis (see page 342). Atopic eczema was thought to be the cause in 19% of cases; the remaining portion was related to a wide variety of pathoses.

Despite a thorough investigation, there often remain a number of patients with classic exfoliative cheilitis for which no underlying cause can be found. These idiopathic cases are most troublesome and often resistant to a wide variety of interventions.

Clinical Features

A marked female predominance is seen in cases of factitious origin, with most cases affecting those younger than 30 years of age. Mild cases feature chronic dryness, scaling, or cracking of the vermilion border of the lip (Fig. 8.42). With progression, the vermilion can become covered with a thickened, yellowish hyperkeratotic crust that can be hemorrhagic or that may exhibit extensive fissuring. The perioral skin may become involved and exhibit areas of crusted erythema (Fig. 8.43). Although this pattern may be confused with perioral dermatitis (see page 343), the most appropriate name for this process is *circumoral dermatitis.* Both lips, or just the lower lip, may be involved. On occasion, the alterations can present in a cyclical pattern in which the changes resolve but subsequently redevelop over a relatively consistent period of time.

• **Fig. 8.42 Exfoliative Cheilitis.** Scaling and erythema of the vermilion border of the lower lip.

• **Fig. 8.43 Circumoral Dermatitis.** Crusting and erythema of the skin surface adjacent to the vermilion border in a child who chronically sucked on both lips.

In patients with chronic cheilitis, development of fissures on the vermilion border is not rare. In a prevalence study of more than 20,000 patients, these fissures involved either lip and were slightly more common in the upper lip. In contrast to typical exfoliative cheilitis, these fissures demonstrate a significant male predilection and a prevalence rate of approximately 0.6%. The majority arise in young adults, with rare occurrence noted in children and older adults.

Although the cause is unknown, proposed contributing factors include overexposure to sun, wind, and cold weather; mouth breathing; bacterial or fungal infections; and smoking. An increased prevalence of lip fissures has been noted in patients with Down syndrome and may be the result of the high frequency of mouth breathing or the tendency to develop orofacial candidiasis. Application of lipstick or lip balm appears to be protective. Fissure occurrence also may be related to a physiologic weakness of the tissues. Those affecting the lower lip typically occur in the midline, whereas fissures on the upper vermilion most frequently involve a lateral position. These are the sites of prenatal merging of the mandibular and maxillary processes.

Treatment and Prognosis

In cases associated with an obvious cause, elimination of the trigger typically results in resolution of the changes. In cases with no underlying physical, infectious, or allergic cause, psychotherapy (often combined with mild tranquilization or stress reduction) may achieve resolution. In cases for which no cause can be found, therapeutic interventions often are not successful.

In patients with ointment pseudo-cheilitis, the crusted material can be removed easily when covered with a saline-soaked gauze, which then reveals an underlying normal mucosa. Although only simple reassurance and cessation of the topical medication is necessary for resolution, many patients refuse to accept this advice. Use of antidepressants such as fluoxetine in several patients has produced improvement in their symptoms with a decrease in their lip preoccupation and the associated labial crusting.

Cases that result from candidal infections often do not resolve until the chronic trauma also is eliminated. Initial topical antifungal agents, antibiotics, or both can be administered to patients in whom chronic trauma is not obvious or is denied. If the condition does not resolve, then further investigation is warranted to discover the true source of the lip alterations.

Hydrocortisone and iodoquinol (antibacterial and antimycotic) cream has been used to resolve chronic lip fissures in some patients (Fig. 8.44). Other reported therapies include various corticosteroid preparations, topical tacrolimus, sunscreens, and moisturizing preparations. In many

dentlearn.ir

• **Fig. 8.44 Lip Fissure. A,** Chronic fissure of the vermilion border of the upper lip. **B,** Same site 2 weeks later, after use of hydrocortisone and iodoquinol cream.

cases, resistance to topical therapy or frequent recurrence is noted. In these cases, cryotherapy or excision with or without Z-plasty has been used successfully.

SUBMUCOSAL HEMORRHAGE

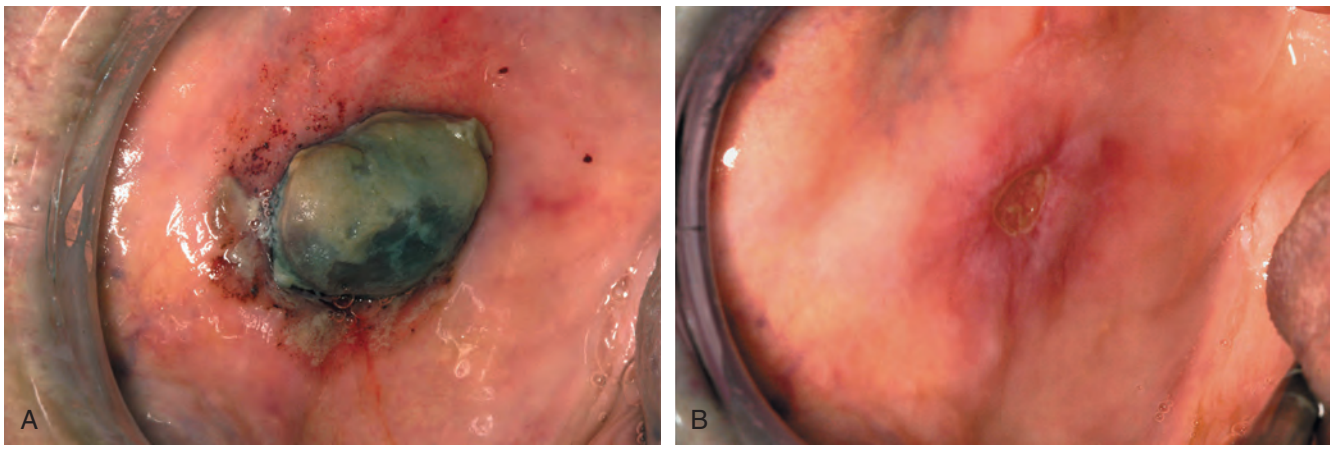
Everyone has experienced a bruise from minor trauma. This occurs when a traumatic event results in hemorrhage and entrapment of blood within tissues. Different terms are used, depending on the size of the hemorrhage:

- Minute hemorrhages into skin, mucosa, or serosa are termed **petechiae.**
- If a slightly larger area is affected, the hemorrhage is termed a **purpura.**
- Any accumulation greater than 2 cm is termed an **ecchymosis.**
- If the accumulation of blood within tissue produces a mass, this is termed a **hematoma.**

Blunt trauma to the oral mucosa often results in hematoma formation. Less well known are petechiae and purpura, which can arise from repeated or prolonged increased intrathoracic pressure (Valsalva maneuver) associated with such activities as repeated coughing, vomiting, convulsions, or giving birth (Fig. 8.45). When considering a diagnosis of traumatic hemorrhage, the clinician should keep in mind that hemorrhages can result from nontraumatic causes, such as anticoagulant therapy, thrombocytopenia, disseminated intravascular coagulation (DIC), and several viral infections, especially infectious mononucleosis and measles.

Clinical Features

Submucosal hemorrhage appears as a nonblanching flat or elevated zone with a color that varies from red or purple to blue or blue-black (Fig. 8.46). As would be expected, traumatic lesions are located most frequently on the labial or buccal mucosa. Blunt facial trauma often is responsible, but injuries as minor as cheek biting may produce a hematoma or areas of purpura (Fig. 8.47). Mild pain may be present.



• **Fig. 8.45 Petechiae.** Submucosal hemorrhage of the soft palate caused by violent coughing.

• **Fig. 8.46 Purpura.** Submucosal hemorrhage of the lower labial mucosa on the left side secondary to blunt trauma.

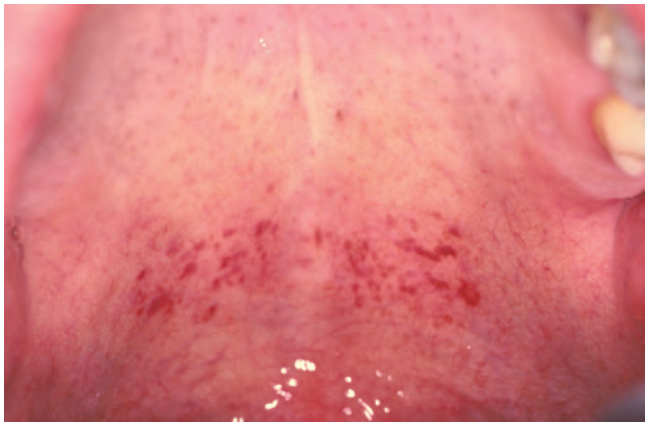
The hemorrhage associated with increased intrathoracic pressure usually is located on the skin of the face and neck and appears as widespread petechiae that clear within 24–72 hours. Although it has not been as well documented as the cutaneous lesions, mucosal hemorrhage can be seen in

dentlearn.ir

• **Fig. 8.47 Hematoma. A,** Dark-purple nodular mass of the buccal mucosa in a patient on Coumadin therapy. **B,** Near resolution of the lesion 8 days later after discontinuation of the medication. (Courtesy of Dr. Charles Ferguson.)

the same setting and most often appears as soft palatal petechiae or purpura.

Treatment and Prognosis



Often, no treatment is required if the hemorrhage is not associated with significant morbidity or related to systemic disease. The areas should resolve spontaneously. Large hematomas may require several weeks to resolve. If the hemorrhage occurs secondary to an underlying disorder, then treatment is directed toward control of the associated disease.

◆ ORAL TRAUMA FROM SEXUAL PRACTICES

Although orogenital sexual practices are illegal in many jurisdictions, they are extremely common. Among homosexual men and women, orogenital sexual activity almost is universal. For married heterosexual couples younger than age 25, the frequency has been reported to be as high as 90%. Considering the prevalence of these practices, the frequency of associated traumatic oral lesions is surprisingly low.

Clinical Features

The most reported lesion related to orogenital sex is submucosal palatal hemorrhage secondary to fellatio. The lesions appear as erythema, petechiae, purpura, or ecchymosis of the soft palate. The areas often are asymptomatic and resolve without treatment in 7–10 days (Fig. 8.48). Recurrences are possible with repetition of the inciting (exciting?) event. The erythrocytic extravasation is thought to result from the musculature of the soft palate elevating and tensing against an environment of negative pressure. Similar lesions have been induced from coughing, vomiting, or forceful sucking on drinking straws and glasses. Forceful thrusting against the vascular soft palate has been suggested as another possible cause.

• **Fig. 8.48 Palatal Petechiae from Fellatio.** Submucosal hemorrhage of the soft palate resulting from the effects of negative pressure.

Oral lesions also can occur from performing cunnilingus, resulting in horizontal ulcerations of the lingual frenum. As the tongue is thrust forward, the taut frenum rubs or rakes across the incisal edges of the mandibular central incisors. The ulceration created coincides with sharp tooth edges when the tongue is in its most forward position. The lesions resolve in 7–10 days but may recur with repeated performances. Linear fibrous hyperplasia has been discovered in the same pattern in individuals who chronically perform the act (Fig. 8.49).

Histopathologic Features

With an appropriate index of suspicion, biopsy usually is not required; however, a biopsy has been performed in some cases of palatal lesions secondary to fellatio. These suction-related lesions reveal subepithelial accumulations of red blood cells that may be extensive enough to separate the surface epithelium from underlying connective tissue. Patchy degeneration of the epithelial basal cell layer can occur. The epithelium classically demonstrates migration of erythrocytes and leukocytes from the underlying lamina propria.

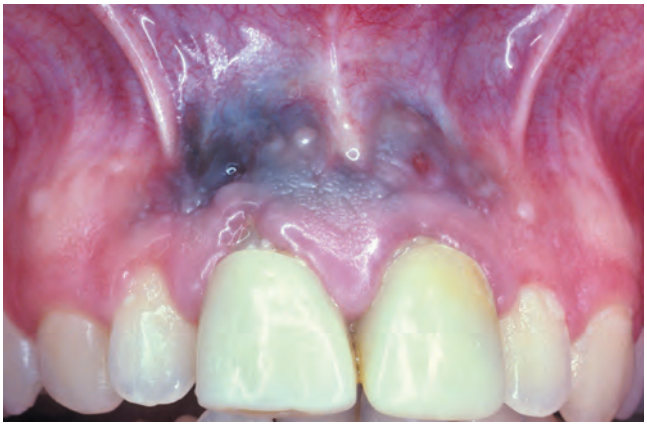
dentlearn.ir

• **Fig. 8.49 Fibrous Hyperplasia From Repeated Cunnilingus.** Linear fibrous hyperplasia of the lingual frenum caused by repeated irritation from lower incisors.

Treatment and Prognosis

No treatment is required, and the prognosis is good. In patients who request assistance, palatal petechiae can be prevented using less negative pressure and avoidance of forceful thrusting. Smoothing and polishing the rough incisal edges of the adjacent mandibular teeth can minimize the chance of lingual frenum ulceration.

◆ AMALGAM TATTOO AND OTHER LOCALIZED EXOGENOUS PIGMENTATIONS

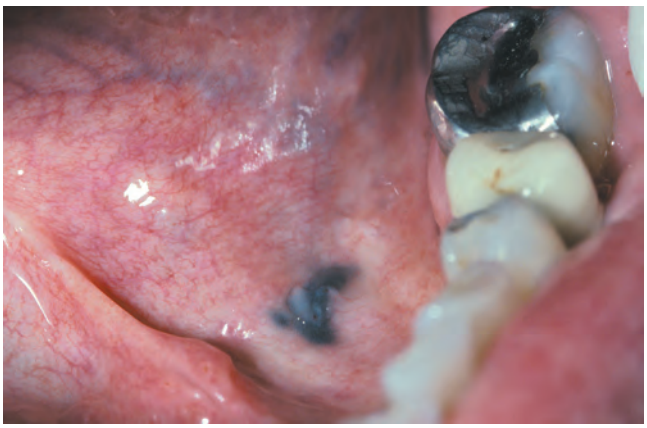


Several pigmented materials can be implanted within the oral mucosa, resulting in clinically evident pigmentations. Implantation of dental amalgam **(amalgam tattoo)** occurs most often, with a frequency that far outdistances that for all other materials. *Localized argyrosis* has been used as another name for amalgam tattoo, but this nomenclature is inappropriate because amalgam contains not only silver but also mercury, tin, copper, zinc, and other metals.

Amalgam can be incorporated into the oral mucosa in several ways. Previous areas of mucosal abrasion can be contaminated by amalgam dust within the oral fluids. Broken amalgam pieces can fall into extraction sites. If dental floss becomes contaminated with amalgam particles of a recently placed restoration, then linear areas of pigmentation can be created in the gingival tissues as a result of hygiene procedures (Fig. 8.50). Amalgam from endodontic retrofill procedures can be left within the soft tissue at the surgical site (Fig. 8.51). Finally, fine metallic particles can be driven through the oral mucosa from the pressure of high-speed air turbines. Theoretically, the use of the rubber dam should decrease the risk; however, immediately after removal of the dam, the occlusion often is adjusted with the potential for amalgam contamination of any areas of mucosal damage.

In one interesting report, metal from silver solder on orthodontic brackets leached into adjacent gingival crevices and created discolorations that were thought to be secondary to formation of insoluble precipitates from metabolic

• **Fig. 8.50 Floss-Related Amalgam Implantation.** Linear strips of mucosal pigmentation that align with the interdental papillae. The patient used dental floss on the mandibular first molar immediately after the placement of the amalgam restoration. Because the area was still anesthetized, the patient impaled the floss on the gingiva and then continued forward using the amalgam-impregnated floss in the bicuspid area to create additional amalgam tattoos.



• **Fig. 8.51 Endodontic-Related Amalgam Implantation.** Multifocal areas of mucosal discoloration overlying the maxillary anterior incisors, which have been treated with apical retrofill procedures.

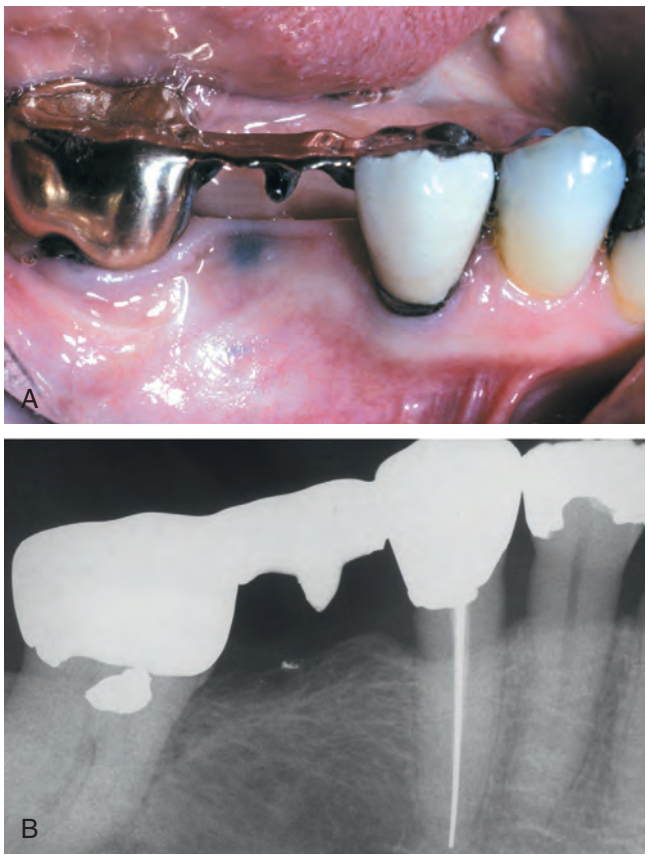
bacterial by-products. Submucosal implantation of pencil graphite, coal and metal dust, fragments of broken carborundum disks, dental burs, and, in the past, charcoal dentifrices, have resulted in similar-appearing areas of discoloration. Localized gingival discoloration also has been seen when fractured zirconia abutments abraded the associated titanium implant, releasing metallic fragments into the surrounding soft tissue.

Intentional tattooing, which can be found in approximately 25% of the world's population, also may be performed in the oral cavity. Although some cases are culturally related, health professionals also are responsible for several intentional oral and facial tattoos for the purpose of demonstrating landmarks, establishing progress of orthodontic treatment, marking sites of uncovered dental implants, judging tumor response to antineoplastic therapies, repigmenting areas of vitiligo, cosmetically disguising

dentlearn.ir

• **Fig. 8.52 Amalgam Tattoo.** Area of mucosal discoloration of the floor of the mouth on the patient's left side.

disfigured areas, and applying permanent cosmetic makeup. Injudicious intraoral use of these marking agents can cause diffusion of the pigment with discoloration of the adjacent skin surface.



Clinical and Radiographic Features

Amalgam tattoos appear as macules or, rarely, as slightly raised lesions. They may be black, blue, or gray. The borders can be well defined, irregular, or diffuse (Fig. 8.52). Lateral spread may occur for several months after the implantation. Any mucosal surface can be involved, but the most common sites are the gingiva, alveolar mucosa, and buccal mucosa (Fig. 8.53).

Periapical radiographs, when taken, are negative in many cases. When metallic fragments are visible radiographically, the clinical area of discoloration typically extends beyond the size of the fragment. The fragments are densely radiopaque, varying from several millimeters to pinpoint in size (see Fig. 8.53). On occasion, the pattern of the amalgam dispersal has been sufficiently unique to be used as a distinctive characteristic in the identification of unknown deceased individuals.

Cosmetic tattooing is gaining in popularity and may include injection of permanent cosmetic inks into the eyelids, eyebrows, and vermilion border of the upper and lower lips. On occasion, patients may react to the material and experience swelling, burning, and itching at the site, followed by enlargement and induration. These reactions are seen most frequently in association with red cosmetic tattoos and may arise days or several years after placement. In such cases, biopsy reveals a granulomatous, lichenoid, or rarely a pseudolymphomatous reaction to the foreign material. Reports also have documented development of squamous cell carcinoma or a keratoacanthoma-like proliferation of the vermilion border arising in patients with minimal sun exposure and prior placement of permanent red makeup tattoo.

Intentional intraoral tattoos occur most frequently on the anterior maxillary facial gingiva of individuals from several

• **Fig. 8.53 Amalgam Tattoo. A,** Area of mucosal discoloration of the mandibular alveolar ridge immediately below the bridge pontic. **B,** Radiograph of the same patient showing radiopaque metallic fragment present at the site of mucosal discoloration.

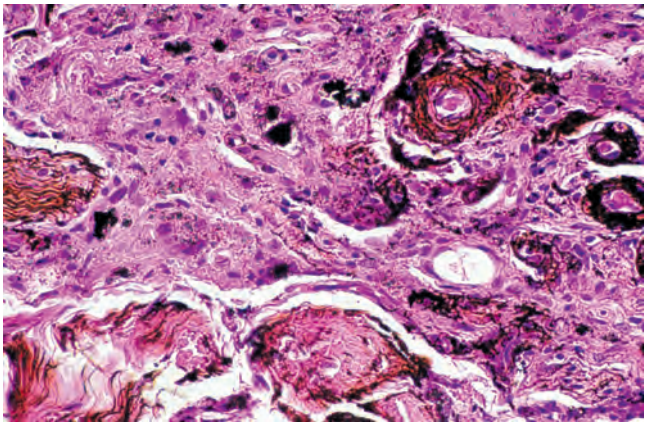
African countries and have been documented at institutions in the United States (Fig. 8.54). In these cases, the anterior maxillary facial gingiva is given a blue-black discoloration that tends to fade to mostly gray over time. Occasionally, tattoos are placed on the labial mucosa of adults in the United States to convey a personal, often vulgar, message (Fig. 8.55).

dentlearn.ir

• **Fig. 8.55 Intentional Intraoral Tattoo.** Amateur tattoo of the lower labial mucosa. (Courtesy of Dr. Edward Herschaft.)



• **Fig. 8.56 Amalgam Tattoo.** Numerous dark, solid fragments of amalgam are surrounded by a lymphohistiocytic inflammatory infiltrate.

Histopathologic Features

Microscopic examination of amalgam tattoos reveals pigmented fragments of the metal within the connective tissue. Scattered, large, dark, solid fragments or numerous fine, black, or dark-brown granules may be seen (Fig. 8.56). The silver salts of the dental amalgam preferentially stain the reticulin fibers, especially those encircling nerves and vascular channels (Fig. 8.57).

The biologic response to amalgam appears related to particle size and the elemental composition of the amalgam. Large fragments often become surrounded by dense fibrous connective tissue with mild inflammation. Smaller particles typically are associated with a more significant inflammatory response that may be granulomatous or a mixture of lymphocytes and plasma cells. Graphite implantation appears similar microscopically to amalgam but usually presents as a coarser material that often can be differentiated by its pattern of birefringence after treatment with ammonium sulfide and by the lack of staining of the reticulin fibers. In addition, energy dispersive X-ray microanalysis can be used to identify the type of material present within areas of foreign body tattoos.

• **Fig. 8.57 Amalgam Tattoo.** Dark amalgam stain encircling numerous vascular channels.

Treatment and Prognosis

To confirm the diagnosis of amalgam tattoo, the clinician can obtain radiographs of the areas of mucosal discoloration to demonstrate the metallic fragments. The films should be capable of high detail, because many of the fragments are no larger than the point of a pin.

No treatment is required if the fragments can be detected radiographically. If no metallic fragments are found and the lesion cannot be diagnosed clinically, then biopsy may be needed to rule out the possibility of melanocytic neoplasia. On occasion, the amalgam implantation may create pigmentation in a cosmetically objectionable location such as the anterior maxillary facial gingiva. In such cases, conservative surgical excision can be performed; alternatively amalgam tattoos have been removed successfully with Q-switched ruby or alexandrite lasers. When located in a cosmetically sensitive location such as the anterior maxillary facial gingiva, a connective tissue graft often is combined with removal of the discolored soft tissue. With respect to the allergic reactions associated with cosmetic tattoos, a variety of treatments such as surgical removal, carbon dioxide laser, and corticosteroids have been used with variable results. In cosmetic tattoos associated with a granulomatous reaction, allopurinol or hydroxychloroquine also have been used successfully.

◆ ORAL PIERCINGS AND OTHER BODY MODIFICATIONS

Historical evidence from almost every continent shows that body piercing is an ancient practice with a strong association with religious, cultural, or superstitious beliefs. In the Western world, body piercing beyond the earlobes has become increasingly popular as a method of self-expression in recent years. In a survey of 481 college students in the United States, 51% admitted body piercing, and the prevalence still appears to be rising. Usually, the piercing is performed to place jewelry in sites such as the eyebrows, helix of the ears, nose, navel, nipples, genitals, and several intraoral sites.

Forked tongue (split tongue, bifid tongue) is a rather recent addition to the art of body modification, with few associated publications. In this practice, the anterior one-

dentlearn.ir

third of the tongue is split down the middle. This has been performed slowly by pulling fishing line through a pierced hole and tightening the loop over a period of 3 weeks or using a surgical instrument or laser to quickly separate the two halves. Some form of cautery is necessary to prevent the halves from reuniting. Forked tongue also has been reported as a complication of tongue piercing.

Another practice with unique orofacial manifestations is implantation of a form of **talisman** (magical charm) called **susuk (charm needles, charm pins).** This practice is common in Southeast Asia, especially Malaysia, Thailand, Singapore, Indonesia, and Brunei. The susuk is placed by a native magician or medicine man termed *bomoh* and is thought to enhance or preserve beauty, relieve pain, bring success in business, or provide protection against harm. Most of the individuals with susuk are Muslims, although Islam strictly prohibits black magic. Therefore, many affected individuals will deny placement of susuk, even when confronted directly with hard evidence.

Clinical and Radiographic Features

Intraoral piercings are noted most frequently in adolescents and young adults, with a female predominance. In a systematic review of the literature, oral and peri-oral piercings were seen in approximately 5.2% of young adults. The most affected sites are the tongue, lips, buccal mucosa, and, rarely, the uvula. If no complications occur, healing of the piercing site takes place within 4–6 weeks. Currently, the jewelry most often is niobium, surgical steel, or titanium; however, a wide variety of materials such as horn, ivory, plastic, stone, wood, aluminum, brass, copper wire, platinum, silver, and gold are used. In the tongue, the most frequent adornment is a **barbell** (Dumbbell might be a better name!) consisting of a metal rod with a ball that screws onto each end (Fig. 8.58). The lip jewelry is termed a **labret** and most often consists of a ring or a rod with a flat end attached to the mucosal side and a round ball for the cutaneous surface (Fig. 8.59).

In a review of US hospital emergency departments from 2002 to 2008, an estimated 24,459 patients presented with oral piercing-related injuries. Complications during the procedure include bleeding, nerve damage, localized infection, and the risk of transmission of infectious diseases, such as hepatitis or HIV. Immediate postoperative complications include pain, swelling, hematoma formation, increased salivary flow, speech impediment, and a local allergic reaction. Serious complications such as Ludwig angina, infective endocarditis, and fatal brain abscesses have been documented. Chronic complications include mucosal or gingival trauma, chipped or fractured teeth, hypersalivation, aspiration or swallowing of jewelry, tissue hyperplasia around the posts, and embedded jewelry. Gingival recession (labrets, barbells) and tooth fracture (barbells) are extremely common, with the prevalence closely related to the duration of use. In a systematic review of previous publications, individuals with lip piercings were 4.14 times more likely to demonstrate gingival recession, whereas individuals with tongue piercing were 2.77 times more likely to exhibit recession and 2.44 times more likely to reveal tooth fracture. Habitual biting or chewing the jewelry often is associated with severe dental abrasion or movement of teeth. A fatal squamous cell carcinoma of the tongue arising at the site of a metal piercing has been reported in a 26-year-old patient.

In individuals with forked tongues, the anterior half of the tongue is split down the middle (Fig. 8.60). Risks of the

procedure include inflammation, infection, profuse or prolonged hemorrhage, and permanent neurovascular damage. After healing, some individuals have developed the ability to control each half independently.

Susuk usually is shaped like a needle that is pointed on one end and blunt on the other. Most are made from silver or gold, measure 0.5 mm in diameter, and vary from 0.5 to 1.0 cm in length. Rarely, they are made from diamonds. The pins vary in number from one to many and are inserted subcutaneously, often in a symmetrical fashion. The orofacial region is the most common location (forehead, cheeks, and lips), but some choose the chest, arms, breasts, pubic region, and spinal area. In most instances, the individuals are middle-aged adults. Normally, no clinical evidence exists, either visually or by palpation, and the pins are discovered during routine radiography for unrelated medical or dental problems (Fig. 8.61).

Treatment and Prognosis

As mentioned, intraoral barbells and labrets are associated with an increasing prevalence of oral complications that relate closely with duration of use. The patient should be encouraged strongly to remove the jewelry. On removal, if the site demonstrates significant inflammation, local débridement, antibiotic therapy, and chlorhexidine mouthwash may be appropriate.

Except for slight sibilant distortions and shortening of the protrusive length of the tongue, few long-term adverse events have been noted in patients with forked tongues.

Susuk have not been associated with harmful effects, and no treatment is required. If the needles have a ferrous content, then magnetic resonance imaging (MRI) would be contraindicated. On occasion, affected individuals request removal of the susuk before they die because they believe their death will be excruciatingly painful. Despite this, the needles should not be removed without consent.

◆ ORAL LESIONS ASSOCIATED WITH COSMETIC FILLERS

In recent years, oral health care providers have encountered a variety of oral lesions secondary to injection of cosmetic fillers. These substances are used to augment the lips, cheeks, and chin or to minimize skin folds in the forehead, around the nose, and perioral surfaces. These fillers can be divided into temporary (collagen, hyaluronic acid), long-term (hyaluronic acid with dextranomer beads, poly-L-lactic acid, calcium hydroxyapatite) and permanent fillers (paraffin, silicon preparations, polymethylmethacrylate microspheres, hydroxyethyl-methacrylate, polyacrylamide gel, polyalkylimide gel, polyvinyl hydroxide microspheres in polyacrylamide gel, polytetrafluoroethylene). A number of these formulations are not approved for use in the United States, but patients may present with complications of fillers placed in other countries. The most encountered agents in an active oral pathology laboratory include hyaluronic acid (Restylane, Juvederm), poly-L-lactic acid (Sculptra), polymethylmethacrylate (Artecoll, ArteFill), and hydroxyapatite (Radiesse). Problems have occurred when these materials present as tumor-like masses in patients who do not make the connection to their previous cosmetic procedure or are reluctant to mention prior use of dermal filler. In order to help pathologists identify these various compounds, an online atlas of foreign materials has been established by the American Academy of Oral & Maxillofacial Pathology (AAOMP).

Clinical and Radiographic Features

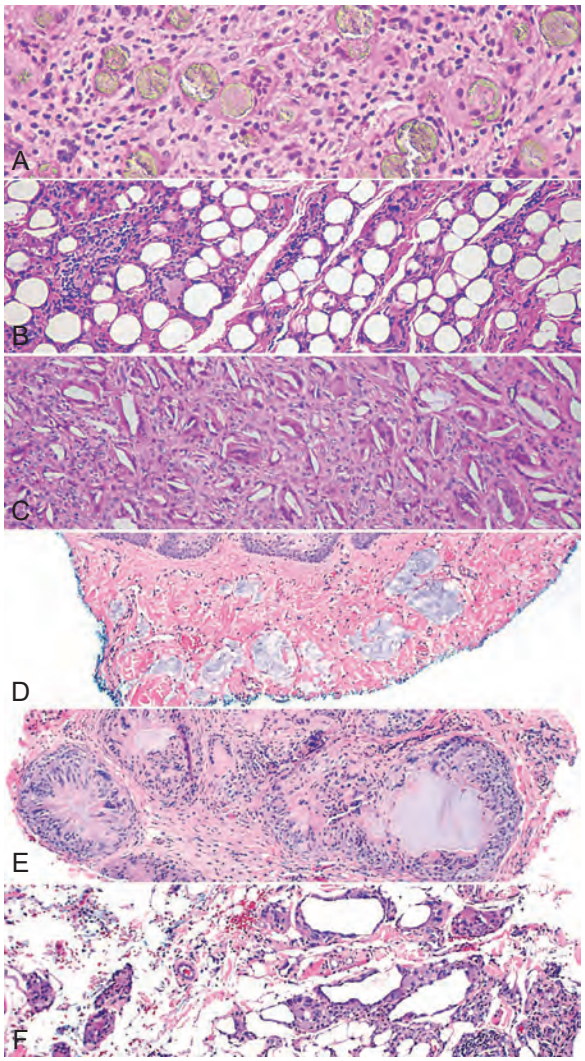
The complications associated with dermal fillers can be divided into early and late. Early complications include ecchymosis, swelling/edema, infection, itching, pain, and rapid onset of dermal/mucosal nodules. Late or delayed complications include persistent ecchymosis, swelling/edema, neovascularization, hyperpigmentation, bluish discoloration from superficial placement of hyaluronic acid, chronic infection, and delayed formation of nodules. Patients also have

dentlearn.ir

been reported with recurring soft tissue swellings that mimic angioedema and orofacial granulomatosis several years after placement of cosmetic filler material.

Severe adverse reactions occur with some materials but are rare. These reactions include local allergic response, anaphylaxis, arthralgia, myalgia, retinal artery thrombosis, facial paralysis, and renal failure. The most common presentations in the dental office are latent tumor-like nodules usually presenting in the lips, anterior buccal mucosa, and mandibular vestibule (Fig. 8.62 and 8.63). These nodules often arise years after placement of the material. In patients with hydroxyapatite filler, clusters of radiopaque material have been discovered on panoramic and cone beam radiographs. In addition, head and neck cancer patients with dermal fillers sometimes have shown false positive uptake in oral tissues and adjacent lymph nodes during positron emission tomography/computed tomography (PET/CT) being used for presurgical staging of head and neck cancer.

• **Fig. 8.62 Cosmetic Filler Material.** Yellow submucosal mass of the mandibular labial vestibule. Biopsy revealed hydroxyapatite (Radiesse) with fibrosis and granulomatous inflammation. (From Daley T, Damm DD, Haden JA, et al: Oral lesions associated with injected hydroxyapatite cosmetic filler, *Oral Surg Oral Med Oral Pathol Oral Radiol* 114:107–111, 2012.)



• **Fig. 8.63 Cosmetic Filler Material.** Firm submucosal mass of the right lower labial mucosa. Biopsy revealed stromal pools of hyaluronic acid (Restylane). (Courtesy of Dr. Walker Pendarvis).

Histopathologic Features

The histopathologic features are variable but often distinctive. In many cases, the identification of the specific material by the pathologist allows the clinician to present the patient with a brand name that often convinces the reluctant individual to admit a previous cosmetic procedure.

The nonpermanent filler, hyaluronic acid, often is nonimmunogenic and presents as pools of amorphous and lightly basophilic material surrounded by dense bands of collagen without a foreign body reaction although it may induce a remarkable granulomatous response in some patients. When removed due to formation of tumor-like nodules, most of the cosmetic filler materials are surrounded by dense collagen and granulomatous inflammation (Fig. 8.64). In many instances, the microscopic appearance of the material is sufficient for identification.

• **Fig. 8.64 Cosmetic Filler Material.** Cosmetic filler materials embedded in dense fibrous connective tissue with associated granulomatous inflammation. **A,** Hydroxyapatite (Radiesse) as seen in the biopsy of lesion depicted in Fig. 8.62. **B,** Different patient exhibiting polymethylmethacrylate (ArteFill). **C,** Different patient exhibiting poly-L-lactic acid (Sculptra). **D,** Different patient exhibiting hyaluronic acid (Restylane). **E,** Different patient exhibiting pools hyaluronic acid encased by granulomatous inflammation. **F,** Different patient exhibiting silicone.

dentlearn.ir

Treatment and Prognosis

In many instances, the diagnostic biopsy is excisional and completely eradicates the problematic mass. In patients with larger lesions, surgical excision can be problematic due to numerous finger-like extensions of the material into the surrounding tissues. Additional therapeutic inventions have been employed and include a variety of antibiotics, hyaluronidase, injectable or systemic corticosteroids, antihistamines, antimalarial medications, 5-fluorouracil, imiquimod, allopurinol, colchicine, retinoic acid, calcineurin inhibitors, and laser removal.

◆ SYSTEMIC METALLIC INTOXICATION

Ingestion or exposure to any one of several heavy metals can cause significant systemic and oral abnormalities. Exposure to heavy metals may be massive, resulting in acute reactions, or it may be minimal over a longer period, producing chronic changes. Oral alterations from ingestion of lead, mercury, silver, bismuth, arsenic, and gold are rare but may occur and warrant discussion. Oral complications from excessive zinc, iron, tin, and manganese are extremely rare.

Lead

Little is known about the prevalence of lead poisoning **(plumbism),** but lead is one of the most widespread environmental toxins affecting children in the United States. Lead solder for plumbing was not banned until 1986. Homes built before then have the potential for significant water contamination, and one of the primary causes of lead intoxication in infants is formula preparation using tap water tainted by the metal.

Another significant source of lead poisoning in children is lead-based paint; children may ingest chips of the paint in older homes or be exposed to the fumes or dust during sanding and renovation. Paint with a high lead content was not restricted until 1977 and remains in many homes. Removal of lead from gasoline began in 1972 but was not completed in the United States until 1995.

Adult exposure also occurs and often is related to industry. The potential for exposure exists during handling of lead oxide batteries, in lead-processing industries, and from the welding of lead-covered surfaces. Some food and drink containers or vegetables grown in lead-contaminated soil also may contain inappropriate levels of the metal. Lead contamination in illicit alcohol has made the distinction between symptoms of lead intoxication and chronic alcohol abuse very difficult in certain sections of the American Deep South. Lead also can be found in pigments, books, brass fixtures, pottery, ceramics, crystal, electrical cable, radiation shielding, folk remedies, and cosmetics. Rarely, plumbism arises from retained lead bullet fragments in gunshot victims.

Mercury

The danger of mercury exposure is well known. Elemental mercury is poorly absorbed, and its ingestion is relatively harmless. In contrast, inhalation of mercury vapor is very hazardous, with a high rate of absorption and systemic retention. Ingestion of mercury salts (e.g., mercurous chloride) also is associated with significant adverse reactions. Exposure has occurred in association with the use of mercury in teething powders, baby powders, diapers, cathartic agents, and anthelmintic preparations. Investigators also have implicated thimerosal, an ethyl mercury antiseptic utilized in some vaccinations.

A great deal of attention has been directed toward the mercury released from dental amalgams, but no well-documented adverse health effects have been identified (except for relatively rare contact hypersensitivity to amalgams, see page 346). The level of mercury that is released from amalgams has been shown not to exceed the range expected from background exposure to environmental mercury. In 2009, the FDA issued a final regulation on dental amalgam, which stated the levels of mercury released by dental amalgam fillings are not high enough to cause harm in patients. To shed light on this controversy, the National Institutes of Health (NIH) funded two large randomized clinical trials that compared the neurologic and renal effects of dental amalgam in a 7-year study of a large cohort of children. In these pivotal investigations, no adverse effects from dental amalgam were seen. Interestingly, the control group that received only composite restorations demonstrated a 50% higher need for additional restorative treatment because of the failure of their restorations during the long-term study.

Silver

Silver has known antibacterial properties and has been associated with several additional health benefits. In the past, silver compounds were used topically in nose drops and systemically for a variety of disorders including mental illness, epilepsy, nicotine addition, common colds, sinusitis, gastrointestinal ulcerations, syphilis, and gonorrhea. Because of the numerous complications, including silver intoxication, in 1999 the FDA concluded that colloidal silver or silver salts generally are not recognized as safe and effective and are misbranded. Several silver nitrate and silver sulfadiazine formulations remain available by prescription. In addition, silver-impregnated dressings are used for their antimicrobial properties and the decreased frequency of dressing changes in patients with toxic epidermal necrolysis (see page 783). Although anecdotal descriptions of subsequent argyria have been reported secondary to use of these dressings, larger series have demonstrated a degree of systemic absorption of silver but no systemic adverse effects. These products should be used only under strict supervision. Well-documented examples of generalized argyria have been seen secondary to long-term treatment of aphthous ulcerations, denture sores, and minor gingival hemorrhage with topical silver nitrate.

Despite the efforts of the FDA, devices for production of homemade colloidal silver suspension and several colloidal silver formulations continue to be marketed over the Internet and in health food stores as essential mineral supplements for diseases such as arthritis, cancer, diabetes, AIDS, and herpes.

dentlearn.ir

During the 2020 COVID-19 epidemic, the US Food and Drug Administration (FDA) and the Federal Trade Commission (FTC) had to issue several cease-and-desist orders to a number of internet vendors who were marketing colloidal silver as a miracle cure for coronavirus. These unregulated silver products have no known physiologic function, and their continued use cannot be supported.

Bismuth and Arsenic

In the United States, excess exposure to bismuth and arsenic currently is rare. The medical use of these metals has diminished dramatically. Most current cases arise from occupational exposure except for excessive arsenic in drinking water seen predominantly in isolated areas of India and Southeast Asia. Bismuth was used in the past for treatment of venereal diseases and various dermatoses, whereas arsenic compounds were prescribed for asthma and skin disorders, such as psoriasis. Bismuth iodoform paraffin paste continues to be used by otolaryngologists and oral surgeons as a surgical pack, with rare reports of associated toxicity. In addition, bismuth subsalicylate tablets (Pepto-Bismol) have been reported to produce localized mucosal discoloration. Chronic exposure to arsenic continues in some lesser developed areas of the world from drinking contaminated water.

Gold

Gold has been used in medical treatment in the past and continues to be used today in selected cases of active rheumatoid arthritis and other immunologically mediated diseases. In these cases, the side effects are well known, and physicians observe the patients closely. In reviews of large-scale skin testing, gold has been found to be among the top 10 most frequent allergens, with positive reactions seen in about 10% of the population, including increased prevalence in patients who have gold dental restorations.

Clinical Features

Lead

Lead poisoning results in nonspecific systemic signs and symptoms, thereby making the ultimate diagnosis very difficult. The presentation is extremely variable and determined by the type of lead and the age of the patient. Patients with acute cases most often have abdominal colic, which may occur along with anemia, fatigue, irritability, and weakness. Encephalopathy and renal dysfunction also may occur. Chronic exposure causes dysfunction of the nervous system, kidneys, marrow, bone, and joints. Symptoms generally include fatigue, musculoskeletal pain, and headache. Bones and teeth represent a major reservoir in patients with chronic plumbism, with 90% of the body's deposition being within bone. In radiographs of the long bones in infants, a radiopaque lead line often is noted along the epiphyseal plates.

Oral manifestations include ulcerative stomatitis and a gingival lead line **(Burton line).** The lead line appears as a bluish line along the marginal gingiva resulting from the action of bacterial hydrogen sulfide on lead in the gingival sulcus to produce a precipitate of lead sulfide. In a review of 187 lead-acid battery workers demonstrating chronic lead toxicity, 49.3% demonstrated a lead line along the gingival margins. As expected, this line was noted more frequently in individuals with poor oral hygiene and greater amounts of plaque. Gray areas also may be noted on the buccal mucosa and tongue.

Mercury

Mercury poisoning also may be acute or chronic. With acute cases, abdominal pain, vomiting, diarrhea, thirst, pharyngitis, and gingivitis typically are present. With chronic cases, gastrointestinal upset and numerous neurologic symptoms occur. The neurologic symptoms are termed **erethism** and include excitability, tremors, memory loss, insomnia, shyness, weakness, and delirium. Because mercury salts formerly were used in the processing of felt, hat makers in past centuries were exposed to the metal and experienced similar symptoms, giving rise to the phrase "mad as a hatter." Oral changes include a metallic taste and ulcerative stomatitis combined with inflammation and enlargement of the salivary glands, gingiva, and tongue. The gingiva may become blue-gray to black. Mercuric sulfide can be generated by the bacterial action on the metal and can cause significant destruction of the alveolar bone with resultant exfoliation of teeth.

Chronic mercury exposure in infants and children is termed **acrodynia (pink disease** or **Swift-Feer disease)**. An erythematous and pruritic rash is present, often with desquamation of the palms and soles. Severe sweating, increased lacrimation, photophobia, neurologic symptoms, hypertension, tachycardia, and gastrointestinal upset also may be present. On occasion, these highly irritable children have torn out patches of their hair. Oral signs include excessive salivation, ulcerative gingivitis, bruxism, and premature loss of teeth. The triad of red, painful desquamating fingers and toes, neurologic symptoms, and hypertension should warn of the possibility of mercury intoxication. Overlap with Kawasaki disease has been noted, suggesting evaluation of 24-hour urine mercury levels when considering that diagnosis.

Silver

Acute silver intoxication can produce coma, pleural edema, hemolysis, and bone marrow failure. Chronic systemic silver intoxication is known as **argyria** and may have toxic effects on the liver, spleen, kidney, intestinal tract, and respiratory system. Silver is disseminated throughout the body with substantial amounts accumulating as subepithelial deposits in the skin. These deposits result in a diffuse grayish discoloration that develops primarily in the sun-exposed areas (Fig. 8.65). The conjunctivae, sclerae, and nails also may be pigmented. One of the first signs of argyria occurs in the oral cavity and appears as a slate-blue silver line along the gingival margins. This discoloration is secondary to deposition of metallic silver and silver sulfide pigments. In addition, the oral mucosa often exhibits a diffuse blue-black discoloration.

dentlearn.ir

• **Fig. 8.65 Argyria.** Grayish discoloration of the face compared with a more normal facial complexion in an individual who used a silver-containing nutritional supplement. Before development of silver intoxication, this blue-eyed, red-haired individual had a very light complexion. (Courtesy of Bradford R. Williams.)

Bismuth

Systemic bismuth toxicity presents with confusion, encephalopathy, hepatorenal impairment, and methemoglobinemia. Chronic bismuth exposure also can result in a diffuse blue-gray discoloration of the skin, conjunctivae, or oral cavity. A blue-gray line along the gingival margin like that seen from lead intoxication is the most common intraoral presentation. Associated ptyalism, burning, stomatitis, and ulceration may be seen. Intoxication from bismuth-containing surgical packs has been associated with CNS symptoms, such as delirium. Chronic use of bismuth subsalicylate tablets can create a removable black discoloration of the otherwise normal filiform papillae (see Fig. 1.26, page 13).

Arsenic

Arsenic is a potent human carcinogen associated with cancers of the skin, lungs, kidney, urinary bladder, and possibly liver. Additional health effects from chronic excess arsenic include hypertension, diabetes mellitus, neurologic abnormalities, and disorders of the cardiovascular, pulmonary, hepatic, and renal systems. Progressive arterial occlusion can result in dry gangrene and spontaneous amputation of extremities, which has been termed "blackfoot disease." Significant cutaneous hyperkeratosis and a diffuse macular hyperpigmentation are seen frequently. The discoloration rarely may involve the oral mucosa and is due to both the presence of the metal and an increased melanin production. Additional oral manifestations are very uncommon and typically appear as excessive salivation and painful areas of necrotizing ulcerative stomatitis. In the past, extensive dorsal hyperkeratosis of the tongue was seen in patients with syphilis and may be related to arsenic therapy used before the advent of antibiotic therapy.

Gold

The most common complication of gold therapy is dermatitis, which often is preceded by a warning signal: pruritus. Although a generalized exfoliative dermatitis with resultant alopecia and loss of nails can be seen, dermatitis about the face, eyelids, and at direct sites of skin contact is the most common presentation. Because of the high frequency of allergy to gold, skin testing often is performed before administration of gold drug therapy.

The second most common adverse reaction to gold is severe oral mucositis, which most frequently involves the buccal mucosa, lateral border of the tongue, palate, and pharynx. These mucosal changes represent a systemic allergic reaction and are different from intraoral contact gold hypersensitivity (see page 346). A metallic taste often precedes development of the oral lesions and should be considered another warning signal. Therapy with gold rarely can bring about a slate-blue discoloration of sun-exposed skin **(chrysiasis).**

Treatment and Prognosis

The management of heavy metal intoxication involves removal from further exposure to the agent, supportive care, decontamination, and use of chelating agents. In some cases, a medication may be responsible and can be discontinued; however, sometimes the source of the metal may be difficult to determine. In infants with radiographic evidence of gastrointestinal lead-containing paint chips, bowel irrigation with a polyethylene glycol electrolyte lavage solution may be warranted. In the past, two chelators, ethylenediaminetetraacetic acid (EDTA) (calcium disodium ethylenediaminetetraacetate) and BAL (2,3-dimercaptopropanol), were first-line therapy in the treatment of lead poisoning, whereas arsenic and mercury intoxication were treated with BAL. These medications may have significant side effects, and less toxic alternatives such as DMSA (2,3-dimercaptosuccinic acid) and DMPS (2,3-dimercaptopropane-1-sulfonate) now are available. No antidote exists for silver intoxication. Attempts to remove the bluish discoloration of facial argyria with dermabrasion have been unsuccessful. Sunscreen, avoiding sunlight, and cosmetics may be somewhat beneficial in minimizing the skin discoloration. Several publications have documented successful treatment of facial argyria with a low-fluence Q-switched 1064-nm Nd:YAG laser. Encephalopathy associated with use of bismuth-containing surgical packs clears on removal of the material, often combined with use of DMPS.

◆ SMOKER'S MELANOSIS

Oral pigmentations are increased significantly in heavy smokers. In one investigation of more than 31,000 whites, 21.5% of tobacco smokers exhibited areas of melanin pigmentation compared with 3% among those not using tobacco. In another study of an ethnically pigmented population, smokers had more oral surfaces exhibiting melanin pigmentation.

Melanin pigmentation in the skin exerts a well-known protective effect against ultraviolet (UV) damage. Investigations of melanocytes located away from sun-exposed areas have shown the ability of melanin to bind to noxious substances. Exposure to polycyclic amines (e.g., nicotine and

dentlearn.ir

benzpyrene) has been shown to stimulate melanin production by melanocytes that also are known to bind strongly to nicotine. Research has suggested that melanin production in the oral mucosa of smokers serves as a protective response against some of the harmful substances in tobacco smoke. This concept is supported by the findings in "reverse" smokers, who smoke with the lit end of the cigarette inside the mouth and demonstrate heavy melanin pigmentation of the palate. In some reverse smokers, areas of melanocytes are lost, and zones of depigmented red mucosa can develop. Cancer is found in 12% of patients with these red zones, further delineating the probable protective effects of melanocytes against toxic substances.

Clinical Features

Although any mucosal surface may be affected, smoker's melanosis most commonly affects the anterior facial gingiva (Fig. 8.66) followed by the buccal mucosa, tongue, and lip. Most people affected by this condition are cigarette users. In contrast, pipe smokers most frequently exhibit brown pigmentations located on the commissural and buccal mucosae, whereas reverse smokers show alterations of the hard palate. Increased oral pigmentation also has been noted in children because of passive smoking.

The areas of pigmentation significantly increase during the first year of smoking and appear correlated to the duration and number of cigarettes smoked each day. A higher frequency is seen in females, and researchers have suggested that female sex hormones exert a synergistic effect when combined with smoking. Reports from Sweden, Germany, and Japan have shown tobacco smoking to be the most common cause for mucosal pigmentation in light-skinned adult populations.

Histopathologic Features

Biopsy specimens of affected areas in people with smoker's melanosis reveal increased melanin pigmentation of the basal cell layer of the surface epithelium, similar to a melanotic macule (see page 372). In addition, collections of incontinent melanin pigmentation are seen free within the superficial connective tissue and in scattered melanophages.

• **Fig. 8.66 Smoker's Melanosis.** Light, diffuse melanin pigmentation in a white female who is a heavy smoker. Pigmentary changes are limited to the anterior facial gingiva.

Diagnosis

The clinician can make the diagnosis by correlating the smoking history with the clinical presentation and medical history. Other causes of melanin pigmentation, such as trauma, neurofibromatosis, Peutz-Jeghers syndrome, drug-related pigmentation, endocrine disturbances, hemochromatosis, chronic pulmonary disease, and racial pigmentation should be excluded.

Treatment and Prognosis

Cessation of smoking results in gradual disappearance of the areas of related pigmentation over a 3-year period. Biopsy should be considered when the pigmentation is in unexpected locations, such as the hard palate, or when there are unusual clinical changes, such as increased melanin density or surface elevation.

◆ DRUG-RELATED DISCOLORATIONS OF THE ORAL MUCOSA

An expanding number of medications have been implicated as a cause of oral mucosal discolorations. Although many medications stimulate melanin production by melanocytes, deposition of drug metabolites is responsible for the color change in others. These pigmentary alterations have been associated with use of retigabine, amiodarone, phenolphthalein, minocycline, tranquilizers, antimalarial medications, estrogen, chemotherapeutic agents, and some medications used in the treatment of patients with AIDS.

The antimalarial agents that are most frequently implicated are chloroquine, hydroxychloroquine, quinidine, and quinacrine; chlorpromazine represents the most frequently implicated tranquilizer. Besides treating malaria, antimalarial agents are used for many other disorders, including lupus erythematosus and rheumatoid arthritis.

Oral mucosal pigmentation also has been associated with the use of chemotherapeutic medications, such as doxorubicin, busulfan, cyclophosphamide, 5-fluorouracil, or imatinib. Although idiopathic hyperpigmentation also may occur, AIDS patients receiving zidovudine (AZT), clofazimine, or ketoconazole have demonstrated increased melanin pigmentation.

Clinical Features

The clinical presentations of pigmentations related to drug use vary. Most agents produce a diffuse melanosis of the skin and mucosal surfaces, but others may cause a unique pattern. As in many cases of increased melanin pigmentation, females are more sensitive, most likely because of an interaction with sex hormones.

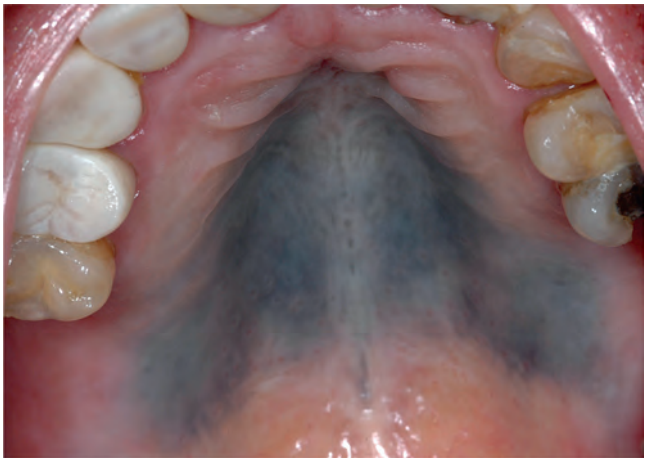
dentlearn.ir

Use of phenolphthalein as a laxative has been associated with numerous small, well-circumscribed areas of hyperpigmentation on the skin. Similar areas of oral mucosal melanosis also can occur. Administration of peginterferon alfa in ethnically pigmented patients with hepatitis C has been associated with hyperpigmentation of the scattered filiform papillae on dorsal surface of the tongue.

Long-term use of minocycline, a semisynthetic derivative of tetracycline, results in discoloration of the bone and developing teeth. The affected bone is dark green but creates a blue-gray discoloration as seen through the translucent oral mucosa. The most common presentations include a linear band above the facial attached gingiva near the mucogingival junction and a broad zone of discoloration on the hard palate (Fig. 8.67). In addition, the dental pulp can become darkly stained, leading to clinically obvious darkened teeth (see page 70).

Minocycline-related pigmentation of the skin and oral mucosa unrelated to discoloration of the underlying bone also has been reported, with patients exhibiting either widespread increased melanosis or focal accumulations of iron-containing particles (Figs. 8.68 and 8.69). The cutaneous pigmentation appears to be dose-dependent and is seen in up to 15% of patients being treated for acne and as many as 70% of those treated for rheumatoid arthritis. Although the cutaneous and oral mucosal staining fades after discontinuation of the medication, the dental discoloration remains.

• **Fig. 8.67 Minocycline-Related Discoloration.** Blue-gray discoloration of the facial surface of the anterior mandibular alveolus because stained alveolar bone is visible through the thin mucosa.



• **Fig. 8.68 Minocycline-Associated Pigmentation.** Sharply demarcated brown pigmentation on the vermilion border of the lips, which arose in association with long-term minocycline use and is the result of increased melanin deposition.

• **Fig. 8.69 Minocycline-Associated Pigmentation.** Multifocal areas of palatal pigmentation secondary to deposition of drug metabolites chelated to iron in association with long-term minocycline use. (From Treister NS, Magalnick D, Woo S-B: Oral mucosal pigmentation secondary to minocycline therapy: report of two cases and a review of the literature, *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 97:718–725, 2004.)

The classic presentation of intraoral pigmentation from use of antimalarial medications or tranquilizers is a blue-black discoloration limited to the hard palate (Fig. 8.70). In addition, the intake of antimalarial medications may occasionally lead to a more diffuse brown melanosis of the oral mucosa and skin. Imatinib (Gleevec™) is a tyrosine kinase inhibitor that is used to treat gastrointestinal stroma tumors and several leukemias. This medication is associated with a pattern of palatal

• **Fig. 8.70 Hydroxychloroquine Pigmentation.** Diffuse grayish pigmentation of the hard palate. (Courtesy of Dr. John Wright.)

dentlearn.ir

• **Fig. 8.71 Imatinib Pigmentation.** Diffuse, dark brown pigmentation of the palate caused by imatinib. (Courtesy of Dr. Walter Cólon).

discoloration that closely resembles the mucosal discoloration caused by antimalarial drugs (Fig. 8.71).

Estrogen, chemotherapeutic agents, and medications used in the treatment of AIDS patients may result in a diffuse brown melanosis of the skin and mucosal surfaces. Any mucosal surface may be involved, but the attached gingiva and buccal mucosa are affected most frequently. The pattern and appearance of the oral mucosal involvement are like those seen in racial pigmentation.

Treatment and Prognosis

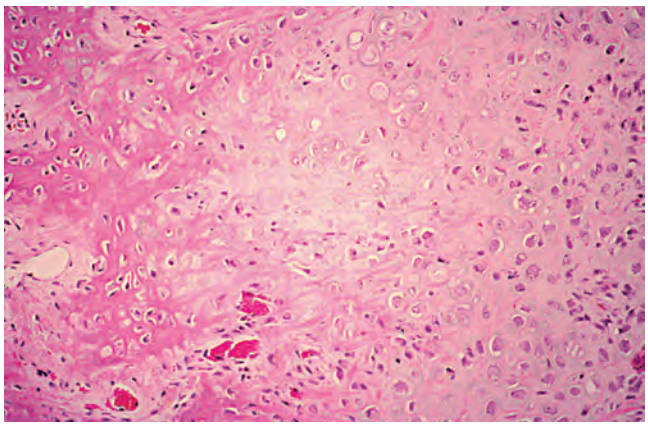
Although the discolorations of the oral mucosa may be aesthetically displeasing, they cause no long-term problems. In most instances, discontinuing the medication results in gradual fading of the areas of hyperpigmentation.

◆ REACTIVE OSSEOUS AND CHONDROMATOUS METAPLASIA (CUTRIGHT LESION)

On occasion, cartilage or bone may be discovered within soft tissue specimens removed from the oral cavity. Cartilaginous rests are known to exist in the area of the nasopalatine duct. In the past, several investigators have reported the presence of cartilage within flabby soft tissue removed from maxillary edentulous alveolar ridges of long-term denture wearers. This finding was thought to represent cartilaginous metaplasia secondary to chronic denture trauma. In retrospect, the islands of cartilage within these cases most likely represent embryologic remnants, not traumatic metaplasia. These rests also are discovered occasionally during histopathologic examination of nasopalatine duct cysts and maxillary gingivectomy specimens.

Despite the suggestion that the anterior maxillary lesions are embryologic and not traumatic, development of **osseous** and **chondromatous metaplasia** from mechanical denture irritation does occur. Although such metaplasia is probably uncommon in the anterior maxilla, its development is not rare along the crest of the posterior mandibular alveolar ridge in long-term denture wearers with atrophic ridges.

Clinical and Radiographic Features



In patients with reactive osseous and chondromatous metaplasia, an extremely tender and localized area of the alveolar ridge typically is noted that may be associated with local enlargement (Fig. 8.72). These changes almost always arise in patients with extensive atrophy of the mandibular alveolar ridge leading to a knife edge–like crest. Although most examples involve the posterior mandible, similar areas rarely may be seen overlying the maxillary alveolar ridge or associated with anterior portions of the mandible. Because of significant associated symptoms and occasional enlargement, biopsy frequently is performed.

Histopathologic Features

Histopathologic examination of reactive osseous and chondromatous metaplasia typically demonstrates a mass of hypercellular periosteum that blends into areas of osseous and chondromatous tissue. The bone and cartilage frequently exhibit atypical features, such as hypercellularity, pleomorphism, nuclear hyperchromatism, and occasional binucleated or multinucleated cells (Fig. 8.73). These alterations are

• **Fig. 8.72 Periosteal Hyperplasia With Osseous and Chondromatous Metaplasia.** Tender, elevated nodule along the thin crest of the mandibular alveolar ridge. (Courtesy of Dr. Steven Tucker.)

• **Fig. 8.73 Osseous and Chondromatous Metaplasia.** High-power photomicrograph demonstrating cellular woven bone and metaplastic cartilage.

dentlearn.ir

worrisome for sarcoma, but the appropriate diagnosis can be made when an appropriate clinicopathologic correlation is made. In contrast, the cartilaginous rest discovered incidentally in maxillary specimens is usually very bland without any atypical features that would suggest malignancy.

Treatment and Prognosis

The thin mandibular ridges may be recontoured or supplemented with graft material to improve shape and to alleviate the symptoms associated with the localized periosteal hyperplasia. Implants also may reduce the traumatic injury to the ridge and lessen the chance of recurrence. If the ridge modification is not made, then the continued injury to the site occasionally results in recurrence of the lesion.

◆ ORAL ULCERATION WITH BONE SEQUESTRATION (SPONTANEOUS SEQUESTRATION; TRAUMATIC SEQUESTRATION)

Focal superficial sequestration of a fragment of cortical bone not related to systemic disease, infection, or a major traumatic event is uncommon. In such instances, the cause of the focal osteonecrosis is not known, although many believe the primary event is a traumatic or aphthous ulceration that leads to osteitis and necrosis of a small focus of adjacent cortical bone. Others have suggested the blood supply of the peripheral cortical plate may be delivered by the periosteal microvasculature, and loss of this supply leads to focal bone necrosis and sequestration. Such lesions tend to occur in anatomically unique sites in which a bony prominence is covered by a thin mucosal surface.

Clinical and Radiographic Features

In many instances, the focal bone necrosis follows a recent traumatic injury related to events such as toothbrushing trauma, excessive occlusal forces during mastication or bruxism, and iatrogenic injuries (trauma during periodontal scaling, dental impressions, intubation, or tooth extraction). On occasion, the lesion cannot be associated with a prior traumatic event or follows the development of an aphthous-like ulceration. The most frequent site of sequestrum development is the lingual surface of the posterior mandible along the mylohyoid ridge (Fig. 8.74). Focal involvement of exostoses also may occur. Although any exostosis may be involved, mandibular tori are affected most frequently. There is a male predominance and a predilection for middle age with rare cases seen under the age of 30.

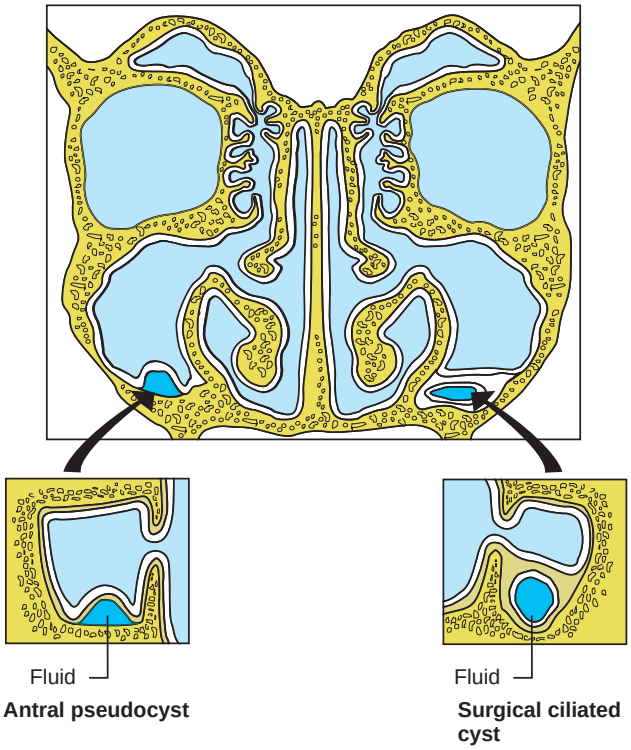
The overlying mucosa typically demonstrates a focal area of ulceration that has been present for a period of time that varies from a few days to several months. The presence and intensity of associated pain are variable. Although most cases are unilateral, bilateral involvement may occur. On occasion, an occlusal radiograph will reveal a faint radiopaque mass superimposed and partially lingual to the intact cortical plate.

• **Fig. 8.74 Spontaneous Sequestration.** Mucosal ulceration with exposed bone of the posterior lingual surface of the mandible.

The mylohyoid ridge often is prominent but typically protected from trauma by the lingual inclination of the adjacent molars. Absence of the adjacent molars or restorations that do not replace the normal inclination could predispose the area to repeated trauma; such alterations have been noted in most affected patients.

Histopathologic Features

The sequestra consist of well-organized lamellar bone that exhibits loss of the osteocytes from their lacunae, along with peripheral resorption and bacterial colonization.



Treatment and Prognosis

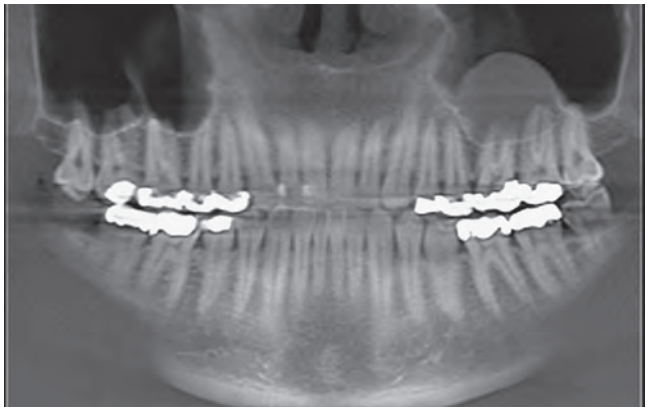
Spontaneous loss of the dead bone or surgical removal of the sequestrum results in rapid healing. Recurrence is uncommon. In some instances, the dead bone is freely movable and easily removed. In other cases, the fragment is adherent to the underlying vital bone and must be surgically excised. To avoid surgery, some clinicians use a tetracycline rinse in addition to topical corticosteroids. Alternatively, these patients can be recalled weekly for 2–4 weeks, during which time the dead bone may exfoliate spontaneously without the need for invasive therapy.

◆ ANTRAL PSEUDOCYSTS

Antral pseudocysts are common findings on panoramic radiographs. The lesion appears as a dome-shaped, faintly radiopaque lesion often arising from the floor of the maxillary sinus. This condition continues to be misunderstood and is inappropriately termed **sinus mucocele** or **sinus retention cyst** by many clinicians (see next section). The antral pseudocyst develops due to an accumulation of an inflammatory exudate (serum, not mucus) beneath the maxillary sinus mucosa, causing a sessile elevation (Fig. 8.75). It must be stressed that the edematous fluid

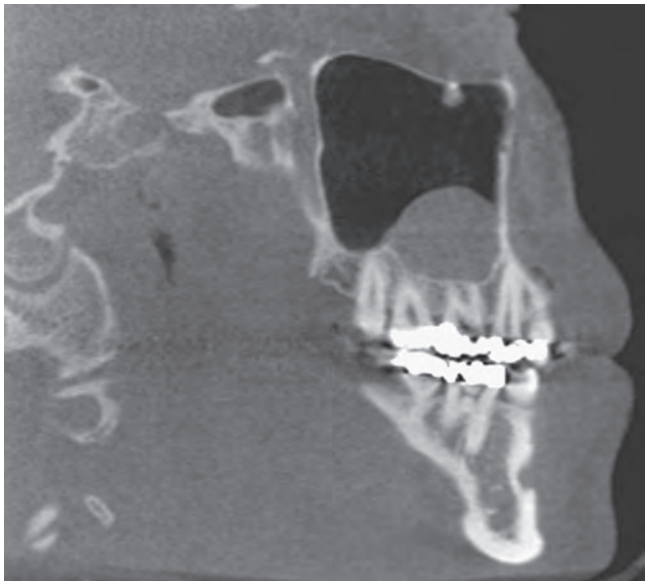
dentlearn.ir

• **Fig. 8.75 Antral Pseudocyst and Surgical Ciliated Cyst.** An antral pseudocyst is an accumulation of serum beneath the sinus lining. A surgical ciliated cyst is an epithelium-lined cystic structure separate from the sinus.



is in the stroma underneath the epithelium, not surrounded by it.

Reviews of large numbers of radiographs have reported a prevalence that ranges from 1.5% to 14% of the population. The cause of the inflammatory infiltrate has not been determined definitively, but in a radiographic review, many cases showed a possible source from an adjacent odontogenic infection. Primary irritation of the sinus lining, such as that seen from a sinus infection or allergies, also can theoretically result in the inflammatory infiltrate.

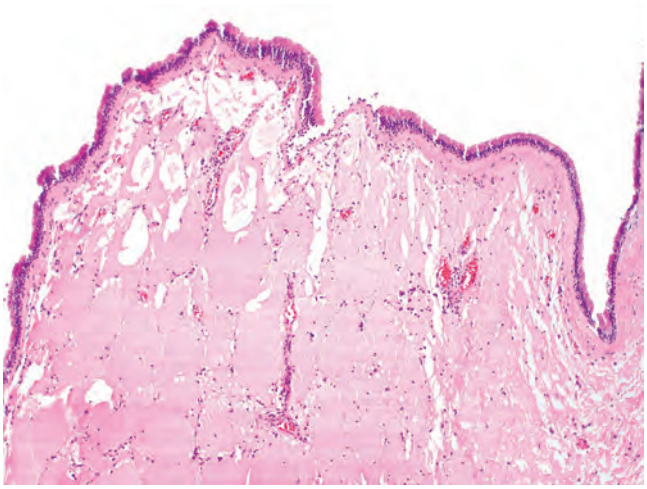


An increased prevalence of pseudocysts has been noted during the cold winter months, leading some investigators to associate these lesions with an increased frequency of upper respiratory tract infections or irritation from dry, forced-air heating. This association is difficult to confirm because these lesions often are asymptomatic, making the timing of their development difficult to pinpoint. Although allergies have been proposed as a cause, no increased prevalence has been noted consistently during the time of peak pollen exposure.

Clinical and Radiographic Features

Most pseudocysts are asymptomatic. On occasion, affected patients report symptoms, such as headache, facial sinus pain, nasal obstruction, postnasal drip, and nasal discharge. Some studies have suggested these symptoms are secondary to other sinus disease and are not relieved by removal of the pseudocyst. Radiographically,

• **Fig. 8.76 Antral Pseudocyst.** Three-dimensional cone-beam radiograph showing dome-shaped radiopacity within the maxillary sinus. (Courtesy of Dr. Scott Jenkins and Dr. Nick Morrow.)



• **Fig. 8.77 Antral Pseudocyst.** Three-dimensional cone-beam sagittal section of same patient depicted in Fig. 8.76. Note that the floor of the sinus remains intact below the lesion. (Courtesy of Dr. Scott Jenkins and Dr. Nick Morrow.)

an antral pseudocyst typically presents as a uniform and spherical or dome-shaped radiodensity arising above the bony floor of the maxillary sinus (Figs. 8.76 and 8.77). Maxillary cysts and neoplasms can simulate the dome-shaped pattern of an antral pseudocyst, but close examination of a pseudocyst typically reveals the radiopaque floor of the sinus is not elevated and does not extend over the superior aspect of the lesion. Less frequently, pseudocysts also may arise from the lateral wall, medial wall, or roof of the antrum. A male predominance has been reported by some authors.

Histopathologic Features

Antral pseudocysts are covered by sinus epithelium and demonstrate a subepithelial inflammatory exudate that consists of serum, occasionally intermixed with inflammatory cells

dentlearn.ir

• **Fig. 8.78 Antral Pseudocyst.** Medium-power photomicrograph demonstrating sinus lining overlying edematous connective tissue.

(Fig. 8.78). Collections of cholesterol clefts and scattered small dystrophic calcifications may be seen.

Treatment and Prognosis

Typically, pseudocysts of the maxillary sinus are harmless, and no treatment is necessary. The adjacent teeth should be evaluated thoroughly, and any foci of infection should be eliminated. A few clinicians prefer to confirm their radiographic impression and rule out a tumor through drainage of the inflammatory exudate. Removal by means of a Caldwell-Luc operation endoscopic surgery should be performed on any radiographically diagnosed lesion that produces significant expansion or is associated definitively with symptoms.

◆ TRUE CYSTS OF THE SINUSES (SINUS MUCOCELE; SURGICAL CILIATED CYST; TRAUMATIC CILIATED CYST; POSTOPERATIVE MAXILLARY CYST; RETENTION CYST)

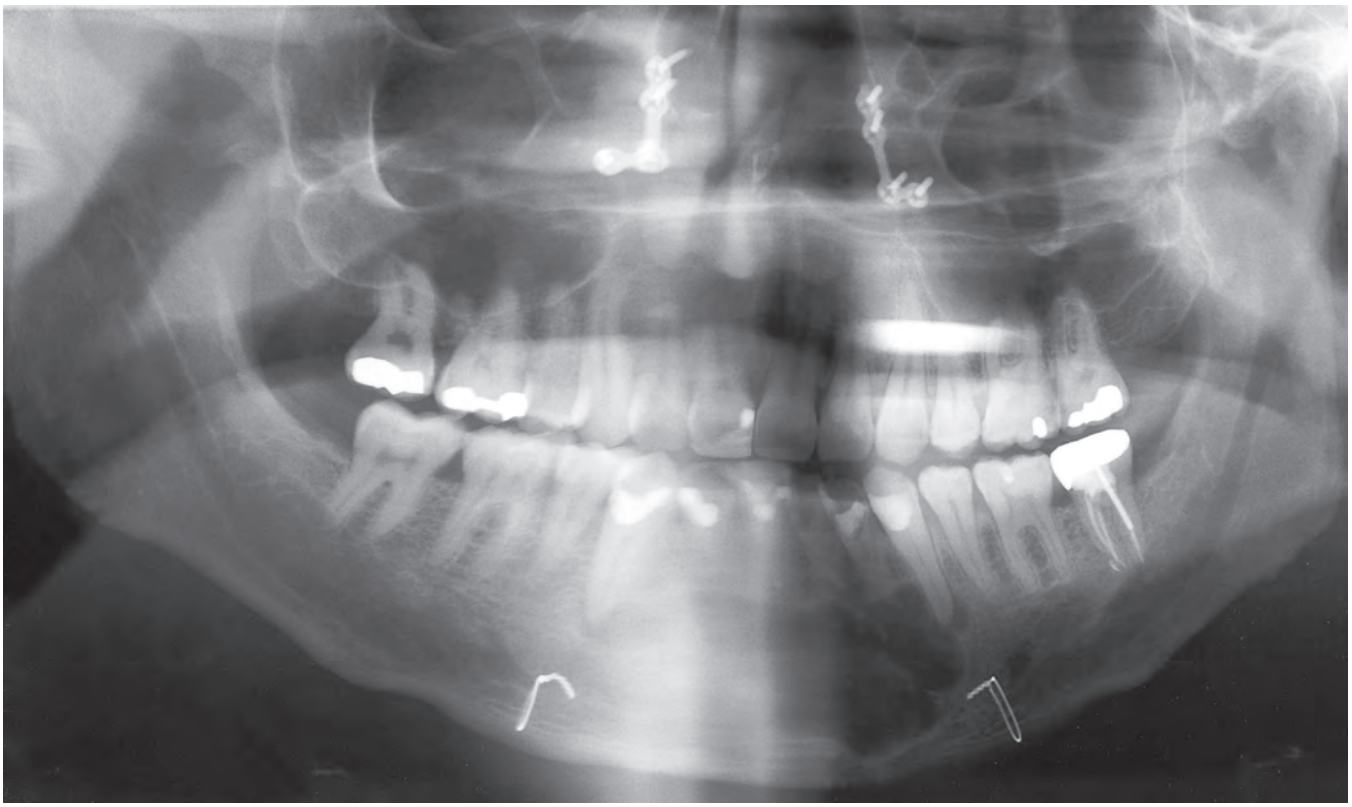
In contrast to the antral pseudocyst, which arises from subepithelial accumulation of edema fluid, true epithelium-lined cysts also may arise from the sinonasal mucosa and glands. They occur in three situations.

One type of cyst occurs after trauma or surgery to the sinus; this type is best known as a **surgical ciliated cyst, traumatic ciliated cyst**, or **postoperative maxillary cyst.** A portion of the sinus lining becomes separated from the main body of the sinus and forms an epithelium-lined cavity into which mucus is secreted. Alternatively, radical surgery may alter the anatomy of the sinus and block the drainage passage, resulting in an expanding cyst-like structure. The cyst most frequently originates after a Caldwell-Luc operation but may arise from difficult extraction of a maxillary tooth in which the floor of the maxillary sinus is damaged. In addition, sinus or nasal epithelium rarely can be transplanted accidentally to the mandible during genioplasty, chin augmentation, or a sagittal split osteotomy and lead to formation of ciliated cysts in ectopic locations (Fig. 8.79). Postoperative cysts often are a late complication and frequently arise 10–30 years after the triggering surgical event.

The second type of cyst, known as a **sinus mucocele,** arises from an obstruction of the sinus ostium, thereby blocking normal drainage. This blocked sinus then acts like a separate cyst-like structure lined by epithelium and filled with mucus. Sinus mucoceles enlarge in size as the intraluminal pressure increases and can distend the walls of the sinus and erode through bone; they often clinically mimic malignancy of sinus origin. (It should be emphasized that a sinus mucocele is a distinct, separate pathologic entity that is unrelated to the common mucocele of minor salivary gland origin [see page 460]).

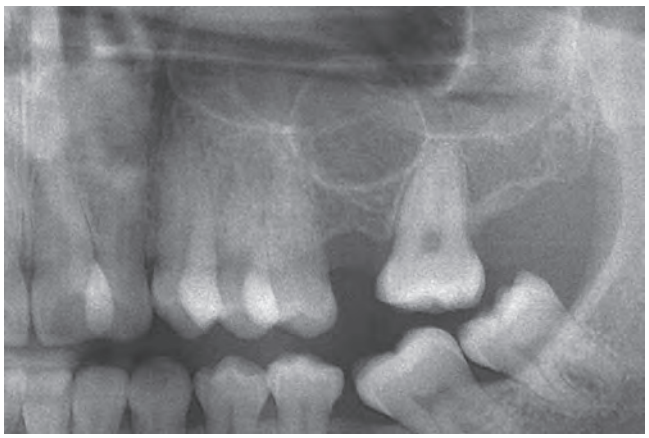
Retention cysts of the maxillary sinus are the third type of true cyst. These lesions arise from the partial blockage of a seromucous gland duct within the sinus wall, or from an invagination of the respiratory epithelium. Most retention cysts are located around the ostium or within antral polyps. The majority of retention cysts are small, not evident clinically, and discovered during histopathologic examination of antral polyps.

Postoperative surgical ciliated cysts appear to be uncommon in the United States and Europe but are reported more frequently in Japan due to the high prevalence of surgical therapy rather than antibiotic treatment for sinusitis prior to the 1970s. Sinus mucoceles arising from ostial obstruction are much more numerous and most frequently involve the frontal sinus, with the ethmoid and sphenoid sinuses being affected less often. Maxillary sinus mucoceles arising from blockage of the ostium are relatively rare and account for less than 10% of paranasal sinus mucoceles.



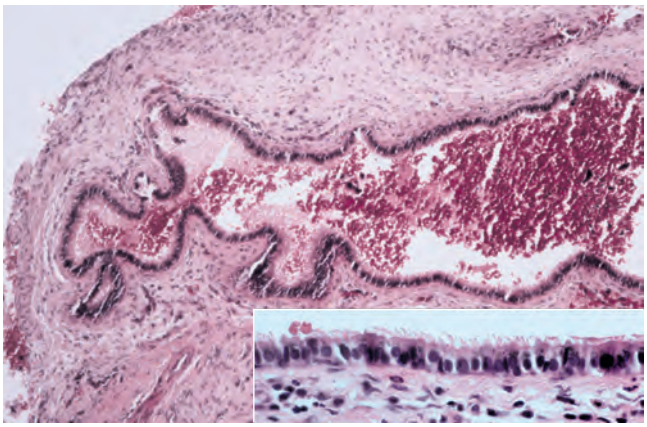
Clinical and Radiographic Features

Surgical ciliated cysts are spherical lesions that are separate from the sinus and lack the dome-shaped appearance of pseudocysts (Fig. 8.80). As these postoperative cysts enlarge, they can lead to perforation of the sinus walls. When the maxillary sinus is involved by a true sinus mucocele, the entire sinus will appear cloudy. As the lesion enlarges, the walls of the sinus may become thinned and eventually eroded. Retention cysts rarely reach a size that would produce detectable radiographic changes. Mandibular postoperative cysts secondary to genioplasty or chin augmentation present as a well-defined unilocular radiolucency in the midline, while those secondary to a sagittal split osteotomy arise in the ascending ramus.



Histopathologic Features

Surgical ciliated cysts and sinus mucoceles are true cystic structures lined by ciliated pseudostratified columnar epithelium, squamous epithelium with mucous cells, or metaplastic squamous epithelium (Fig. 8.81). A sinus retention cyst



dentlearn.ir

• **Fig. 8.81 Surgical Ciliated Cyst.** True cyst lined by respiratory epithelium. Inset provides high-power view of the ciliated pseudostratified columnar epithelium that lines the cyst.

shows focal dilation of a duct associated with the seromucous glands of the sinus lining. The lumen of the dilated duct is filled with thick mucus, often intermixed with chronic inflammatory cells.

Treatment and Prognosis

Because surgical ciliated cysts and sinus mucoceles are expansile and destructive lesions, surgical removal is necessary. Although many of the maxillary lesions are removed via a Caldwell-Luc operation, cysts close to the nasal cavity are treated best with transnasal endoscopic marsupialization. The mandibular lesions respond well to thorough curettage with marsupialization utilized in large cysts to reduce the size prior to definitive removal. Numerous investigators also have shown that sinus mucoceles arising from ostial obstruction often do not require surgical excision, but they respond well to endoscopic middle meatal antrostomy and marsupialization of the mucocele.

dentlearn.ir

CERVICOFACIAL EMPHYSEMA

Cervicofacial emphysema arises from the introduction of air into subcutaneous or fascial spaces of the face and neck. The forced air may spread through the spaces to the orbital, retropharyngeal, mediastinal, pleural, and peritoneal areas. A physician, Alexander Turnbull, reported the first case in 1900 that arose as a result of blowing into a bugle a short time after tooth extraction.

Cervicofacial emphysema of dental origin may arise in several ways:

- After the use of compressed air by the clinician
- After difficult or prolonged extractions
- As a result of increased intraoral pressure (e.g., vigorous nose blowing, sneezing, balloon blowing, playing wind instruments, habitual Valsalva maneuvers). The risks of these procedures are increased immediately after an oral surgical procedure
- Use of hydrogen peroxide for irrigation during an endodontic procedure
- From no obvious cause

Introduction of air within tissue has been seen after a large number of dental procedures, but most instances involve either surgical extraction of teeth, endodontic procedures, osteotomies, significant trauma, or the use of air or water syringes. In addition, the prevalence has increased because of the use of air-driven handpieces during oral surgery or use of lasers with compressed air systems designed to remove tissue debris from the operative field. On occasion, cervicofacial emphysema has resulted from compressed air being accidentally forced into small intraoral lacerations located away from the field of operation. An analogous problem termed **pneumoparotid** can arise when air enters the parotid duct, leading to enlargement of the parotid gland caused by air insufflation. This can be accidental, self-induced, or occupational (e.g., glassblowers and wind instrument players). Stensen duct has numerous redundant mucosal folds that seal as intraoral pressure is increased; in addition, contraction of the buccinator muscle further prevents entrance of air by compressing the duct. Despite this protection, dramatic increases in intraoral pressures can result in air filling the parotid ductal system.

Clinical and Radiographic Features

More than 90% of cases of cervicofacial emphysema develop during surgery or within the first postoperative hour. Cases with delayed onset are associated with increased postoperative pressure created by the patient. The initial change is one of soft tissue enlargement from the presence of the air in deeper tissues (Fig. 8.82). Pain usually is minimal, and crepitus is detected easily with gentle palpation. Subsequently, the enlargement increases and spreads because of secondary inflammation and edema. Variable pain, facial erythema, dysphagia, dysphonia, vision difficulties, and mild fever may occur. The facial enlargement often is confused with an angioedema, but the diagnosis can be made by identifying crepitus within the swelling. In addition, computed tomography (CT) using the Hounsfield density measuring scale can confirm the presence of soft tissue air pockets.

• **Fig. 8.82 Cervicofacial Emphysema.** Periorbital and facial enlargement caused by use of an air-driven handpiece during third molar removal.

Significant spread into the mediastinum can result in dysphonia, dysphagia, or dyspnea. Cardiac auscultation often reveals crepitus synchronous with the heartbeat **(Hamman's crunch)** in cases with mediastinal involvement. Pneumomediastinum can be confirmed on chest radiographs by observing displacement of the mediastinal pleura. Pericardial space involvement often can be detected through at 12-lead electrocardiogram that may demonstrate inverted T waves, ST segment elevation, and an electrical axis shift.

Pneumoparotid typically appears as a unilateral enlargement of the parotid that demonstrates crepitus on gentle palpation. Milking the parotid duct produces frothy, air-filled saliva, rather than the typical clear, water-like secretion.

Treatment and Prognosis

Broad-spectrum antibiotic coverage is recommended in all dental-related cases of cervicofacial emphysema. The body gradually removes the entrapped air during a 2- to 5-day period. Most cases spontaneously resolve without significant difficulty. Administration of 100% oxygen with a nonrebreather mask can shorten recovery, because the oxygen reduces the partial pressure of nitrogen in the lungs compared to the peripheral tissues with the resultant pressure gradient allowing nitrogen to diffuse more rapidly out of the peripheral tissues (the entrapped air is 78% nitrogen, 21%

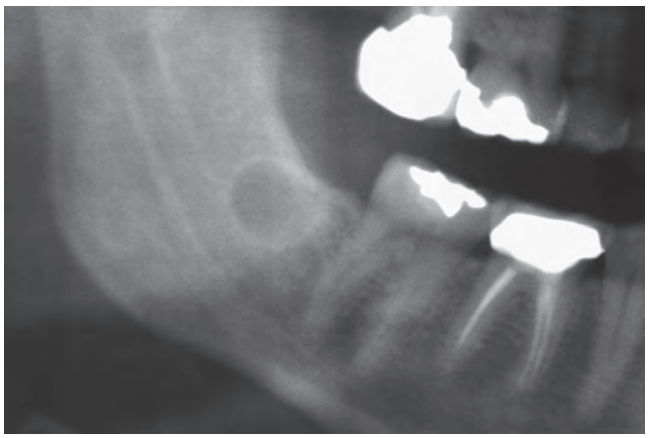
dentlearn.ir

oxygen). Rare cases of respiratory distress have been noted, and assisted ventilation was required. Associated deaths have been reported secondary to rare severe complications such as mediastinitis, tension pneumothorax, cardiac tamponade, cardiac failure, and air embolism.

The first goal of therapy for pneumoparotid is discovery of the inciting event. In occupation-related cases, such as those seen in trumpet players, the individual should be coached to compress the cheeks during playing. This procedure contracts the buccinator muscle and compresses the parotid duct. Acute symptoms are treated with antibiotics, massage, hydration, sialogogues, and warm compresses.

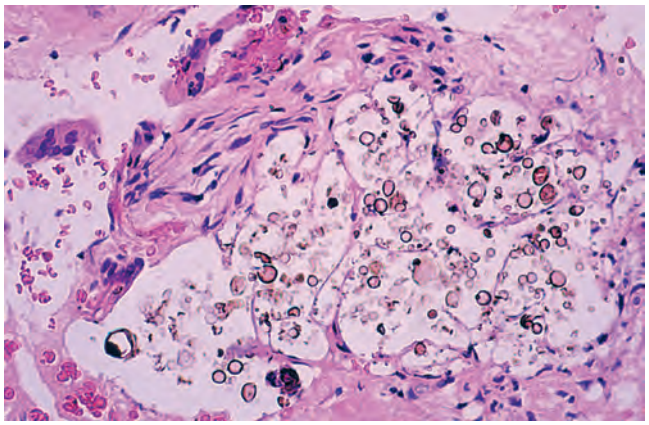
◆ MYOSPHERULOSIS

Placement of a topical antibiotic or hemostatic agent in a petrolatum or petroleum base into a surgical site occasionally may result in a unique foreign body reaction, known as **myospherulosis.** The resultant histopathologic pattern demonstrates spherical bodies initially thought to represent an endosporulating fungus but shown to be red blood cells altered by physical emulsion with the lipid-containing petrolatum.



Clinical and Radiographic Features

Myospherulosis may occur at any site within soft tissue or bone where the antibiotic has been placed. Most cases in the dental literature have occurred within bone at previous extraction sites where an antibiotic had been placed to prevent alveolar osteitis. Although maxillary and oral soft tissue examples have been documented, most cases have occurred within mandibular surgical sites. In addition, myospherulosis is reported occasionally in other anatomical sites, most often in the nose or a paranasal sinus following a surgical procedure in which a gauze packing coated with an antibiotic ointment was used. A similar microscopic pattern also has been seen in renal cell carcinoma, steatocystoma, cystic teratomas, breast tissue, and perirenal adipose tissue secondary to a reaction between endogenous lipid and blood.



Although rare cases may present as a multilocular lesion, myospherulosis classically presents as a circumscribed unilocular radiolucency in a site of previous surgery (Fig. 8.83). In some cases, swelling, pain, or purulent drainage may be present. On exploration of the lesion, a black, greasy, tarlike material is found.

Histopathologic Features

The histopathologic pattern demonstrates dense collagenous tissue intermixed with a granulomatous inflammatory response showing macrophages and multinucleated giant cells. Within the connective tissue are multiple cyst-like spaces that contain numerous brown-to-black-staining spherules (Fig. 8.84). The collections of spherules sometimes are surrounded by an outer membrane known as a *parent body,* forming structures that resemble a "bag of marbles."

• **Fig. 8.83 Myospherulosis.** Radiolucency has persisted after extraction of the mandibular third molar. An antibiotic ointment was placed at the time of initial surgery.

• **Fig. 8.84 Myospherulosis.** High-power photomicrograph exhibiting multiple cystlike spaces containing numerous brown-stained spherules.

The unusual dark coloration is due to the degradation of hemoglobin. To complicate matters, myospherulosis arising in a paranasal sinus occasionally is contaminated with respiratory fungal organisms, such as the Zygomycetes or *Aspergillus*.

Treatment and Prognosis

Myospherulosis is treated by surgical removal of the foreign material and associated tissue. Histopathologic examination of the altered tissue provides the definitive diagnosis. Recurrence is not expected. Those arising in a paranasal sinus and exhibiting fungal infestation respond well to local measures and do not require systemic antimicrobial therapy.

9 Allergies and Immunologic Diseases

◆ TRANSIENT LINGUAL PAPILLITIS

Transient lingual papillitis (lie bumps, tongue torches) represents a common oral pathosis that rarely has been documented. Affected patients experience clinical alterations that involve a variable number of fungiform papillae of the tongue. These papillae are covered with thin nonkeratinized epithelium containing scattered taste bud pores associated with a highly innervated stroma. This unique anatomy that appears relatively susceptible to injury has been proposed to be responsible for the selective involvement of fungiform papillae in transient papillitis. The pathogenesis currently is unknown, but the lesions most likely arise from a variety of influences. Suggested causes include local irritation, stress, gastrointestinal disease, hormonal fluctuation, upper respiratory tract infection, viral infection, and topical hypersensitivity to foods, drinks, or oral hygiene products.

Clinical Features

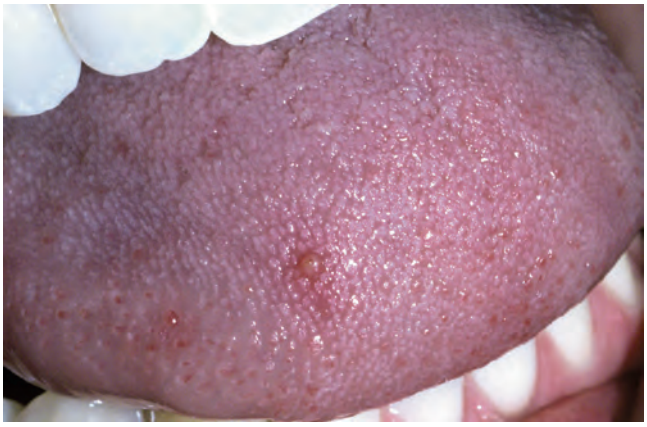
Three patterns of transient lingual papillitis have been documented. The first pattern is localized and involves one to several fungiform papillae that become enlarged and present as elevated papules that are red but may demonstrate a yellow, ulcerated cap (Fig. 9.1). The lesions appear most frequently on the anterior portion of the dorsal surface, are associated with mild to moderate pain, and resolve spontaneously within hours to several days. In a survey of 163 dental school staff members, 56% reported previous episodes of transient lingual papillitis. There was a female predominance, and the vast majority reported a single affected papilla. In one report, the occurrence of the lesions appeared to be associated with a food allergy.

In the second pattern, the involvement is more generalized and affects a large percentage of the fungiform papillae on the tip and lateral portions of the dorsal surface (Fig. 9.2). Individual papillae are very sensitive, enlarged, erythematous, and occasionally display focal surface erosion. Fever and cervical lymphadenopathy may be seen in some individuals. In such cases, spread of the process among family members has been reported, suggesting a possible correlation to an unknown virus. Spontaneous resolution occurs in about 7 days with occasional recurrences reported.

The third pattern of transient lingual papillitis also demonstrates more diffuse involvement. The altered papillae are asymptomatic, appear as elevated white to yellow papules, and have been termed the *papulokeratotic variant* because of a thickened parakeratotic cap (Fig. 9.3). Although these lesions could be the result of a topical allergy, the histopathology demonstrates features similar to chronic nibbling and suggests the possibility of an unusual pattern of frictional hyperkeratosis.

Histopathologic Features

On histopathologic examination of the first two variants, affected papillae demonstrate normal surface epithelium that may reveal focal areas of exocytosis or ulceration. The underlying lamina propria exhibits a proliferation of numerous small vascular channels and a mixed inflammatory cellular infiltrate. Investigation for evidence of human papillomavirus (HPV), herpes simplex, and fungal infestation has been negative. The papulokeratotic variant demonstrates marked hyperparakeratosis in which the surface is ragged and reveals bacterial colonization. A chronic lymphocytic infiltrate is noted in the superficial lamina propria with extension into the basilar portion of the adjacent epithelium.



Treatment and Prognosis

Although transient lingual papillitis resolves without therapy, topical corticosteroids, anesthetics, and coating agents have been used to reduce the pain or duration. In an attempt to eliminate the pain, occasional patients have reported removing the affected papillae with devices such as fingernail clippers. The papulokeratotic variant is asymptomatic and requires no therapy. Although frequently unsuccessful, search for a local or systemic triggering event seems prudent.

◆ RECURRENT APHTHOUS STOMATITIS (RECURRENT APHTHOUS ULCERATIONS; CANKER SORES)

Recurrent aphthous stomatitis (**RAS**) is one of the most common oral mucosal pathoses. The name arises from the Greek work *aphtha,* which refers to an ulcer of the mucosal surface. The reported prevalence in the general population varies from 5% to 66%, with a mean of 20%. Different subgroups of patients appear to have different causes for the

dentlearn.ir

• **Fig. 9.1 Transient Lingual Papillitis.** Tender, yellow-pink papule on the dorsum of the tongue.

• **Fig. 9.2 Transient Lingual Papillitis.** Multiple painful white papules on the lateral dorsum and tip of tongue.

• **Fig. 9.3 Transient Lingual Papillitis.** Clusters of asymptomatic, elevated, yellow papules on the dorsolateral surface of the tongue. (Courtesy of Dr. Craig Fowler.)

occurrence of aphthae. These factors suggest a common disease process that may be initiated by a variety of causative agents, each of which can produce the disease in certain subgroups of patients. To state it simply, the cause appears to be "different things in different people."

Although no single triggering agent is responsible, the mucosal destruction appears to represent a T cell–mediated immunologic reaction with involvement of tumor necrosis factor-alpha (TNF-α). This factor is a major inflammatory cytokine and assists in the ultimate targeting of the surface epithelium for destruction by cytotoxic T cells (CD8+). Evidence of the destruction of the oral mucosa mediated by these lymphocytes is strong, but the initiating causes are elusive and most likely highly variable.

The following all have been reported to be responsible in certain subgroups of patients (and each discounted in other subgroups!):

- Allergies
- Genetic predisposition
- Hematologic abnormalities
- Hormonal influences
- Immunologic factors
- Infectious agents
- Nutritional deficiencies
- Smoking cessation
- Stress (mental and physical)
- Trauma

Investigators have theorized that aphthae develop from an immunologic reaction to an oral antigen. This reaction may arise due the presence of a highly antigenic reagent, a decrease in the mucosal barrier that previously masked the antigen, or immunodysregulation resulting in an abnormal response to a normally present antigen. All previously described triggers can be grouped into one of these three categories. One or more of these three factors may be involved in subgroups of patients.

Genetic predisposition appears to be important in many patients with approximately 40% of affected individuals reporting a positive family history. Children with a family history of RAS demonstrate a 90% chance of developing aphthae, whereas the prevalence drops to 20% in children without affected parents.

An antigenic stimulus appears to be the primary initiating factor in the immune-mediated cytotoxic destruction of the mucosa in many patients. The list seems endless, and every item on the list may be important in small subsets of patients. Commonly mentioned potential antigens include sodium lauryl sulfate in toothpaste, many systemic medications (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], bisphosphonates, various beta blockers, angiotensin receptor blockers, cyclooxygenase-2 inhibitors, rapamycin inhibitors, trimethoprim-sulfamethoxazole, and nicorandil), microbiologic agents (e.g., L forms of streptococci, *Helicobacter pylori,* herpes simplex virus [HSV], varicella-zoster virus [VZV], adenovirus, and cytomegalovirus [CMV]), and many foods (e.g., cheese, chocolate, coffee, cow's milk, gluten, nuts, strawberries, tomatoes, dyes, flavoring agents, and preservatives).

dentlearn.ir

The mucosal barrier appears to be important in the prevention of aphthous stomatitis and might explain the almost exclusive presence of aphthous stomatitis on nonkeratinized mucosa. Numerous factors that decrease the mucosal barrier increase the frequency of occurrence (e.g., trauma, nutritional deficiencies, and smoking cessation); conversely, those associated with an increased mucosal barrier have been correlated with decreased ulcerations (e.g., smoking, hormonal changes, and marked absence of aphthae on mucosa bound to bone).

An increased prevalence of aphthous-like ulcerations has been noted in a variety of systemic disorders (Box 9.1). These ulcerations typically are identical clinically and histopathologically to those noted in otherwise healthy individuals. In many cases, resolution of the systemic disorder produces a decreased frequency and severity of the mucosal ulcerations.

Three clinical variations of aphthous stomatitis are recognized:

1. Minor
2. Major
3. Herpetiform

Minor aphthae (Mikulicz aphthae) are the most common and represent the pattern present in more than 80% of those affected. Major aphthae (Sutton disease or periadenitis mucosa necrotica recurrens [PMNR]) occur in approximately 10% of the patients referred for treatment. The remaining patients have herpetiform aphthae. The minor and major forms most likely represent variations of the same process, although herpetiform aphthae demonstrate a unique pattern. Some investigators differentiate the herpetiform variant because of supposed evidence of a viral cause, but the proof is weak and does not justify its distinction from the other aphthous ulcerations. Some authors include Behçet syndrome as an additional variation of aphthous stomatitis, but this multisystem disorder is more complex and is considered later in this chapter.

• BOX 9.1 Systemic Disorders Associated With Recurrent Aphthous Stomatitis

- Behçet syndrome
- Celiac disease
- Cyclic neutropenia
- Nutritional deficiencies (iron, folate, zinc, B_1, B_2, B_6, and B_{12})
- Immunoglobulin A (IgA) deficiency
- Immunocompromised conditions, including human immunodeficiency virus (HIV) disease
- Inflammatory bowel disease (ulcerative colitis, Crohn disease)
- MAGIC syndrome (mouth and genital ulcers with inflamed cartilage)
- PFAPA syndrome (periodic fever, aphthous stomatitis, pharyngitis, cervical adenitis)
- Systemic lupus erythematosus
- *H. pylori* disease
- Reactive arthritis
- Sweet syndrome
- Ulcus vulvae acutum

Clinical Features

Aphthous stomatitis is noted more frequently in children and young adults, with approximately 80% of affected individuals reporting their first ulceration before the age of 30. If persistent RAS arises after the third decade of life, there should be an increased suspicion of an association with a systemic condition such as a hematologic disorder, immune dysfunction, or Behçet syndrome.

Minor Aphthous Stomatitis

Patients with minor aphthae experience the fewest recurrences, and the individual lesions exhibit the shortest duration of the three variants. The ulcers arise almost exclusively on nonkeratinized mucosa and may be preceded by an erythematous macule in association with prodromal symptoms of burning, itching, or stinging. The ulceration demonstrates a yellow-white, removable fibrinopurulent membrane that is encircled by an erythematous halo (Fig. 9.4). Classically, the ulcerations measure between 3 and 10 mm in diameter, demonstrate a variable recurrence rate, and heal without scarring in 7–14 days (Fig. 9.5). Although scores of ulcerations

• **Fig. 9.4 Minor Aphthous Stomatitis.** Erythematous halo encircling a yellowish ulceration of the soft palate on the left side.

• **Fig. 9.5 Minor Aphthous Stomatitis.** Two ulcerations located on the mandibular labial mucosa.

dentlearn.ir

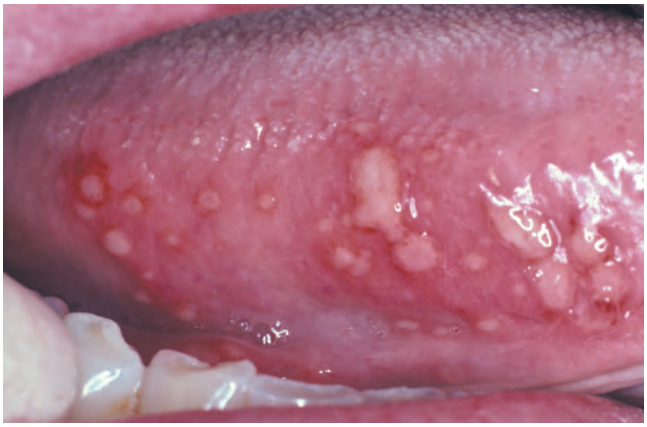
may be present at once, from one to five lesions typically are present during a single episode, and the pain often is out of proportion for the size of the ulceration. The buccal and labial mucosae are affected most frequently, followed by the ventral surface of the tongue, mucobuccal fold, floor of the mouth, and soft palate (Fig. 9.6). Involvement of keratinized mucosa (e.g., hard palate, gingiva, dorsal surface of the tongue, and vermilion border) is rare and usually represents extension from adjacent nonkeratinized epithelium.

Major Aphthous Stomatitis

Major aphthae are larger than minor aphthae and demonstrate the longest duration per episode. The ulcerations are deeper than the minor variant, measure from 1 to 3 cm in diameter, take from 2 to 6 weeks to heal, and may cause scarring (Fig. 9.7). The number of lesions varies from 1 to 10. Any oral surface area may be affected, but the labial mucosa, soft palate, and tonsillar fauces are involved most commonly (Fig. 9.8). The onset of major aphthae is after puberty, and recurrent episodes may continue to develop for up to 20 years or more. With time, the associated scarring can become significant, and in rare instances may lead to a restricted mouth opening.

• **Fig. 9.6 Minor Aphthous Stomatitis.** Single ulceration of the anterior buccal mucosa.

• **Fig. 9.7 Major Aphthous Stomatitis.** Large, deep, and irregular ulceration of the posterior buccal mucosa. Note extensive scarring of the anterior buccal mucosa from previous ulcerations.



Herpetiform Aphthous Stomatitis

Herpetiform aphthae demonstrate the greatest number of lesions and the most frequent recurrences. The individual lesions are small, averaging 1–3 mm in diameter, with as many as 100 ulcers present in a single recurrence. Because of their small size and large number, the lesions bear a superficial resemblance to a primary HSV infection, leading to the confusing designation, **herpetiform.** It is common for individual lesions to coalesce into larger irregular ulcerations (Fig. 9.9). The ulcerations heal within 7–10 days, but the recurrences tend to be closely spaced. Although the nonkeratinized, movable mucosa is affected most frequently, any oral mucosal surface may be involved. There is a female predominance, and typically the onset is in adulthood.

Further classification of all three types is valuable when planning the most appropriate diagnostic evaluation and therapy. The lesions are diagnosed as **simple aphthosis** when they appear in patients with few lesions that heal within 1–2 weeks and recur infrequently. In contrast, patients with **complex aphthosis** have multiple (three or more) and almost constant oral ulcerations that often develop as older lesions resolve. Severe pain and large size

• **Fig. 9.8 Major Aphthous Stomatitis.** Large, irregular ulceration of the soft palate.

• **Fig. 9.9 Herpetiform Aphthous Stomatitis.** Numerous pinhead ulcerations of the ventral surface of the tongue, several of which have coalesced into larger, more irregular areas of ulceration.

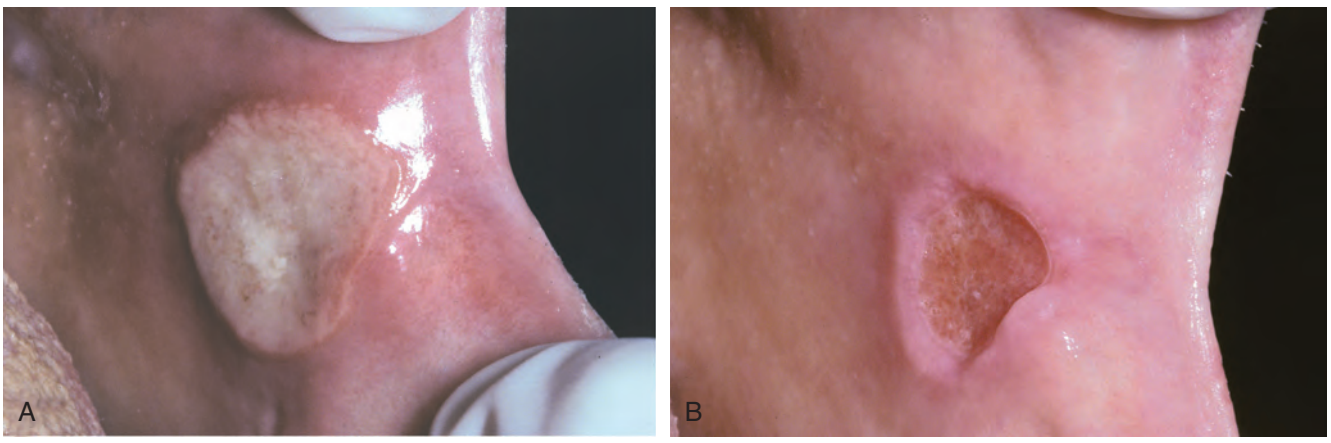
dentlearn.ir

are common. Although associated genital or perianal lesions also may be present, there is no other evidence of an associated systemic disease.

Histopathologic Features

The histopathologic picture of aphthous stomatitis is characteristic but not pathognomonic. The early ulcerative lesions demonstrate a central zone of ulceration, which is covered by a fibrinopurulent membrane. Deep to the area of ulceration, the connective tissue exhibits an increased vascularity and a mixed inflammatory cellular infiltrate that consists of lymphocytes, histiocytes, and polymorphonuclear leukocytes. The epithelium at the margin of the lesion demonstrates spongiosis and numerous mononuclear cells in the basilar one-third. A band of lymphocytes intermixed with histiocytes is present in the superficial connective tissue and surrounding deeper blood vessels.

Diagnosis



No laboratory procedure provides definitive diagnosis. The diagnosis is made from the clinical presentation and from exclusion of other diseases that produce ulcerations that closely resemble aphthae (see Box 9.1). In patients with complex aphthosis, a systematic evaluation for an underlying trigger or associated systemic condition is prudent. In a review of 244 patients with complex aphthosis, an associated triggering condition (e.g., hematologic deficiency, gastrointestinal disease, immunodeficiency, and drug reaction) was discovered in almost 60%. Because the histopathologic features are nonspecific, a biopsy is useful only in eliminating differential possibilities and is not beneficial in arriving at the definitive diagnosis.

Treatment and Prognosis

The patient's medical history should be reviewed for signs and symptoms of any systemic disorder that may be associated with aphthous-like ulcerations. Most patients with mild aphthosis receive either no treatment, therapy with several over-the-counter anesthetics or protective bioadhesive products, or periodic topical medicaments that minimize the frequency and severity of the attacks.

In patients with mild disease who fail or reject over-the-counter products, the mainstay of therapy is the use of topical corticosteroids, and the list of possible choices is long. Most patients with diffuse minor or herpetiform aphthae respond well to dexamethasone solution (0.5 mg/5 mL) used in a rinse-and-expectorate method. Patients with localized ulcerations can be treated successfully with 0.05% augmented betamethasone dipropionate gel or 0.05% fluocinonide gel. Adrenal suppression does not occur with appropriate use of these medications. Major aphthae are more resistant to therapy and often warrant more potent corticosteroids (Fig. 9.10). The individual lesions may be injected with triamcinolone acetonide or covered with 0.05% clobetasol propionate gel or 0.05% halobetasol propionate ointment. Triamcinolone tablets also can be dissolved directly over the lesions. In hard-to-reach areas, such as the tonsillar pillars, beclomethasone dipropionate aerosol spray can be used. In resistant cases, systemic corticosteroids may be required to supplement the topical medications and gain control. In such instances, prednisolone oral suspension in a swish-and-swallow method is preferable to prednisone tablets. In this way, the ulcerations receive both topical and systemic therapy.

An almost endless list of alternatives to corticosteroid agents has been used to treat patients suffering from aphthous stomatitis. Caution should be exercised, however, because many of these agents have not been examined in a double-blind, placebo-controlled fashion to assess the degree of effectiveness compared with placebo. Furthermore, some of these treatments may have significant side effects or may be quite expensive. Accepted topical alternatives include chlorhexidine, tetracycline oral suspension, and triclosan mouthrinse. In a Cochrane meta-analysis, no single systemic therapy was found to be effective in a wide variety of patients. Frequently mentioned systemic therapies include several

• **Fig. 9.10 Major Aphthous Stomatitis. A,** Large ulceration of the left anterior buccal mucosa. **B,** Same lesion after 5 days of therapy with betamethasone syrup used in a swish-and-swallow method. The patient was free of pain by the second day of therapy. The ulceration healed completely during the next week.

dentlearn.ir

immunomodulatory agents, such as azathioprine, colchicine, dapsone, levamisole, pentoxifylline, and thalidomide. A growing list of medications that inhibit inflammatory cytokines such as TNF-α have been shown to be effective against RAS but often demonstrate significant adverse reactions and associated high cost. Included in this list are apremilast, adalimumab, etanercept, infliximab, and golimumab, with these therapies often reserved for complex aphthosis that has failed numerous more conservative therapies.

Although laser ablation shortens the duration and decreases associated symptoms, its use is of very limited practical benefit because patients cannot return on each recurrence. Chemical cautery with silver nitrate continues to be suggested as an effective therapy, but it can no longer be recommended because of the numerous safer alternatives and its rare association with massive necrosis (see page 279) and systemic argyria (see page 305). A cautery that uses sulfuric acid and phenolic agents is indicated in certain situations but must be used with caution due to the potential for significant local tissue necrosis related to its misuse.

The success of these different therapeutic approaches is variable from patient to patient. In addition, these interventions do not resolve the underlying problem and are merely an attempt to "beat back brush fires." Recurrences often continue, although breaking up the cycle may induce longer disease-free intervals between attacks. Surgical removal of aphthous ulcerations has been used but is an inappropriate therapy.

Patients with complex aphthosis require a more extensive evaluation for occult systemic disease and a search for possible triggers of the immune-mediated mucosal destruction. To go beyond the management of individual recurrences is difficult, expensive, and often frustrating. Despite this, patients with severe disease should be offered the opportunity to investigate the underlying causes.

◆ BEHÇET DISEASE (BEHÇET SYNDROME; ADAMANTIADES SYNDROME; SILK ROAD DISEASE)

The combination of chronic ocular inflammation and orogenital ulcerations was reported as early as the era of the ancient Greeks and later described in 1931 by a Greek ophthalmologist, Benedict Adamantiades. The classic triad was not delineated until 1937, when a Turkish dermatologist, Hulusi Behçet, defined the disease that bears his name. Although the disease traditionally has been thought primarily to affect the oral, genital, and ocular regions, it now is recognized to be a systemic vasculitis that also may demonstrate cutaneous, articular, vascular, gastrointestinal, and neurologic involvement.

Although no clear causation has been established, **Behçet disease** appears to represent an abnormal immune process triggered by an infectious or environmental antigen in a genetically predisposed individual. Investigators have correlated attacks to several environmental agents, including bacteria (especially streptococci), viruses (especially herpes simplex virus 1), pesticides, and heavy metals. Interestingly, reduction of oral bacterial load via periodontal therapy has been shown to reduce the prevalence of associated oral ulcerations in patients with Behçet disease. It is thought that antigens of some microorganisms exhibit a high homology with human proteins resulting in a cross-reaction that leads to the autoinflammatory response. Although the exact immune reactions have not been defined, T cells, neutrophils, and antigen-presenting cells appear to be involved significantly. Antigen-presenting cells are thought to trigger neutrophilic hyperactivity followed by stimulation of T helper cells with several cytokines released from neutrophils.

Histocompatibility antigen B-51 (HLA-B51) has been linked closely to Behçet disease, and the frequency of both the disease and this haplotype is high in Turkey, Japan, and the Eastern Mediterranean countries. This distribution appears correlated to the ancient trading route known as the "Silk Road" that extended from Japan to Rome and was traveled by the Turks. Sexual reproduction between immigrants and locals along the route appears to have spread the genetic vulnerability. Interestingly, when predisposed populations migrate to nonendemic locations, the prevalence decreases, suggesting environmental factors also are involved.

Clinical Features

Behçet disease is uncommon in blacks and usually arises in the third and fourth decades with the disease rarely presenting before puberty or beyond the age of 50. Men exhibit a slightly increased prevalence and tend to have a worse clinical course.

Virtually all affected patients demonstrate oral ulcerations that often herald the onset of the more generalized disease process. Other less frequently associated features in order of prevalence include genital ulcerations, cutaneous lesions, arthritis, uveitis, thrombophlebitis, gastrointestinal manifestations, and central nervous system (CNS) involvement.

The oral lesions are similar to aphthae occurring in otherwise healthy individuals and demonstrate the same duration and frequency. The individual lesions vary in size and are surrounded by a larger zone of diffuse erythema (Fig. 9.11). All three forms of oral aphthous stomatitis may be seen. Although most affected patients have lesions that resemble minor aphthae, some reports have documented a prevalence of major aphthae that approaches 40% in patients affected with Behçet disease. The herpetiform variant remains uncommon and is noted in approximately 3%. Although the lesions closely resemble conventional aphthae, the ulcerations in Behçet disease often are increased in number and frequently involve the soft palate and oropharynx.

The genital lesions occur in 75% of the patients. In males, approximately 90% of the lesions involve the scrotum, whereas those in females are most frequent on the vulva, vagina, or uterine cervix. Perineal, perianal, and groin involvement is seen in both genders (Fig. 9.12). These

dentlearn.ir

• **Fig. 9.11 Behçet Syndrome.** Diffuse erythema surrounding numerous irregular ulcerations of the soft palate.

• **Fig. 9.12 Behçet Syndrome.** Numerous irregular ulcerations of the labia majora and perineum. (From Helm TN, Camisa C, Allen C, et al: Clinical features of Behçet's disease, *Oral Surg Oral Med Oral Pathol* 72:30, 1991.)

lesions recur less frequently than do the oral ulcerations, but they are deeper and tend to heal with scarring.

Common cutaneous lesions include erythema nodosum-like alterations, papulopustular lesions, pseudofolliculitis, and acneiform nodules. From a diagnostic standpoint, one of the most important skin manifestations is the presence of positive "pathergy." One or 2 days after the oblique insertion of a 20-gauge or smaller needle under sterile conditions, a tuberculin-like skin reaction or sterile pustule develops (Fig. 9.13). Positive pathergy is geographically variable with a prevalence of 60% in Middle Eastern patients but seen in only approximately 3% of affected Caucasian patients.

Arthritis is one of the more common minor manifestations of the disease and usually is self-limiting and

• **Fig. 9.13 Behçet Syndrome.** Sterile pustule of the skin that developed 1 day after injection of saline. This reaction is termed *cutaneous pathergy.*

nondeforming. The knees, wrists, elbows, and ankles are affected most frequently.

Ocular involvement occurs in up to 70% of the cases and is more frequent and severe in males. The most common findings are posterior uveitis, conjunctivitis, corneal ulceration, papilledema, and arteritis. The most common secondary ocular complications are cataracts, glaucoma, and neovascularization of the iris and retina. Despite therapy, blindness occurs in 25% of patients with ocular involvement.

Although the vascular disease may involve arteries, veins are affected more frequently and present as superficial and deep thrombophlebitis. The thrombi tend to be adherent to the diseased veins without a tendency toward embolism. Behçet disease is a variable vessel vasculitis because it can affect vessels of any size with involvement of both the venous and arterial systems.

Gastrointestinal disease is variable and includes abdominal pain, anorexia, diarrhea, dyspepsia, and vomiting. CNS involvement is not common but, when present, is associated with a poor prognosis. From 10% to 25% of the patients demonstrate CNS involvement, and the alterations produced result in several changes that include paralysis and severe dementia.

Diagnosis

No laboratory finding is diagnostic of Behçet disease. To standardize diagnoses, definitive criteria have been developed. Table 9.1 delineates the requirements proposed by the Behçet International Study Group (ISG). Diagnostic criteria also were proposed by the International Criteria for Behçet Disease (ICBD Criteria). In this system, oral ulcerations, genital ulcerations, and ocular involvement are assigned 2 points for each site. Additional areas of involvement (cutaneous, articular, vascular, GI, CNS) are given 1 point. Patient involvement scoring 4 points or more is diagnosed as Behçet Disease. The ICBD criteria appear to be more sensitive but less specific than the ISG system and are thought possibly to be associated with overdiagnosis in some patients.

dentlearn.ir

TABLE 9.1 International Study Group Criteria for the Diagnosis of Behçet Disease

Criteria	Description
Recurrent oral ulceration	Minor, major, or herpetiform aphthae
Plus two of the following:	
Recurrent genital ulcerations	Aphthae-like ulcerations
Eye lesions	Anterior or posterior uveitis, cells in vitreous on slit-lamp examination, or retinal vasculitis
Skin lesions	Erythema nodosum, pseudofolliculitis or papulopustular lesions, or acneiform nodules noted in postadolescent patients not receiving corticosteroids
Positive pathergy test	Read by physician at 24–48 hours

Histopathologic Features

The histopathologic features are not specific for Behçet disease and can be seen in many disorders, including aphthous stomatitis. The pattern most frequently seen is called *leukocytoclastic vasculitis*. The ulceration is similar in appearance to that seen in aphthous stomatitis, but the small blood vessels classically demonstrate intramural invasion by neutrophils, karyorrhexis of neutrophils, extravasation of red blood cells, and fibrinoid necrosis of the vessel wall.

Treatment and Prognosis

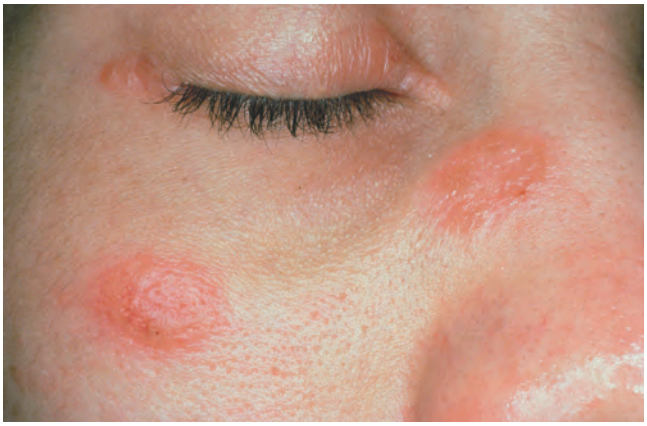
Therapy is tailored to the disease severity and prognostic factors. Many patients are treated symptomatically, with the disease often going into remission as the patient ages. Females and older patients have a better prognosis than males or young patients. Ocular lesions and CNS involvement are associated with significant morbidity and mandate more aggressive therapy. Occasional disease-related mortality is noted and usually is associated with major vessel disease or central nervous system involvement.

The therapeutic regimens vary widely, depending on the involved sites and severity of disease. The oral lesions often respond to topical corticosteroids. Initial systemic treatment for mucocutaneous involvement is colchicine, with azathioprine, interferon (IFN) blockers and tumor necrosis factor (TNF) inhibitors suggested for refractory lesions. For patients who have ocular involvement, azathioprine and systemic steroids are first line therapies, and refractory cases are managed with cyclosporine, IFN blockers, and TNF inhibitors. Major vessel involvement is treated with immunosuppressive agents such as systemic steroids, azathioprine, cyclophosphamide, or cyclosporine. Methotrexate, IFN blockers, and TNF inhibitors are utilized in resistant cases. Gastrointestinal ulcerations are treated with 5-aminosalicylic acid with or without corticosteroids. Alternative therapy for refractory GI disease includes azathioprine, thalidomide, and TNF inhibitors. Neurologic involvement is treated with systemic corticosteroids and azathioprine with mycophenolate mofetil, methotrexate, and cyclophosphamide reserved for refractory cases.

In the future, wider use of a variety of biological treatments is expected in patients not responding to the current standard of care. These biologics include monoclonal antibodies against CD20, a growing list of tumor necrosis factor inhibitors, and many blocking agents directed against interleukins.

Behçet disease has a highly variable course. A relapsing and remitting pattern is typical, with attacks becoming more intermittent after 5–7 years. In the absence of CNS disease or significant vascular complications, the prognosis generally is good.

SARCOIDOSIS



Sarcoidosis is a multisystem granulomatous disorder of unknown cause. Jonathan Hutchinson initially described the disease in 1875, but Boeck coined the term *sarcoidosis* (Greek meaning "flesh-like condition") 14 years later. The evidence implicates improper degradation of antigenic material with the formation of noncaseating granulomatous inflammation. The nature of the antigen is unknown, and probably several different antigens may be responsible. Possible involved antigens include infectious agents (e.g., mycobacterium, propionibacteria, Epstein-Barr virus, human herpesvirus 8 [HHV-8]), and several environmental factors (e.g., wood dust, pollen, clay, mold, and silica). Several investigators have confirmed a genetic predisposition and positive associations with certain HLA types.

Clinical Features

Sarcoidosis has a worldwide distribution with an increased prevalence in females and blacks. The process demonstrates a bimodal age distribution with one peak in young adults and another around 60 years of age. The disease may present acutely or demonstrate a chronic course with periods of remission and exacerbation. Acute cases often exhibit fever, fatigue, anorexia, or weight loss combined with other manifestations, such as respiratory symptoms, polyarthritis, visual problems, and skin lesions. In chronic cases, pulmonary symptoms are common and include dry cough, dyspnea, and chest discomfort. Approximately 20% of patients have no symptoms, and the disease is discovered on routine chest radiographs.

Although any organ may be affected, the lungs, lymph nodes, skin, eyes, and salivary glands are the predominant sites. Lymphoid tissue is involved in almost all cases. The mediastinal and paratracheal lymph nodes are involved commonly, and chest radiographs frequently reveal bilateral hilar

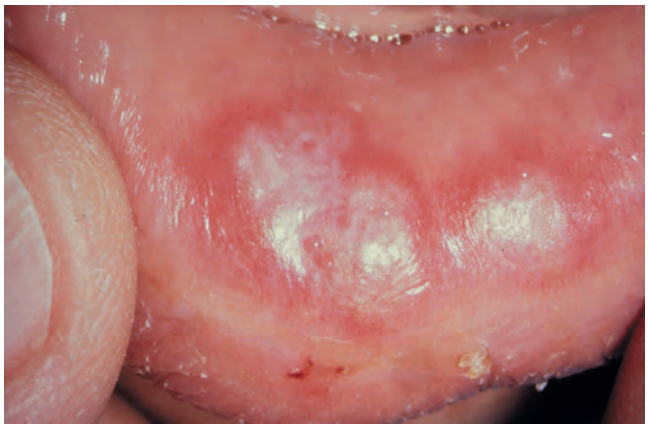
• **Fig. 9.15 Sarcoidosis.** Multiple erythematous macules of the hard palate. (Courtesy of Dr. George Blozis.)



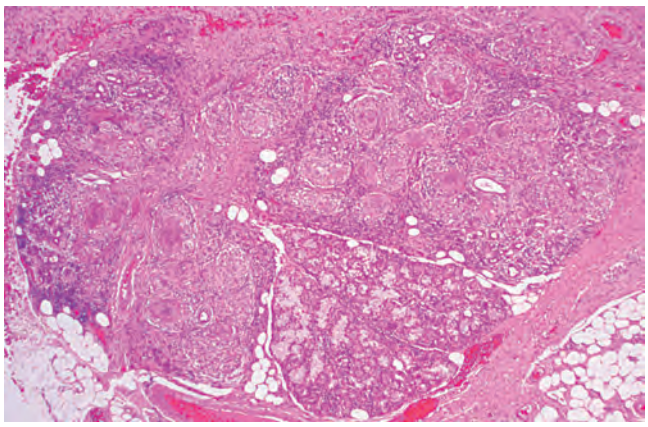
lymphadenopathy. Approximately 90% of affected patients will reveal an abnormal chest radiograph sometime during the course of the disease. Cutaneous manifestations occur about 25% of the time. These often appear as chronic, violaceous, indurated lesions that are termed **lupus pernio** and frequent the nose, ears, lips, and face (Fig. 9.14). Scattered, nonspecific, tender erythematous nodules, known as **erythema nodosum,** frequently occur on the lower legs.

Ocular involvement is noted in 25% of the cases and most often appears as anterior uveitis. Lesions of the conjunctiva and retina may occur. Involvement of the lacrimal glands often produces keratoconjunctivitis sicca; the salivary glands can be altered similarly, with resultant clinical enlargement and xerostomia. The salivary gland enlargement, xerostomia, and keratoconjunctivitis sicca can combine to mimic Sjögren syndrome (see page 472).

Although lymphoid, pulmonary, cutaneous, and ocular lesions are most common, virtually any organ system may be affected. Other potential sites include the endocrine system, gastrointestinal tract, heart, kidneys, liver, nervous system, and spleen. Intraosseous lesions may occur and most commonly involve the phalanges, metacarpals, and metatarsals. Less frequently, the skull, nasal bones, ribs, and vertebrae are affected.

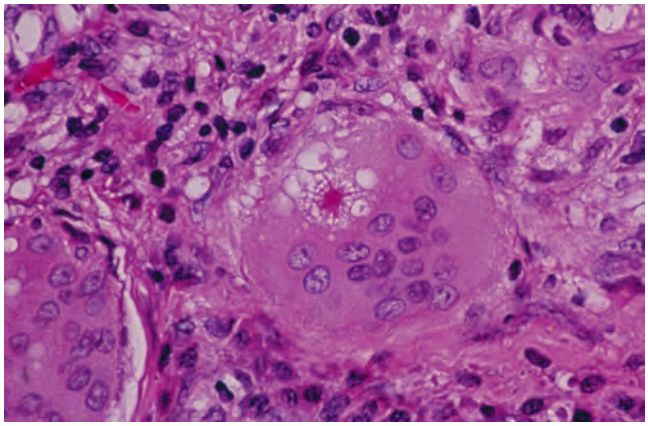
Two distinctive clinical syndromes are associated with acute sarcoidosis. **Löfgren syndrome** consists of erythema nodosum, bilateral hilar lymphadenopathy, and arthralgia. Patients with **Heerfordt syndrome (uveoparotid fever)** have parotid enlargement, anterior uveitis of the eye, facial paralysis, and fever.

If salivary gland and lymph node involvement are excluded, clinically evident oral manifestations in sarcoidosis are uncommon. Any oral mucosal site can be affected, most often appearing as a submucosal mass, an isolated papule, an area of granularity, or ulceration. The mucosal lesions may be normal in color, brown-red, violaceous, or hyperkeratotic (Figs. 9.15 and 9.16). The most frequently affected intraoral soft tissue site is the buccal mucosa, followed by the gingiva, lips, tongue, and palate. Lesions of the floor of the mouth occur but usually are secondary to



• **Fig. 9.16 Sarcoidosis.** Erythematous macules with central hyperkeratosis of the lower labial mucosa.

salivary gland involvement. Intraosseous lesions affect either jaw and represent approximately one-fourth of all reported intraoral cases. Of these cases, most appeared as ill-defined radiolucencies that occasionally eroded the cortex but never created expansion. In the previously reported intraoral cases, most patients demonstrated multisystem involvement, but the oral lesion was the initial manifestation in two-thirds of the patients.



Histopathologic Features

Microscopic examination of sarcoidosis exhibits a classic picture of granulomatous inflammation. Tightly clustered aggregates of epithelioid histiocytes are present, with a surrounding rim of lymphocytes. Intermixed with the histiocytes are scattered Langhans' or foreign body type giant cells (Fig. 9.17). The granulomas often contain laminated basophilic calcifications, known as **Schaumann bodies** (degenerated lysosomes), or stellate inclusions, known as **asteroid bodies** (entrapped fragments of collagen) (Fig. 9.18). None of these structures are specific for sarcoidosis. Special stains for fungal and bacterial organisms are negative. No polarizable, dissolvable, or pigmented foreign material can be detected.

• **Fig. 9.18 Sarcoidosis.** Photomicrograph illustrating multinucleated giant cell with intracytoplasmic asteroid body.

Diagnosis

The diagnosis is established by the clinical and radiographic presentations, the histopathologic appearance, and the presence of negative findings with both special stains and cultures for organisms. Elevated serum angiotensin-converting enzyme (ACE) levels and appropriate documentation of pulmonary involvement strongly support the diagnosis. Despite this, elevated ACE is reported in only 60% of patients with sarcoidosis and in a minority of those with oral involvement. Other laboratory abnormalities that may be seen include eosinophilia; leukopenia; anemia; thrombocytopenia; and elevation of the serum alkaline phosphatase level, erythrocyte sedimentation rate, serum calcium concentration, and urinary calcium level.

In the past, a skin test for sarcoidosis, the **Kveim test,** was performed by intradermal injection of a sterilized suspension of human sarcoid tissue. However, this procedure is no longer used because of difficulty in obtaining material for the test, concern related to its accuracy, and the inability to guarantee the absence of contamination (e.g., prions) in this human tissue.

Minor salivary gland biopsy has been promoted as a diagnostic aid in suspected cases of sarcoidosis (see Fig. 9.17) but is less effective than a parotid biopsy. Previously, biopsy of the parotid was avoided because of the fear of salivary fistula formation and damage to the facial nerve. These concerns have been reduced through biopsy of the posterior superficial lobe of the parotid gland, and confirmation of sarcoidosis has been reported in 93% of patients from this procedure.

Treatment and Prognosis

In approximately 60% of patients with sarcoidosis, the symptoms resolve spontaneously within 2 years without treatment. Most initial diagnoses are followed by a 3- to 12-month period of observation to define the general course of the disease. Active intervention is recommended for progressive disease and patients with cardiac or neurologic involvement, hypercalcemia, disfiguring skin disease, or serious ocular lesions that do not respond to local therapy. In patients requiring treatment, corticosteroids remain first-line therapy, but resistance and relapses are common. Medications used in patients with refractory disease include methotrexate, azathioprine, chlorambucil, chloroquine, and cyclophosphamide. Several studies have shown promising results with TNF-α antagonists such as etanercept, infliximab, pentoxifylline, and thalidomide. In 10%–20% of those affected by sarcoidosis, resolution does not occur even with treatment. Approximately 4%–10% of patients die of pulmonary, cardiac, or CNS complications.

◆ OROFACIAL GRANULOMATOSIS

Since Wiesenfeld introduced it 1985, **orofacial granulomatosis** has become a well-accepted and unifying term encompassing a variety of clinical presentations that, on biopsy, reveal the presence of nonspecific granulomatous inflammation.

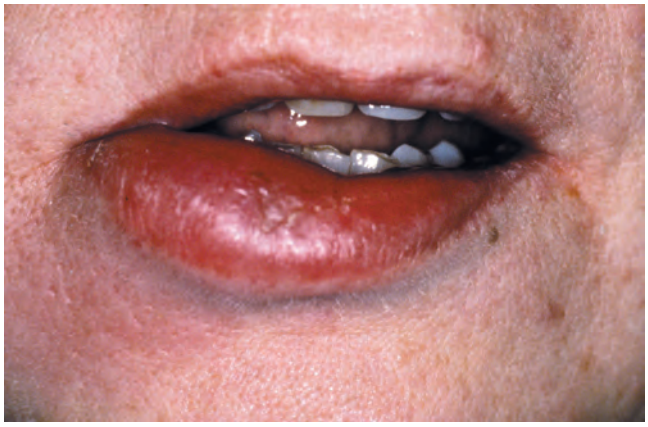
The disorder is idiopathic but appears to represent an abnormal immune reaction to a variety of inciting agents. In addition, similar lesions can be seen in association with several systemic diseases. Table 9.2 delineates systemic diseases that may mimic orofacial granulomatosis, and Table 9.3 lists several additional possible triggers.

Clinical Features

The clinical presentation of orofacial granulomatosis is highly variable. Most patients are adults; however, the process may occur at any age. By far, the most frequent site of involvement is the lips. The labial tissues demonstrate a nontender, persistent swelling that may involve one or both lips (Fig. 9.19). When these signs are combined with facial paralysis and a fissured tongue, the clinical presentation is called **Melkersson-Rosenthal syndrome** (Figs. 9.20 and 9.21). Involvement of the lips alone is called **cheilitis granulomatosa (of Miescher).** Neither of these two clinical

dentlearn.ir

TABLE 9.2 Systemic Evaluation of Patients With Orofacial Granulomatosis



Systemic Cause	Preliminary Screening Procedure
Systemic drug reaction	Review medications, such as checkpoint inhibitors, highly active antiretroviral therapy, interferons, and tumor necrosis factor-α antagonists, which have been shown to trigger a sarcoid-like reaction
Chronic granulomatous disease	Neutrophil nitroblue tetrazolium reduction test (perform if medical history of chronic infections is noted)
Crohn disease	Hematologic evaluation for evidence of gastrointestinal malabsorption (e.g., low albumin, calcium, folate, iron, and red blood cell count; elevated erythrocyte sedimentation rate), serum IgA antibodies to *Saccharomyces cerevisiae*, leukocyte scintigraphy using ^{99m}Tc-HMPAO (hexamethyl propylene amine oxime), and fecal calprotectin; if initial screen is positive, then recommend esophagogastroduodenoscopy, ileocolonoscopy, and small-bowel radiographs
Sarcoidosis	Serum angiotensin–converting enzyme and chest radiograph (hilar lymphadenopathy)
Tuberculosis	Skin test and chest radiograph (negative acid-fast bacteria [AFB] stain on biopsy specimen does not rule out mycobacterial infection)

TABLE 9.3 Interventions to Rule Out Local Causes for Orofacial Granulomatosis

Local Cause	Intervention
Chronic oral infection	Eliminate all oral foci of infection.
Foreign material	The debris noted in foreign body gingivitis often is subtle and difficult to associate definitively with the diffuse inflammatory process. If lesions are nonmigrating and isolated to gingiva, then response to local excision of a single focus should be evaluated.
Allergy	Cosmetics, foods and food additives (aspartate, benzoate, carbone piperitone, carmoisine, carvone, chocolates, cinnamon, cocoa, dairy products, eggs, monosodium glutamate, peanuts, sun yellow dye, tartrazine, and wheat) flavorings, oral hygiene products (e.g., toothpaste and mouth rinses), and dental restorative metals have been implicated. Patch testing (i.e., contact dermatitis standard series with oral battery) or elimination diet may discover the offending antigen.

• **Fig. 9.19 Orofacial Granulomatosis (Cheilitis Granulomatosa).** Nontender, persistent enlargement of the upper lip. (From Allen CM, Camisa C: Diseases of the mouth and lips. In Sams WM, Lynch P, editors: *Principles of dermatology,* New York, 1990, Churchill Livingstone.)

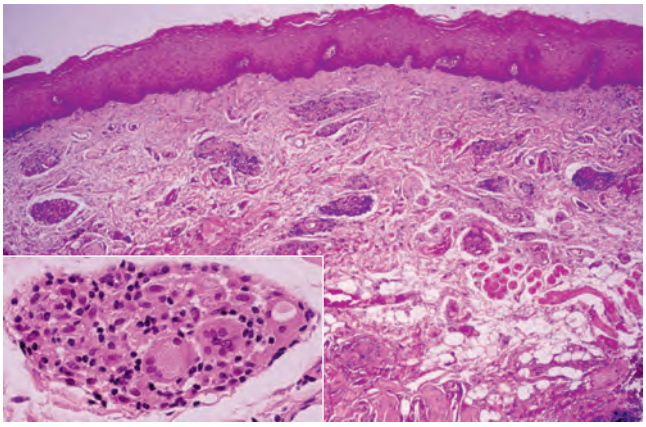
• **Fig. 9.20 Orofacial Granulomatosis (Melkersson-Rosenthal Syndrome).** Persistent enlargement of the lower lip. (Courtesy of Dr. Richard Ziegler.)

presentations represents a specific disease, and it appears best to include both under the term *orofacial granulomatosis.*

Intraoral sites also can be affected, and the predominant lesions are edema, ulcers, and papules. The tongue may develop fissures, edema, paresthesia, erosions, or taste alteration. The gingiva can develop swelling, erythema, pain, or erosions. The buccal mucosa often exhibits a cobblestone appearance of edematous mucosa or focal areas of submucosal enlargement. Linear hyperplastic folds may occur in the sulcus, often with elongated ulcerations in

dentlearn.ir

• **Fig. 9.21 Orofacial Granulomatosis (Melkersson-Rosenthal Syndrome).** Same patient as depicted in Fig. 9.20. Note numerous furrows on the dorsal surface of the tongue. (Courtesy of Dr. Richard Ziegler.)



• **Fig. 9.22 Orofacial Granulomatosis.** Hyperplastic mucosa noted bilaterally in the mandibular mucobuccal fold. (Courtesy of Dr. Steven A. Anderson.)

the base of these folds (Fig. 9.22). The palate may have papules or large areas of hyperplastic tissue. Hyposalivation rarely is reported.

Histopathologic Features

In classic cases of cheilitis granulomatosa, edema is present in the superficial lamina propria with dilation of lymphatic vessels and scattered lymphocytes seen diffusely and in clusters. Fibrosis may be present in long-term lesions. Scattered aggregates of noncaseating granulomatous inflammation, consisting of lymphocytes and epithelioid histiocytes, are present,

• **Fig. 9.23 Orofacial Granulomatosis.** Clusters of granulomatous inflammation around scattered vessels. The inset illustrates the histiocytes and multinucleated giant cells within the granulomas.

with or without multinucleated giant cells. Typically, the granulomas appear to cluster around scattered vessels and are not as well formed or discrete as those seen in sarcoidosis (Fig. 9.23).

Special stains for fungal organisms and acid-fast bacteria are negative. No dissolvable, pigmented, or polarizable foreign material should be present. When the lesions are confined to the gingiva, a thorough histopathologic evaluation search should be performed, because many cases of foreign body gingivitis are due to subtle collections of foreign material (see page 154).

Diagnosis

The initial diagnosis of orofacial granulomatosis is made on histopathologic demonstration of granulomatous inflammation that is associated with negative special stains for organisms and no foreign material. Because clinical and histopathologic features of orofacial granulomatosis can be produced by a variety of underlying causes, this diagnosis is the beginning, not the end, of the patient's evaluation. Prior to administering any medication or considering surgical intervention, the patient should be evaluated for the systemic diseases and local processes (see Tables 9.2 and 9.3) that may be responsible for similar oral lesions. If features diagnostic of one of these more specific disorders are discovered, then the oral lesions presumably would be related to that disease. If a specific diagnosis cannot be made, then potential foci of infection should be eliminated. If no resolution is noted after reducing local inflammatory factors, then referral of the patient for allergy testing should be considered.

Patients ultimately discovered to have Crohn disease often present at a younger age and have less lip swelling, although lesions of the buccal vestibule are more likely. Because gastrointestinal involvement has been discovered in up to 60% of patients with orofacial granulomatosis who have no intestinal symptoms, several investigators have suggested thorough gastrointestinal evaluation of all children and

dentlearn.ir

young adults presenting with orofacial granulomatosis. Conversely, others suggest evaluation for serum IgA antibodies to *Saccharomyces cerevisiae* and fecal calprotectin to assist in choosing those patients without intestinal symptoms who require further gastrointestinal evaluation.

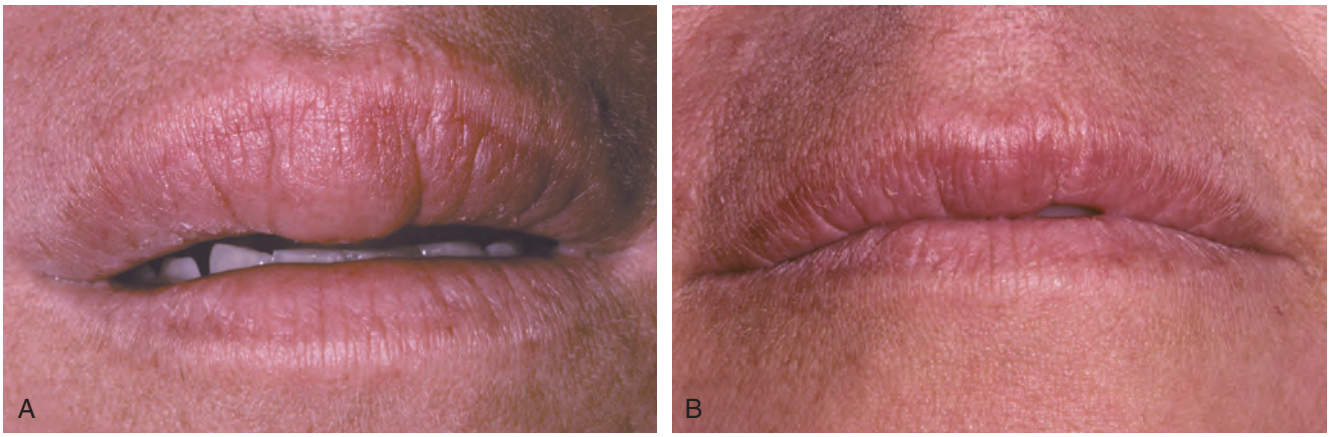
The worldwide prevalence of allergy is estimated to be 15%–20%, whereas the frequency noted in patients with orofacial granulomatosis is up to 80% in several studies. Although allergy testing has been useful in many patients, diet restriction has been successful irrespective of patch test results in occasional individuals. Several investigators have suggested a cinnamon- and benzoate-free diet in all patients in whom an obvious trigger cannot be found.

Treatment and Prognosis

The first goal of management should be discovery of the initiating cause, although this may be difficult because the trigger often is elusive.

Oral lesions have been treated with a variety of interventions, with variable results. Topical or intralesional corticosteroids, topical tacrolimus, radiotherapy, sulfasalazine, hydroxychloroquine sulfate, azathioprine, cyclosporine A, methotrexate, danazol, dapsone, TNF-α antagonists (adalimumab, infliximab, and thalidomide), 5-aminosalicylic acid, clofazimine, metronidazole, and numerous other antibiotics have been tried. Currently, most investigators administer intralesional delayed-release high-concentrate triamcinolone to control the progression of this disease (Figs. 9.24 and 9.25). In those who have failed intralesional triamcinolone, a small number of reports have documented subsequent success with low-level laser therapy. In refractory cases, surgical recontouring has been used by some but carries a considerable risk of recurrence and rarely appears to be warranted.

The primary concern in affected patients is the cosmetically objectionable appearance, with the response to treatment being highly variable. No therapy has proved to be the "silver bullet" in resolving the individual lesions. In some cases, lesions resolve spontaneously, with or without therapy; in others, they continue to progress despite a myriad of therapeutic attempts to stop the progression.



◆ GRANULOMATOSIS WITH POLYANGIITIS (WEGENER GRANULOMATOSIS)

Granulomatosis with polyangiitis is a well-recognized, although uncommon, disease process of unknown cause that was described initially in the German literature by Friedrich Wegener in 1936. The disorder has been termed **Wegener granulomatosis** until being renamed after discovery of Dr. Wegener's membership in a violent paramilitary branch of the Nazi party and his extensive activities in Jewish concentrations camps during the war. The disorder includes necrotizing granulomatous lesions of the respiratory tract, necrotizing glomerulonephritis, and systemic vasculitis of small arteries and veins. The pathogenesis of the disease is unknown but may be due to an abnormal immune reaction to an infectious, environmental, chemical, toxic, or pharmacological trigger in genetically predisposed individual.

Clinical Features

Granulomatosis with polyangiitis demonstrates a wide age range from childhood to old age, with a mean of age of 41 years and no sex predilection. Although most frequently presenting in adults, approximately 15% of the cases arise prior to age 20. A prevalence of 3 out of 100,000 has been reported, and 90% of the cases arise in Caucasians. The disease can involve almost every organ system in the body. With classic Wegener granulomatosis, patients initially show involvement of the upper and lower respiratory tract; if the condition remains untreated, then renal involvement often rapidly develops **(generalized Wegener granulomatosis).**

Limited Wegener granulomatosis is diagnosed when there is involvement of the respiratory system without rapid development of renal lesions. One subset of patients exhibits

• **Fig. 9.24 Orofacial Granulomatosis. A,** Diffuse enlargement of the upper lip. **B,** Same patient after intralesional triamcinolone injections.

dentlearn.ir

• **Fig. 9.25 Orofacial Granulomatosis.** Same patient depicted in Fig. 9.24. **A,** Clinical appearance before local therapy. **B,** Significant resolution after intralesional corticosteroid therapy.

lesions primarily of the skin and mucosa, a condition termed **superficial Wegener granulomatosis.** In this form of the disease, systemic involvement develops slowly. These three different clinical patterns highlight the variability of the clinical aggressiveness that can occur in patients with granulomatosis with polyangiitis.

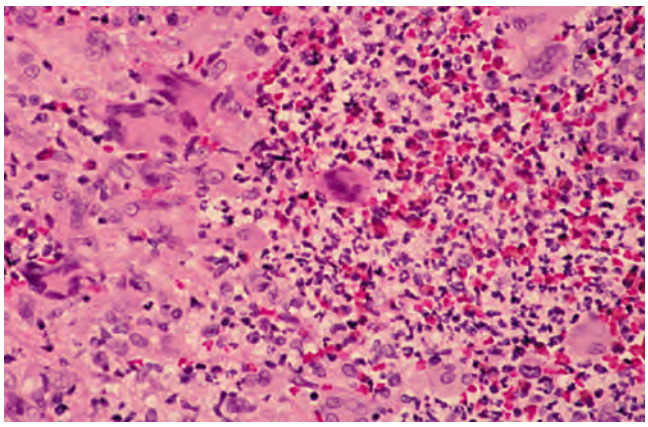
Purulent nasal drainage, chronic sinus pain, nasal ulceration, congestion, and fever are frequent findings from upper respiratory tract involvement. Persistent otitis media, sore throat, and epistaxis also are reported. With progression, destruction of the nasal septum can result in a saddle-nose deformity. Patients with lower respiratory tract involvement may be asymptomatic, or they may have dry cough, hemoptysis, dyspnea, or chest pain. Renal involvement usually occurs late in the disease process and is the most frequent cause of death. The glomerulonephritis results in proteinuria and red blood cell casts. Occasionally, the eyes, ears, and skin also are involved.

The reported prevalence of oral lesions varies widely with oral involvement representing the initial presentation in 2% of affected patients. The most characteristic oral manifestation is **strawberry gingivitis.** This distinctive but uncommon pattern of gingival alteration appears to be an early manifestation of Wegener granulomatosis and has been documented before renal involvement in most cases. The affected gingiva demonstrates a florid and granular hyperplasia. The surface forms numerous short bulbous projections, which are hemorrhagic and friable; this red, bumpy surface is responsible for the strawberry-like

• **Fig. 9.26 Granulomatosis with Polyangiitis.** Hemorrhagic and friable gingiva (strawberry gingivitis). (Courtesy of Dr. Sam McKenna.)

appearance (Figs. 9.26 and 9.27). On occasion, scattered yellow papules correlating to subepithelial neutrophilic pustules may be noted intermixed with the hemorrhagic and hyperplastic gingiva. At the time of diagnosis, the involvement may be localized or generalized to multiple quadrants.

Oral ulceration also may be a manifestation of Wegener granulomatosis. These lesions are clinically nonspecific and may occur on any mucosal surface (Fig. 9.28). In contrast to the gingival changes, the oral ulcerations are diagnosed at a later stage of the disease, with more than 60% of the affected patients demonstrating renal involvement. Other less common orofacial manifestations include facial paralysis,



dentlearn.ir

• **Fig. 9.28 Granulomatosis with Polyangiitis.** Deep, irregular ulceration of the hard palate on the left side. (From Allen CM, Camisa C, Salewski C, et al: Wegener's granulomatosis: report of three cases with oral lesions, *J Oral Maxillofac Surg* 49:294–298, 1991.)

• **Fig. 9.29 Granulomatosis with Polyangiitis.** Connective tissue containing proliferation of numerous vascular channels and a heavy inflammatory infiltrate consisting of lymphocytes, neutrophils, eosinophils, and multinucleated giant cells.

• **Fig. 9.30 Granulomatosis with Polyangiitis.** Gingival biopsy specimen showing a mixed inflammatory cellular infiltrate obscured by extensive extravasation of red blood cells.

labial mucosal nodules, sinusitis-related toothache, arthralgia of the temporomandibular joint (TMJ), jaw claudication, palatal ulceration from nasal extension, oral-antral fistulae, and poorly healing extraction sites.

Enlargement of one or more major salivary glands from primary involvement of the granulomatous process also has been reported. The glandular involvement also appears early in the course of the disease and may lead to early diagnosis and treatment.

Histopathologic Features

Granulomatosis with polyangiitis appears as a pattern of mixed inflammation centered around blood vessels. Involved vessels demonstrate transmural inflammation, often with areas of heavy neutrophilic infiltration, necrosis, and nuclear dust (leukocytoclastic vasculitis). The connective tissue adjacent to the vessel has an inflammatory cellular infiltrate, which contains a variable mixture of histiocytes, lymphocytes, eosinophils, and multinucleated giant cells (Fig. 9.29). Special stains for organisms are negative, and no foreign material can be found. In oral biopsy specimens, the mucosa may demonstrate pseudoepitheliomatous hyperplasia and subepithelial abscesses. Because of the paucity of large vessels in many oral mucosal biopsies, vasculitis may be difficult to demonstrate, and the histopathologic presentation may be one of ill-defined collections of epithelioid histiocytes intermixed with eosinophils, lymphocytes, and multinucleated giant cells. In addition, the lesions of strawberry gingivitis typically demonstrate prominent vascularity with extensive red blood cell extravasation (Fig. 9.30).

Diagnosis

The diagnosis of granulomatosis with polyangiitis is made from the combination of the clinical presentation and the microscopic finding of necrotizing and granulomatous vasculitis. The American College of Rheumatology proposed four diagnostic criteria with a minimum of two required for the diagnosis (Box 9.2). Radiographic evaluation of the chest and sinuses is recommended to document possible involvement of these areas. The serum creatinine and urinalysis results are used to rule out significant renal alterations.

dentlearn.ir

• BOX 9.2 American College of Rheumatology Criteria for Diagnosis of Granulomatosis With Polyangiitis

- Oral ulcerations or nasal discharge
- Nodules, fixed infiltrates, or cavities on chest radiograph
- Abnormal urinary sediment (red blood cell casts or more than five red blood cells/high power field)
- Granulomatous inflammation upon biopsy

Detection of antineutrophil cytoplasmic antibodies (ANCA) has proven to be an important laboratory marker for granulomatosis with polyangiitis and is performed by immunofluorescence and enzyme-linked immunosorbent assay (ELISA). Indirect immunofluorescence for ANCA reveals two patterns, cytoplasmic reactivity termed c-ANCA and perinuclear reactivity termed p-ANCA, which correlate respectively to antibodies directed against serine proteinase 3, (PR3-ANCA) and myeloperoxidase (MPO-ANCA). Serine proteinase 3 is a component of neutrophilic azurophilic cytoplasmic granules, whereas myeloperoxidase is present in neutrophilic lysosomal granules.

PR3-ANCA is most useful in the diagnosis of Wegener granulomatosis and is seen in approximately 85% of generalized Wegener granulomatosis and 60% of the early or localized cases. Immunofluorescence for ANCA should be ordered along with the specific enzyme-linked immunosorbent assay (ELISA) test for antibodies against proteinase 3 (PR3). These combined tests are associated with a sensitivity of 73% and a diagnostic specificity of 99% for Wegener granulomatosis. In contrast, MPO-ANCAs are detected in several vasculitides that typically do not present in the oral cavity and are positive in only 10% of patients with Wegener granulomatosis. False positives are uncommon and may be associated with a variety of other diseases. As mentioned in Chapter 8 (see page 292), a cocaine-induced midline destructive lesion (CIMDL) can be confused with Wegener granulomatosis due to similarities in the histopathologic findings and frequent positivity of PR3-ANCA. Although nasal involvement is common in Wegener granulomatosis, palatal perforation is rare. In addition, CIMDL often demonstrates antineutrophil cytoplasmic antibodies against human neutrophil elastase, a finding not seen in Wegener granulomatosis.

Treatment and Prognosis

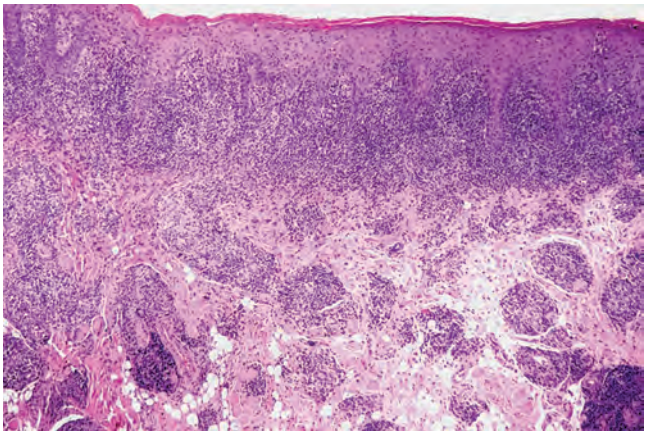
The mean survival of untreated patients with disseminated classic granulomatosis with polyangiitis is 5 months; 80% of the patients are dead at 1 year and 90% within 2 years. The prognosis is better for the limited and superficial forms of the disease, although a proportion of patients with localized disease eventually will develop classic Wegener granulomatosis.

Treatment of granulomatosis with polyangiitis typically involves induction phase chemotherapy followed by a maintenance phase. The first line of therapy is oral prednisone and cyclophosphamide. On remission, the prednisone is gradually discontinued, with continuation of the cyclophosphamide for at least 1 year. Although high response rates are noted, serious side effects related to the therapy are not rare, especially those associated with cyclophosphamide. Rituximab is an effective and increasingly utilized alternative. Trimethoprim/sulfamethoxazole has been used successfully in localized cases. When added to the standard regimen, this antibiotic combination seems to reduce associated infections and to lower the relapse rate. Low-dose methotrexate and corticosteroids also have been used in patients whose disease is not immediately life threatening or has not responded appropriately to cyclophosphamide. Additional alternatives for the cyclophosphamide include cyclosporine, or infliximab. For maintenance therapy, cyclophosphamide often is replaced with rituximab, methotrexate, or azathioprine.

Treatment has a profound effect on the progression of the disease. With appropriate therapy, prolonged remission is noted in up to 75% of affected patients; a cure often is attainable when the disease is diagnosed and appropriately treated while the involvement is localized. Because of a relapse rate up to 30%, maintenance therapy is necessary in most patients. The PR3-ANCA levels can be used to monitor the disease activity. Patients appear less likely to have relapses if their antineutrophilic antibodies disappear during treatment; in contrast, patients whose levels of antibodies persist are at greater risk for relapse.

◆ LICHENOID AND GRANULOMATOUS STOMATITIS

For over two decades, a small number of publications have described a very distinctive clinical and histopathologic process known as **lichenoid and granulomatous stomatitis** which especially involves the upper labial mucosa. Although the cause currently is unknown, various proposed triggers include hypersensitivity to adjacent dental restorations, response to microbial agents such as local plaque/calculus, and a fixed allergic eruption to a medication or other systemic agent. Candidal infection often is superimposed and may be responsible for the associated symptoms. Treating the yeast often relieves any discomfort, but the erythematous lesion remains. A significant number of affected patients have reported use of drugs known to be associated with lichenoid reactions, most commonly nonsteroidal anti-inflammatory medications, angiotensin-converting enzyme inhibitors, and β-adrenoceptor blockers. Although the number of publications associated with this process is low, the unique clinical and microscopic presentation is not uncommon in an active practice of clinical and histopathologic oral pathology.

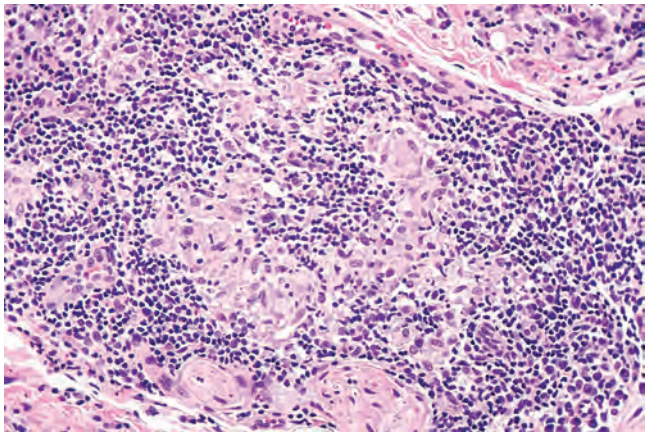


Clinical Features

Although the process may occur in both genders, most reported cases have been documented in women over 50 years of age. Affected individuals present with a chief complaint of mucosal burning that worsens with exposure

dentlearn.ir

• **Fig. 9.31 Lichenoid and Granulomatous Stomatitis.** Diffuse erythema of the upper labial mucosa with intermixed erosions.



• **Fig. 9.32 Lichenoid and Granulomatous Stomatitis.** Biopsy of the labial mucosa demonstrating intense chronic interface mucositis with deeper perivascular/perineural lymphoid nodules.

to spicy foods. Oral examination reveals an erythematous alteration noted most frequently on the upper labial mucosa but with occasional involvement of the lower labial mucosa and buccal mucosa. The erythematous mucosa may be intermixed with small papules, white striae, or erosions (Fig. 9.31). In about half of the patients, the adjacent gingiva also is erythematous and tender.

Histopathologic Features

Biopsy of the labial mucosa typically demonstrates diffuse exocytosis of the epithelium with a thinned spinous cell layer and degeneration of many basal cells. Superficial candidiasis may be noted but not present in all patients. The superficial stroma reveals an intense band-like infiltrate of lymphocytes immediately adjacent to the surface epithelium. Deeper nodules of lymphocytes are noted in a perivascular/perineural distribution, often intermixed with clusters of epithelioid histiocytes (Figs. 9.32 and 9.33). Multinucleated giant cells are seen occasionally, but well-formed granulomas are not present.

• **Fig. 9.33 Lichenoid and Granulomatous Stomatitis.** Deeper lymphoid nodule with clusters of epithelioid histocytes.

Treatment and Prognosis

In the small number of cases reported to date, no consistently effective therapy has been documented. In individuals taking medications associated with lichenoid drug reactions, replacement with an alternative should be considered. In patients with composite resin restorations adjacent to the labial lesions, replacement with porcelain crowns has resolved the lesions in some patients. In other patients with extensive plaque/calculus, improved oral hygiene combined with chlorhexidine rinses may lead to resolution. In many patients, adjacent dental restorations and/or plaque are not noted. In these patients, use of topical corticosteroids has led to improvement in some individuals but has not been effective in others. Even in the absence of local plaque, antimicrobials such as antifungal medications, chlorhexidine rinses, or systemic clarithromycin with or without corticosteroids has been used successfully in small cohorts of patients.

◆ MUCOSAL REACTIONS TO SYSTEMIC DRUG ADMINISTRATION

The future of dentistry and medicine will involve a high volume of patients suffering from adverse drug reactions. By 2030, 20% of the population will be more than 65 years old. As the population ages and those affected with chronic diseases increase, patients taking multiple medications most likely will escalate. In the United States during the year 2000, more than 2.8 billion prescriptions were filled, enough to supply each inhabitant with 10 prescriptions annually. Although use of two medications is associated with a 6% risk of an adverse reaction, the frequency rises to 50% with five drugs and almost 100% when eight or more medications are used simultaneously.

Although difficult to confirm, oral mucosal reactions to systemic medications most likely are extremely common. In a review of 155 patients presenting with intraoral lesions consistent with lichen planus, 87.8% of the individuals were

dentlearn.ir

taking medications known to be associated with lichen planus-like reactions. At one time, the clinical triad of oral lichen planus, diabetes mellitus, and hypertension was recognized under the historical term, *Grinspan syndrome*. However, this combination currently is believed to represent a lichen planus-like reaction secondary to the medications utilized to control the diabetes and hypertension. In all likelihood, a large percentage of patients presenting with lichen planus-like lesions in the oral cavity represent chronic drug reactions, not primary lichen planus.

Two types of adverse drug reactions are seen. Type A (augmented reactions) arise from an exaggerated but otherwise expected pharmacologic action of the prescribed medication (such as, bleeding associated with warfarin). Approximately 80% of the total adverse drug reactions are Type A. Type B (bizarre reactions) are idiosyncratic reactions that are not expected, the majority of which arise from immune-mediated effects, such as hypersensitivity reactions.

Lists of medications related to several patterns of drug-related mucosal alteration are provided. Because new drug reactions are being reported on a regular basis and large numbers of new medications continue to appear, these lists should be considered incomplete at the time of publication and additional investigation is prudent. When presented with a patient with a possible drug reaction, all medications, both prescribed and over-the-counter, that the patient is taking should be researched with a reputable pharmaceutical reference. This should include not only the information within the drug insert but also the constantly updated results of a complete search of the health care literature.

In addition to drug-related problems, such as aphthous stomatitis (see page 321), angioedema (see page 348), medication-related osteonecrosis (see page 286), cancer therapy-related mucositis (see page 281), cleft lip/palate (see page 1), erythema multiforme/Steven-Johnson Syndrome (see page 781), gingival hyperplasia (see page 156), methemoglobinemia, mucosal discolorations (see page 307), burning mouth disorder (see page 868), tardive dyskinesia, taste disturbances (see page 869), sialorrhea (see page 469), and xerostomia (see page 470), medications can induce a wide variety of mucosal ulcerations and erosions. A reaction of the oral mucosa to the systemic administration of a medication is called **stomatitis medicamentosa.** Several different patterns of oral mucosal disease can be seen:

- Anaphylactic stomatitis
- Intraoral fixed drug eruptions
- Lichenoid drug reactions
- Pemphigoid-like drug reactions
- Pemphigus-like drug reactions
- Lupus erythematosus–like eruptions
- Nonspecific erosive or ulcerative lesions

Anaphylactic stomatitis arises after the allergen enters the circulation and binds to immunoglobulin E (IgE)–mast cell complexes. Although systemic anaphylactic shock can result, localized alterations also occur. Fixed drug eruptions are inflammatory alterations of the mucosa or skin that recur at the same site after the administration of any allergen, often a medication. Medications reported to be associated with fixed drug eruptions are listed in Box 9.3, lichenoid drug eruptions in Box 9.4, lupus erythematosus–like drug eruptions in Box 9.5, pemphigus-like drug reactions in Box 9.6, and mucosal pemphigoid–like eruptions in Box 9.7. In addition, a long list of medications is known to be associated with nonspecific erosive, ulcerative, or aphthae-like

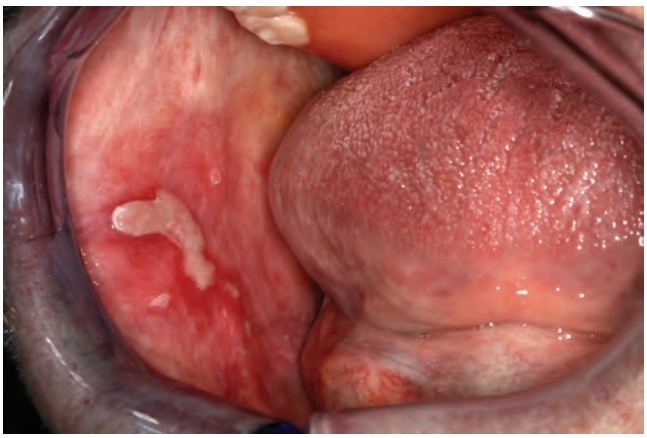
vomiting). The affected mucosa may exhibit multiple zones of erythema or numerous aphthae-like ulcerations. Mucosal fixed drug eruptions appear as localized areas of erythema and edema, which can develop into vesiculoerosive lesions and are located most frequently on the labial mucosa. Lichenoid, lupus-like, pemphigoid-like, and pemphigus-like drug reactions resemble their namesakes clinically, histopathologically, and immunologically (Figs. 9.34 and 9.35). These latter chronic drug reactions may involve any mucosal surface, but the most common sites are the posterior buccal mucosa and the lateral borders of the tongue (Figs. 9.36 and 9.37).



• **Fig. 9.34 Allergic Mucosal Reaction to Systemic Drug Administration. A,** Bilateral erosions of lower labial mucosa with intermixed striae. Biopsy revealed lichenoid pattern of mucositis but with numerous plasma cells intermixed with the lymphocytes. The erosions ultimately were proven to be associated with simvastatin. **B,** Same patient depicted in **A** after discontinuation of simvastatin.

• **Fig. 9.36 Lichenoid Drug Reaction to Allopurinol.** Irregular area of superficial erosion of the right buccal mucosa.

• **Fig. 9.37 Allergic Mucosal Reaction to Systemic Drug Administration.** Large irregular erosion of the right ventral surface of the tongue. The lesion arose secondary to use of oxaprozin, a nonsteroidal anti-inflammatory drug (NSAID).

• **Fig. 9.38 Mucosal Erosions Due to Methotrexate Administration**. Multiple mucosal erosions of the ventral tongue, floor of mouth, and labial mucosa.

Bilateral and symmetrical lesions are common. In addition to drug reactions that mimic the patterns of classic vesiculoerosive diseases, nonspecific ulcerations and erosions arise secondary to a wide variety of medications such as methotrexate (Fig. 9.38).

Histopathologic Features

Anaphylactic stomatitis typically reveals a nonspecific pattern of subacute mucositis that contains lymphocytes intermixed with eosinophils and neutrophils. Fixed drug eruptions also reveal a mixed inflammatory cellular infiltrate that consists of lymphocytes, eosinophils, and neutrophils, often combined with spongiosis and exocytosis of the epithelium. Vacuolar change of the basal cell layer and individual necrotic epithelial cells occasionally are noted. The drug reactions that simulate lichen planus, lupus erythematosus, pemphigoid, and pemphigus resemble their namesakes. The histopathologic and immunologic features of these chronic drug reactions cannot be used reliably to separate them from their associated primary immunologic disease.

Immunofluorescence has been used to separate drug reactions from primary vesiculoerosive disease. In most instances, this technique has proven to be unsatisfactory. Despite these findings, a unique pattern of reaction has been seen when indirect immunofluorescence for IgG has been performed in patients with lichenoid drug reactions. In many of these patients, a distinctive annular fluorescent pattern, termed **string of pearls,** has been reported along the cell membrane of the basal cell layer of stratified squamous epithelium. The detected circulating antibody has been termed **basal cell cytoplasmic antibody.** Although further study is desirable, this technique may prove to be a useful adjunct during evaluation of oral lichenoid lesions.

Diagnosis

A definitive diagnosis of a chronic drug reaction of the oral mucosa is difficult because the initial clinical symptoms may arise months to years after initiation of offending medication. In addition, the clinical alterations may persist for months after cessation of the medication, occasionally requiring immunosuppressive therapy to achieve complete resolution. A detailed medical history must be obtained, and the patient should be questioned closely concerning the use of both prescription and over-the-counter medications. If the patient can provide an accurate history, all medications initiated after the oral lesions arose can be removed from the list of possible offenders. Once a potentially offending medication is discovered, a temporal relationship between the drug's use and the mucosal alteration should be investigated. The association may be acute and obvious, or the onset of the oral lesions may be delayed. If more than one medication is suspected, the most recently administrated medication often is the culprit. If the last-to-be-introduced drug does not appear responsible, serial elimination of the medications can be performed in collaboration with the patient's physician until the offending agent is discovered.

In chronic drug reactions, definitive diagnosis can be made if the mucosal alterations resolve after discontinuation of the medication and recur on reintroduction of the agent. Presumptive diagnosis usually is sufficient and justified when the mucosal alterations clear after cessation of the offending

dentlearn.ir

medication. If immunosuppressive medications are necessary to achieve resolution, the mucosal alterations should not recur after removal of the medication and cessation of therapy. If the lesions recur following complete resolution, then the medication was not involved in the mucosal alteration.

In possible lupus-like drug reactions, serum evaluation for generic antinuclear antibodies (ANAs) and antibodies against double-stranded DNA and histones often can be beneficial. Lupus-like drug reactions typically are associated with circulating generic ANAs and antibodies against histones, whereas lupus erythematosus also reveals antibodies to double-stranded DNA (a finding not typically noted in drug reactions). This pattern does not hold true in reactions associated with the TNF-α antagonists, infliximab and etanercept, which simulate systemic lupus erythematosus (SLE) very closely and are associated with antibodies to double-stranded DNA.

Treatment and Prognosis

The responsible medication should be discontinued and, if necessary, replaced with another drug that provides a similar therapeutic result. Localized acute reactions can be resolved with topical corticosteroids. When systemic manifestations are present, anaphylactic stomatitis often warrants systemic administration of adrenaline (epinephrine), corticosteroids, or antihistamines. Chronic oral lesions often resolve on cessation of the offending drug, but topical corticosteroids may sometimes be required for complete resolution.

If discontinuation of the medication is contraindicated, palliative care can be provided; however, corticosteroids often are ineffective if the offending medication is continued.

◆ ALLERGIC CONTACT STOMATITIS (STOMATITIS VENENATA)

The list of agents reported to cause **allergic contact stomatitis** reactions in the oral cavity is extremely diverse. Numerous foods, food additives, chewing gums, candies, dentifrices, mouthwashes, glove and rubber dam materials, topical anesthetics, dental restorative materials, acrylic denture materials, dental impression materials, and denture adhesive preparations have been mentioned. Two types of allergens, cinnamon (see page 344) and dental restorative materials (see page 346), demonstrate clinical and histopathologic patterns that are sufficiently unique to justify separate descriptions.

Although the oral cavity is exposed to a wide variety of antigens, the frequency of a true allergic reaction to any one antigen from this contact appears to be rare. This was verified in a prospective study of 13,325 dental patients, in which only 7 acute and 15 chronic cases of adverse effects were attributed to dental materials. The oral mucosa is much less sensitive than the surface of the skin; this is most likely because of the following:

- The period of contact is often brief.
- The saliva dilutes, digests, and removes many antigens.
- The limited keratinization of oral mucosa makes hapten binding more difficult, and the high vascularity tends to remove any antigen quickly.
- The allergen may not be recognized (because of the lower density of Langerhans cells and T lymphocytes).

If the skin has been sensitized originally, the mucosa may or may not demonstrate future clinical sensitization. In contrast, if the mucosa is sensitized initially, then the skin usually demonstrates similar changes with future exposure. Long-term oral exposure may induce tolerance and reduce the prevalence of cutaneous sensitivity in some instances. For example, exposure to nickel-containing orthodontic hardware has been associated with a reduced prevalence of future cutaneous sensitivity to nickel jewelry.

In addition to oral lesions, allergic contact reactions may produce exfoliative cheilitis (see page 294) or perioral dermatitis (see next section). As mentioned in Chapter 8, most cases of chronic cheilitis represent local irritation, usually from chronic lip licking. Despite this, investigation has revealed that approximately 25% of affected cases are allergic contact cheilitis from a variety of antigens that include medications, lipsticks, sunscreens, toothpaste, dental floss, nail polishes, and cosmetics.

Clinical Features

Allergic contact stomatitis can be acute or chronic. Of those cases diagnosed, there is a distinct female predominance in both forms. After eliminating focal trauma, localized signs and symptoms suggest mucositis from an isolated allergen (e.g., dental metal); in contrast, widespread mouth pain suggests an association with a more diffuse trigger, such as food, drink, flavorings, or oral hygiene materials.

In patients with acute contact stomatitis, burning is the most frequent symptom. The appearance of the affected mucosa is variable, from a mild and barely visible redness to a brilliantly erythematous lesion with or without edema. Vesicles are seen rarely and, when present, rapidly rupture to form areas of erosion (Fig. 9.39). Superficial ulcerations that resemble aphthae occasionally arise. Itching, stinging, tingling, and edema may be noted.

In chronic cases the affected mucosa is typically in contact with the causative agent and may be erythematous or white and hyperkeratotic. Periodically, erosions may develop within the affected zones. Some allergens, especially toothpastes, can cause widespread erythema, with desquamation of the superficial layers of the epithelium (Fig. 9.40). Allergic contact cheilitis demonstrates clinical features identical to those cases created through chronic irritation, and it most frequently appears as chronic dryness, scaling, fissuring, or cracking of the vermilion border of the lip. Rarely, symptoms identical to orolingual paresthesia can be present without any clinically evident signs. One distinctive pattern, plasma cell gingivitis, is discussed elsewhere (see page 152).

dentlearn.ir

• **Fig. 9.39 Allergic Contact Stomatitis to Aluminum Chloride.** Mucosal erythema and vesicles of the lower labial mucosa caused by use of aluminum chloride on gingival retraction cord.

• **Fig. 9.40 Allergic Contact Stomatitis to Toothpaste.** Erythematous mucosa with superficial epithelial desquamation.

Diagnosis

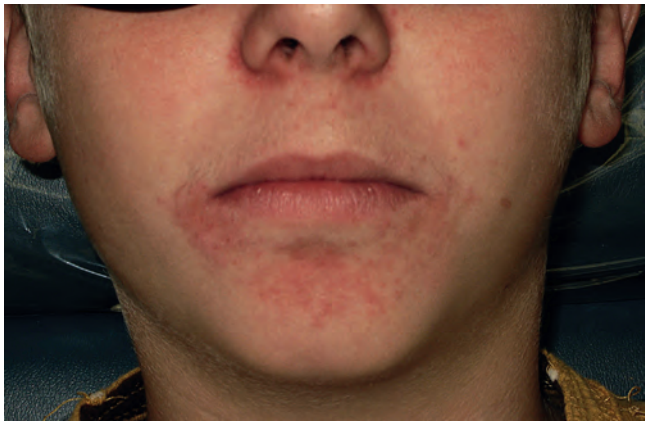
Usually, the diagnosis of acute contact stomatitis is straightforward because of the temporal relationship between the use of the agent and the resultant eruption. If an acute oral or circumoral reaction is noted within 30 minutes of a dental visit, then allergy to all used dental materials, local anesthetics, and gloves should be investigated. In some cases, the clinical presentation of an allergic contact stomatitis can be difficult to distinguish from an irritant contact stomatitis in which the mucosal alteration is related to chemical or physical irritation rather than a hypersensitivity. Patch testing may prove beneficial in separating these contact reactions.

The diagnosis of chronic contact stomatitis is much more difficult. Most investigators require good oral health, elimination of all other possible causes, and visible oral signs, together with a positive history of allergy and a positive skin test result to the suspected allergen. If allergic contact stomatitis is strongly suspected but skin test results are negative, then direct testing of the oral mucosa can be attempted. The antigen can be placed on the mucosa in a mixture with Orabase or in a rubber cup that is fixed to the mucosa.

Treatment and Prognosis

In mild cases of acute contact stomatitis, removal of the suspected allergen is all that is required. In more severe cases, antihistamine therapy, which is combined with topical anesthetics, usually is beneficial. Chronic reactions respond to removal of the antigenic source and application of a topical corticosteroid gel or oral suspension.

When attempting to discover the source of a diffuse allergic mucositis, use of plain baking soda or toothpaste that is free of flavoring or preservatives is recommended. The patient also should be instructed to avoid mouthwash, gum, mints, chocolate, cinnamon-containing products, carbonated drinks, and excessively salty, spicy, or acidic foods. If an association cannot be found, then cutaneous patch testing may provide helpful information.



◆ PERIORAL DERMATITIS (PERIORIFICIAL DERMATITIS)

Perioral dermatitis does not refer to every rash that occurs around the mouth but is specific for a unique inflammatory skin disease that involves the cutaneous surfaces surrounding the facial orifices. Because the disorder also often involves the paranasal and periorbital skin, **periorificial dermatitis** is the most appropriate designation. Although the process is idiopathic, the dermatitis is associated strongly with excessive use of potent topical corticosteroids on the facial skin. Many believe the corticosteroid use leads to local immunosuppression and infection in the hair follicles by organisms such as *Propionibacterium acnes* and *Fusobacterium* that release chemotactic factors for neutrophils leading to significant associated inflammation. Fluorinated toothpaste and overuse of heavy facial cosmetics, creams, and moisturizers also are implicated in some patients. Weaker correlations have been seen with systemic corticosteroids, corticosteroid inhalers, and nasal corticosteroids. Heavy exposure to ultraviolet light, heat, and wind appears to worsen the dermatitis. Some of these substances may initially induce an irritant or allergic contact dermatitis, whereas others are thought to produce inappropriate occlusion of the skin surface with subsequent proliferation of skin flora.

Clinical Features

Perioral dermatitis appears with persistent erythematous papules, vesicles, and pustules that involve the skin surrounding the vermilion border of the upper and lower lips. In addition, involvement of the perinasal skin is seen in approximately 40% of affected patients, and 25% have

dentlearn.ir

• **Fig. 9.41 Perioral Dermatitis.** Multiple erythematous papules of the skin surrounding the vermilion border of the lips. Note similar involvement around the nasal orifices (periorificial dermatitis). (Courtesy of Dr. Billy Millay.)

periorbital dermatitis (Fig. 9.41). Classically, there is a zone of spared skin immediately adjacent to the vermilion border. Cases related to fluoridated toothpaste often do not reveal sparing of the skin just outside the lip vermilion. Pruritus and burning are variable. Most of the cases are diagnosed in women between the ages of 20–45 years, lending further support to the association with cosmetic use. In some affected females, there appears to be a hormonal influence as evidenced by premenstrual flares or exacerbation associated with pregnancy or use of contraceptive pills. There is a less common pediatric variant that is seen between the age of 7 months to 13 years, which does not demonstrate the strong gender predilection observed in adults.

Histopathologic Features

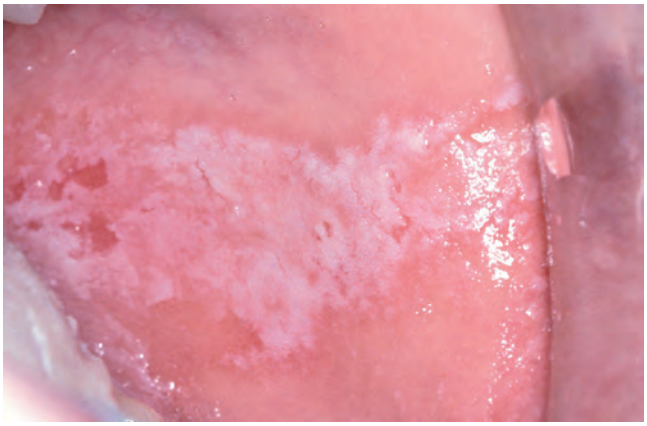
Biopsy of perioral dermatitis demonstrates a variable pattern. In many cases there is a chronic lymphohistiocytic dermatitis that often exhibits spongiosis of the hair follicles. In other patients a rosacea-like pattern is noted in which there is perifollicular granulomatous inflammation. On occasion, this histopathologic pattern has been misdiagnosed as sarcoidosis.

Treatment and Prognosis

Most cases resolve with "zero therapy," which includes discontinuation of corticosteroids, cosmetics, facial creams, etc. Discontinuation of potent topical corticosteroid use often is followed by a period of exacerbation. Oral tetracycline is considered the therapeutic gold standard for perioral dermatitis but must be avoided during childhood and pregnancy. Alternative therapies include topical metronidazole, erythromycin, clindamycin, sulfacetamide, and pimecrolimus or systemic azithromycin, erythromycin, doxycycline, or clarithromycin. Isotretinoin has been used successfully in patients who are refractory to other therapies. The pathosis typically demonstrates significant improvement within several weeks and total resolution in a few months. Recurrence is uncommon.

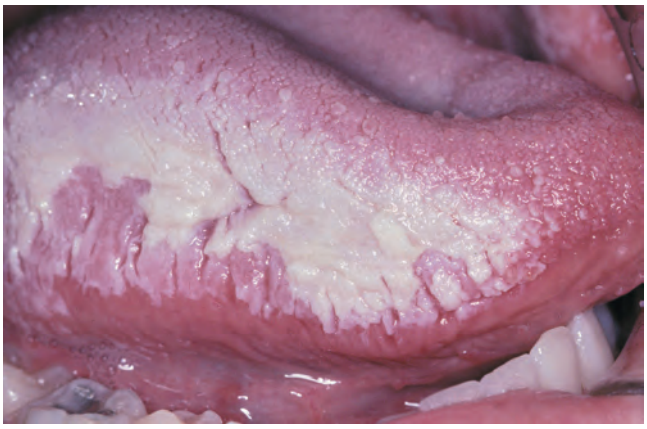
◆ CONTACT STOMATITIS FROM ARTIFICIAL CINNAMON FLAVORING

Mucosal abnormalities secondary to the use of artificially flavored cinnamon products are fairly common, but the range of changes was not recognized widely until the late 1980s. Cinnamon oil is used as a flavoring agent in confectionery, ice cream, soft drinks, alcoholic beverages, processed meats, gum, candy, toothpaste, breath fresheners, mouthwashes, and even dental floss. Concentrations of the flavoring are up to 100 times that in the natural spice. The reactions are documented most in those products associated with prolonged or frequent contact, such as candy, chewing gum, mouthwash, and toothpaste. The anticalculus components of tartar-control toothpastes have a strong bitter flavor and require a significant concentration of flavoring agents including cinnamon to hide the taste, resulting in a greater chance these formulations will cause oral mucosal lesions. Although much less common, reactions to cinnamon in its natural spice form have been documented.



Clinical Features

The clinical presentations of contact stomatitis vary somewhat, according to the medium of delivery. Toothpaste and mouthwash often result in a more diffuse pattern; the signs associated with chewing gum and candy are more localized. Pain and burning are common symptoms in all cases. Anaphylaxis associated with cinnamon exposure has been reported but is rare.



The gingiva is the most frequent site affected by toothpaste, often resembling **plasma cell gingivitis** (see page 152); enlargement, edema, and erythema are common. Sloughing of the superficial oral epithelium without creation of an erosion is seen commonly. Erythematous mucositis, occasionally combined with erosion, has been reported on the buccal mucosa and tongue. Exfoliative cheilitis and circumoral dermatitis also may occur.

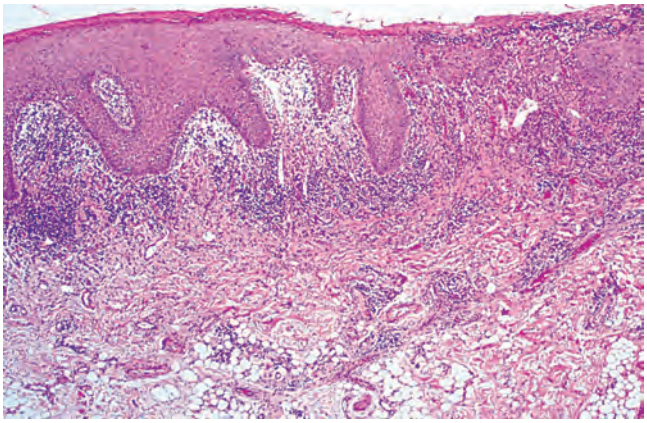
Reactions from chewing gum and candy are more localized and typically do not affect the lip vermilion or perioral skin. Most of the lesions appear on the buccal mucosa and lateral borders of the tongue. Buccal mucosal lesions often are oblong patches that are aligned along the occlusal plane (Fig. 9.42). Individual lesions have an erythematous base but often are predominantly white because of hyperkeratosis of the surface epithelium. Ulceration within the lesions may occur. Hyperkeratotic examples often exhibit a ragged surface and occasionally may resemble the pattern seen in morsicatio (see page 272). Lingual involvement may become extensive and spread to the dorsal surface (Fig. 9.43). Significant thickening of the surface epithelium can occur and may raise clinical concern for oral hairy leukoplakia (OHL) (see page 253) or carcinoma (Fig. 9.44).

dentlearn.ir

• **Fig. 9.42 Contact Stomatitis from Cinnamon Flavoring.** Oblong area of sensitive erythema with overlying shaggy hyperkeratosis.

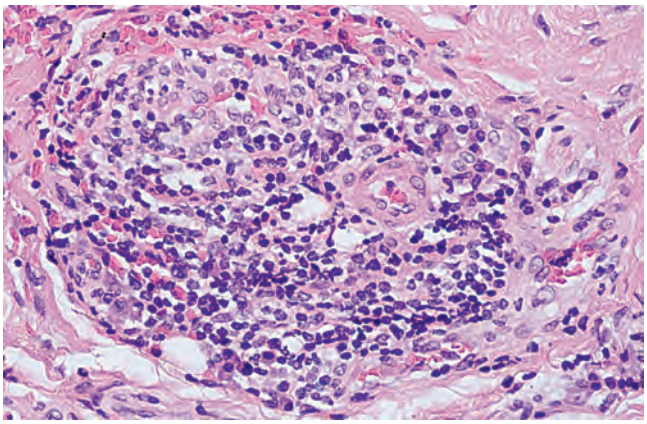
• **Fig. 9.43 Contact Stomatitis from Cinnamon Flavoring.** Sensitive and thickened hyperkeratosis of the lateral and dorsal surface of the tongue on the right side.

Histopathologic Features



Usually, the epithelium in contact stomatitis from artificial cinnamon flavoring is acanthotic, often with elongated rete ridges and thinning of the suprapapillary plates. Hyperkeratosis and extensive neutrophilic exocytosis may be present. The superficial lamina propria demonstrates a heavy inflammatory cell infiltrate that consists predominantly of lymphocytes that may be intermixed with plasma cells, histiocytes, or eosinophils. This infiltrate often obscures the epithelium and connective tissue interface (Fig. 9.45). A characteristic feature in localized cases caused by gum, mints, or candies is the frequent presence of an obvious perivascular inflammatory infiltrate that extends well below the interface zone (Fig. 9.46).

Diagnosis



With a high index of suspicion and knowledge of the variations of the clinical pattern, the diagnosis of localized contact stomatitis often can be made from the clinical appearance and the history of cinnamon use. Occasionally, biopsies are performed for atypical or extensive cases because of the differential diagnosis, which includes several significant

• **Fig. 9.44 Contact Stomatitis from Cinnamon Flavoring.** Left lateral border of the tongue demonstrating linear rows of hyperkeratosis that resemble oral hairy leukoplakia (OHL).

• **Fig. 9.45 Contact Stomatitis From Cinnamon Flavoring.** Oral mucosa demonstrating significant interface mucositis and deeper perivascular inflammation.

• **Fig. 9.46 Contact Stomatitis From Cinnamon Flavoring.** Perivascular inflammatory infiltrate consisting predominantly of lymphocytes and plasma cells.

vesiculoerosive and neoplastic conditions. The histopathologic features are not specific, but they are sufficient to raise a high index of suspicion in an oral and maxillofacial pathologist who is familiar with the pattern. Use of cinnamon-containing toothpaste should be investigated in every patient

dentlearn.ir

with an atypical pattern of gingivitis. Diet-related examples often are the most difficult to diagnose and may necessitate cutaneous allergy patch testing or a diet diary to isolate the cause. Cutaneous patch testing often does not always correlate to the intraoral manifestations. Patients with positive patch testing may not demonstrate intraoral reactions, and patients with an obvious intraoral reaction to cinnamon may not exhibit positivity to cutaneous patch testing. The best method of diagnostic confirmation is elimination of the suspected allergen with rapid clearance of the mucosal alterations.

Treatment and Prognosis

Typically, the signs and symptoms disappear within 1 week after the discontinuation of the cinnamon product. If the patient resumes intake of the product, then the lesions reappear, usually within 24 hours. On occasion, resolution is more gradual; and the patient may benefit from short-term use of a topical corticosteroid.

◆ LICHENOID CONTACT REACTION FROM DENTAL RESTORATIVE MATERIALS

Dental amalgam has been in active use for over 180 years and has proven to be a durable and relatively inexpensive material that remains one of the most commonly placed dental restorations. Because of an associated low-level release of mercury from these fillings (an amount significantly less than the daily contribution from food and nondental sources), its use has been blamed for a wide variety of health concerns. Due to the controversy, several controlled studies were performed, showing no association between the presence of dental amalgams and systemic disease. Two oral pathoses, burning mouth syndrome and orofacial granulomatosis, also have been correlated with the presence of amalgams by some investigators, but no conclusive evidence exists to associate these disorders with the dental restorative material. The primary adverse effects that are well documented include acute and chronic hypersensitivity reactions.

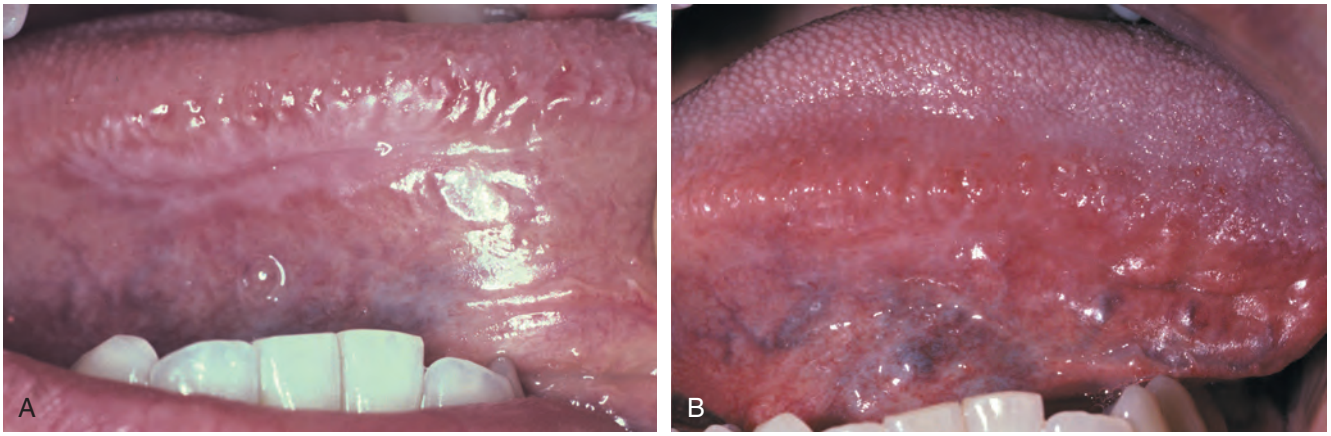
Dental amalgams contain mercury, silver, tin, and copper, with some variations also including zinc, indium, palladium, or platinum. Most hypersensitivity reactions to dental restorative materials are to dental amalgam. Reactions have been seen much less frequently to other dental restorations containing materials such as gold, beryllium, chromium, cobalt, or composite resins.

Although rare acute reactions may be seen following placement of amalgam, the vast majority of adverse alterations represent chronic type IV hypersensitivity reactions that are seen most commonly associated with older and corroded amalgams. It is believed the metal ions released by corrosion haptenize with oral keratinocyte surface proteins and initiate a cell-mediated autoimmune response directed at the basal cell layer of the epithelium. Some investigators have called these chronic alterations "galvanic lesions," but neither clinical nor experimental studies support the electrogalvanic hypothesis of origin.

These chronic contact reactions appear clinically and histopathologically similar to lichen planus (see page 787) but demonstrate a different mucosal distribution. When patients with true oral lichen planus are examined, the lesions migrate and exhibit no direct correlation to contact with dental materials. In addition, patients with lichen planus do not demonstrate a significantly increased positive patch testing to dental restorative materials and exhibit minimal-to-no clinical improvement on removal of their amalgams.

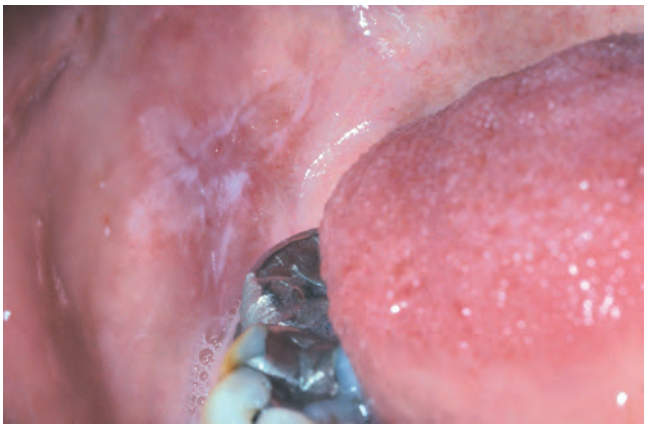
However, there is a subgroup of patients whose lichenoid lesions do not migrate and usually involve only the mucosa adjacent to a dental metal. On patch testing, most of these patients react to the offending metal, and the lesions resolve rapidly after removal of adjacent amalgams. Such lesions should be diagnosed as a **lichenoid contact reaction** to a dental restorative material, not as true lichen planus. Although many of these mucosal alterations appear to represent allergic contact reactions, occasional lesions may be secondary to a sharp cusp, a rough-surfaced restoration, or altered tooth anatomy that is difficult to clean and results in local accumulation of plaque.

Clinical Features



Acute reactions to dental amalgams are extremely rare and related to an immediate hypersensitivity reaction. The signs tend to arise within hours after placement of an amalgam and present with erythematous, pruritic, and urticarial lesions of the ipsilateral oral mucosa and facial skin. In severe reactions, soft tissue edema, tachycardia, and breathing difficulties also are seen.

Most chronic lichenoid contact reactions affect the posterior buccal mucosa and the ventral surface of the lateral borders of the tongue. In contrast to lichen planus, in which the mucosal alterations tend to be bilateral and symmetrical, lichenoid reactions to dental materials usually are confined to the area of contact and may be white or erythematous, with or without peripheral striae (Fig. 9.47). Most patients have no symptoms, but periodic erosion may be noted. In all likelihood, many of the lesions previously reported as the so-called plaque type of lichen planus were, in reality, lichenoid contact reactions or possibly evolving epithelial dysplasias or proliferative verrucous leukoplakia with an associated lichenoid immune response.



Diagnosis

The diagnosis of a lichenoid contact reaction is made from the clinical appearance of the lesion, the lack of lesional migration, and the correlation to adjacent dental metal (Fig. 9.48). Although the histopathologic features may be indistinguishable from lichen planus, biopsy occasionally is performed to confirm the clinical impression and to rule out other pathoses such as epithelial dysplasia. Although patch testing is positive

dentlearn.ir

• **Fig. 9.47 Oral Mucosal Contact Reaction to Dental Amalgam. A,** Hyperkeratotic lesion with a peripheral radiating pattern on the lateral border of the tongue on the right side; the altered mucosa contacted the amalgams of the adjacent mandibular molar teeth. The lesion remained in the same location for 5 years and periodically became erosive and symptomatic. Smoothing and polishing of the adjacent restorations had no effect. **B,** Appearance of previously altered area of the tongue 14 days after removal of adjacent amalgams. Note total resolution of the mucosal alterations.

• **Fig. 9.48 Oral Mucosal Contact Reaction to Dental Amalgam.** Radiating pattern of hyperkeratotic striae on the posterior buccal mucosa that contacts a large distobuccal amalgam of the permanent mandibular second molar.

in up to 70% of patients with contact reactions and similarly reactive in less than 4% of patients with true lichen planus, the clinical presentation has proven to be a more reliable diagnostic indicator than patch testing. Many clinicians reserve patch testing for patients with large numbers of amalgams and extensive lichenoid lesions in which it is difficult clinically to distinguish lichen planus from lichenoid contact reactions. As an alternative to cutaneous patch testing in this situation, a single-test amalgam can be replaced to assess the response of the adjacent mucosa. If clearance is seen locally in the area of amalgam removal, then elimination of the remaining offending restorations is justified.

Histopathologic Features

Biopsy of allergic contact stomatitis from dental materials exhibits numerous features of lichen planus. The surface epithelium may be hyperkeratotic, atrophic, or ulcerated. Areas of hydropic degeneration of the basal cell layer often are present. The superficial lamina propria contains a dense band-like chronic inflammatory cellular infiltrate consisting predominantly of lymphocytes. In addition to the superficial lichenoid mucositis, some biopsies also reveal features typically not noted in classic lichen planus such as a deeper lymphocytic infiltrate often intermixed with plasma cells, occasional germinal centers, and variable numbers of eosinophils. Occasionally, the deeper infiltrate also will demonstrate a perivascular pattern.

Treatment and Prognosis

In patients with acute hypersensitivity reactions to an amalgam, the process usually is self-limiting and resolves spontaneously within 2–3 days. Despite this, systemic symptoms, such as significant breathing difficulties, may necessitate removal of the newly placed amalgam.

For chronic lichenoid reactions, local measures, such as improved oral hygiene, smoothing, polishing, and recontouring of the amalgam restoration, should be attempted before more aggressive measures, because clinically similar lesions have been noted because of surface plaque accumulation. If this is unsuccessful, then the amalgam in question should be replaced. Because patients rarely may exhibit hypersensitivity to composite resins, use of inert materials (such as glass ionomer, feldspathic ceramic, porcelain, or porcelain-fused-to-metal) is recommended. Like lichen planus, some investigators believe untreated lichenoid contact reactions rarely may evolve into carcinoma, although the possibility that some preneoplastic leukoplakias are mistaken for lichenoid contact reactions cannot be ruled out. Although this association is far from proven, removal of amalgams adjacent to possible lichenoid contact reactions appears prudent. Lichenoid lesions that fail to resolve following removal of the adjacent metal should be evaluated further.

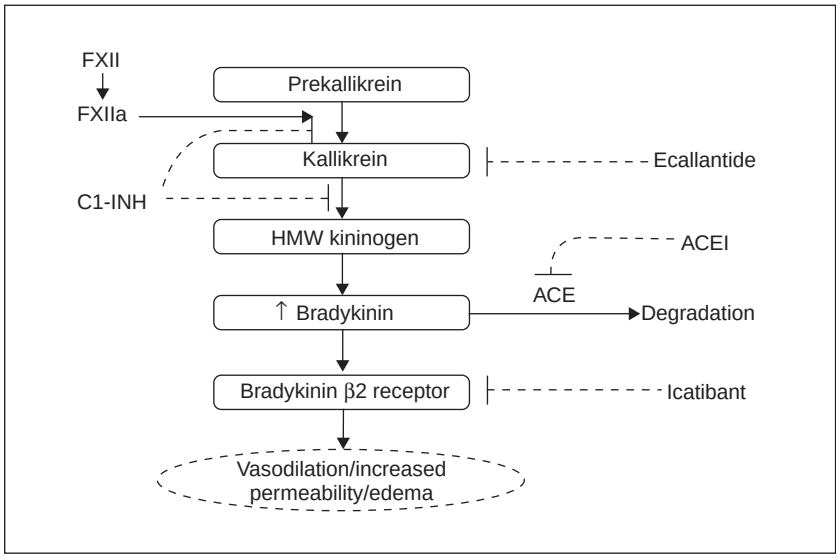
◆ ANGIOEDEMA (ANGIONEUROTIC EDEMA; QUINCKE DISEASE)



Angioedema is a diffuse edematous swelling of the soft tissues that most commonly involves the subcutaneous and submucosal connective tissues but may affect the gastrointestinal or respiratory tract, occasionally with fatal results. The disorder has been referred to as **Quincke disease,** after the clinician who initially related the changes to an alteration in vascular permeability. The outdated term **angioneurotic edema** also has been used, because affected patients often complained of a choking sensation and were labeled neurotic.

The most common cause is mast cell degranulation, which leads to histamine release and the typical clinical alterations. IgE-mediated hypersensitivity reactions caused by drugs, foods, plants, dust, and inhalants produce mast cell degranulation and are common. Contact allergic reactions to foods, cosmetics, topical medications, and even dental rubber dams also have been responsible. Mast cell degranulation can even result from physical stimuli, such as heat, cold, exercise, emotional stress, sun exposure, and significant vibration. This latter pattern is termed **vibratory angioedema** with intraoral examples seen secondary to stimuli such as prolonged snoring or use of musical instruments with a mouthpiece.

An unusual pattern of drug reaction that can produce severe forms of angioedema that are not mediated by IgE is the type associated with use of drugs called *angiotensin-converting enzyme (ACE) inhibitors.* These medications represent one of the most frequently prescribed drugs, with 35–40 million patients currently taking these antihypertensives. Some of the most popular are captopril, enalapril, and lisinopril. The swelling associated with these drugs does not respond to antihistamines and is the result of excess bradykinin. As illustrated in Fig. 9.49, activation of coagulation factor XII causes conversion of plasma prekallikrein to kallikrein, with the kallikrein pathway leading to production of bradykinin. Angioedema results if the bradykinin is not degraded. Angiotensin converting enzyme plays a role in degrading bradykinin, and if significant inhibition of this enzyme by ACE inhibitors occurs, angioedema is seen.

To avoid this angioedema, a second generation of medications called *angiotensin II receptor blockers* (e.g., losartan and valsartan) was developed specifically to avoid any inhibition of bradykinin degradation. These newer medications lower the frequency of angioedema but do not eliminate the adverse reaction. The prevalence of this pattern of angioedema is estimated to be 0.1%–0.2% of those who use ACE inhibitors. In most affected patients, the angioedema arises within hours of initial use of the drug. In up to 30% of the cases, the angioedema is delayed, with the longest reported interval between drug use initiation and the initial attack being 10 years. Attacks precipitated by dental procedures have been reported in long-term users of ACE inhibitors. Many clinicians overlook the association between angioedema and ACE inhibitors, with studies demonstrating continued administration of the medication in more than 50% of affected patients.

As shown in Fig. 9.49, C1 esterase inhibitor (C1-INH) is antagonistic to bradykinin formation by actively blocking the formation of kallikrein and kininogen. Insufficient functional C1-INH predisposes to angioedema and may be hereditary or acquired. Two major autosomal dominant forms and an extremely rare third hereditary type are known. **Type I hereditary angioedema (HAE I)** accounts for approximately 85% of hereditary cases and is caused by a

• **Fig. 9.49 Kallikrein Pathway in Angioedema**. Diagram demonstrating the kallikrein pathway with the over-production of bradykinin in angioedema. Note the blockage of bradykinin degradation by ACE inhibitors and the three medical interventions that can halt the process (C1-INH, ecallantide, icatibant). (From Craig TJ, Bernstein JA, Farkas H, et al.: Diagnosis and treatment of bradykinin-mediated angioedema expert consensus meeting, *Int Arch Allergy Immunol* 165:119–127, 2014).

dentlearn.ir

quantitative reduction in C1-INH. **Type II hereditary angioedema (HAE II)** is responsible for 15% of hereditary cases and exhibits normal levels of C1-INH, but the inhibitor is dysfunctional. The third type is extremely rare and presents with normal levels of functional C1-INH. Previously this pattern was referred to as type III hereditary angioedema but currently is called **hereditary angioedema with normal C1-INH (HAE-nC1-INH)**. In this rare pattern, the cause is unknown in the majority but 25% demonstrate a mutation in coagulation factor XII, the primary trigger of the kallikrein pathway. In HAE-nC1-INH, the major trigger is estrogen, with pregnancy or oral contraceptives associated with exacerbations and increased severity of attacks. High levels of estrogen are known to increase the levels of factor XII, and mutation of this clotting factor may be responsible for triggering the kallikrein pathway.

The acquired type of C1-INH deficiency is seen in association with certain types of lymphoproliferative diseases (Caldwell syndrome) or in patients who develop specific autoantibodies. In lymphoproliferative diseases, monoclonal antibodies directed against the tumor cells activate C1 and lead to consumption of C1-INH. In the autoimmune variant, the antibody attaches to the C1 receptor on the C1-INH molecule, leading to dysfunctional C1-INH and consumption of C1. In both the acquired and the hereditary forms of abnormal C1-INH activity, minor trauma, such as a dental procedure, can precipitate an attack.

A number of patients also have developed intraoral angioedema following administration of the clot buster tissue plasminogen (tPA, alteplase) for strokes, predominantly those arising in the frontal, insular, and peri-insular regions of the brain. Plasminogen leads to development of plasmin that triggers fibrinolysis and activates the complement cascade and kallikrein pathway with subsequent generation of bradykinin. The reason this reaction seems strongly correlated to use of tPA in specific patterns of stroke is unclear. The frequency of this complication is increased in patients utilizing ACE-inhibitors.

Finally, angioedema has been seen in the presence of high levels of antigen-antibody complexes (e.g., lupus erythematosus and viral or bacterial infections) and in patients with grossly elevated peripheral blood eosinophil counts.

Clinical Features

Angioedema is characterized by the relatively rapid onset of soft, nontender tissue swelling, which may be localized or diffuse (Fig. 9.50). In the hereditary forms, the initial onset typically is noted in childhood or adolescence except in the rare estrogen-related HAE-n-C1-INH pattern that usually arises in 20- to 30-year-old women. The episodes are unpredictable and intermixed with edema-free intervals. Recurrent skin swelling and abdominal pain are the most frequent presentations. The extremities are the most common cutaneous sites of involvement, although the face, genitals, trunk, and neck also can be affected. Although

• **Fig. 9.50 Angioedema.** Diffuse upper lip swelling that arose rapidly.

not individually frequent, edema of the larynx, pharynx, uvula, or soft palate may be noted when patients are monitored for extended periods (and may be associated with respiratory distress). A deeper voice, hoarseness, aphonia, and dyspnea are important warning signs. Recurrent snoring-induced edema of the soft palate has been reported and associated with severe dyspnea. Isolated tongue involvement is uncommon. Involvement of the skin and mucous membranes can cause enlargements that may measure up to several centimeters in diameter (Fig. 9.51). Although pain is unusual, itching is common, and erythema may be present. The enlargement typically resolves over 24–72 hours. In contrast to the hereditary variants, the allergic, acquired, and ACE inhibitor–associated angioedemas demonstrate significant involvement of the head and neck, such as the face, lips, tongue, floor of mouth, pharynx, and larynx. The risk of angioedema associated with ACE inhibitors is significantly greater in blacks (three to four times that of other races), and this pattern is the type most frequently encountered by oral health practitioners.

Diagnosis

In cases of allergic causation, the diagnosis of angioedema often is made from the clinical presentation in conjunction with the known antigenic stimulus. When multiple antigenic exposures occur, the diagnosis of the offending agent can be difficult and involves dietary diaries and antigenic testing.

Those patients whose conditions cannot be related to antigenic exposure or medications should be evaluated for the presence of adequate functional C1-INH. Except for the estrogen-related pattern, the hereditary types exhibit normal levels of C1 and decreased levels of *functional* C1-INH. Type I demonstrates a decreased quantity of C1-INH; type II exhibits normal levels of the inhibitor, but it is dysfunctional. The acquired type associated with lymphoproliferative diseases demonstrates low C1 and low C1-INH, whereas the autoimmune variant exhibits low C1 and dysfunctional C1-INH.

dentlearn.ir

• **Fig. 9.51 Angioedema. A,** Soft, nontender tissue swelling of the face arose relatively rapidly after dental treatment. **B,** Facial appearance after resolution of edematous facial enlargement.

Treatment and Prognosis

The treatment of allergic angioedema usually consists of oral antihistamine therapy. If the attack is not controlled or if laryngeal involvement is present, then intramuscular epinephrine should be administered. If the epinephrine does not stop the attack, then intravenous corticosteroids and antihistamines should be given. Vibratory angioedema is treated via elimination of the triggering physical stimulus. In cases related to chronic snoring, use of a continuous positive airway pressure (C-PAP) unit has proven successful.

The hereditary types of angioedema, those related to ACE inhibitors, and cases related to tPA use in strokes do not respond to antihistamines and corticosteroids, because the primary cause is generation of bradykinin. As highlighted in Fig. 9.49, the kallikrein pathway can be blocked by administration of C1-INH concentrate or by either one of two medications: ecallantide or icatibant. If none of these interventions are available, fresh frozen plasma contains C1-INH and represents an acceptable substitute. Although significantly less expensive than the alternatives, some investigators do not recommend use of fresh frozen plasma, because there is a risk of transmitting infection. In addition, it replaces not only C1-INH but also potentially harmful C1 esterase, C1, C2, and C4. Laryngeal edema is the most common cause of death from angioedema and reinforces the need for intubation or tracheostomy in patients with serious airway blockage. Patients experiencing ACE inhibitor–associated angioedema should avoid all medications in this class of drugs, and their physicians should consider alternative hypertension management strategies. Angiotensin II receptor blockers do not appear to be safe alternatives.

All patients with hereditary angioedema should carry medical warning cards that state the diagnosis and list elementary precautions. Prophylaxis for C1-INH deficiency is recommended in patients who have more than three attacks per year. Patients should avoid violent physical activity and trauma. Medical prophylaxis is recommended before any dental or surgical procedure, even interventions as minor as a dental impression. Current guidelines suggest administration of 1000 units of C1-INH concentrate as near as possible to the start of the procedure. Fresh frozen plasma also can be used but is less safe than C1-INH concentrate due to the problems delineated in the previous paragraph. Second-line prophylaxis is an attenuated androgen such as danazol or stanozolol which induces hepatic synthesis of C1-INH. Because epinephrine can trigger an attack, use of local anesthetic without a vasoconstrictor is recommended. Even with infusions of C1-INH concentrate prior to a dental procedure in a patient with the hereditary types, life-threatening angioedema remains possible with its occurrence possibly delayed up to 48 hours. For this reason, extended continuous monitoring of patients with hereditary angioedema is recommended following dental procedures. The autoimmune acquired type of angioedema is best prevented using corticosteroids.

10 Epithelial Pathology

◆ BENIGN EPITHELIAL LESIONS ASSOCIATED WITH HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) comprises a large group of double-stranded DNA viruses, belonging to the family *Papillomaviridae.* HPV exhibits tropism for squamous epithelium and may infect skin or mucosa. Mucosal infection may arise in the anogenital region, upper aerodigestive tract, and other sites. More than 200 HPV types have been identified in humans, including more than 30 types known to infect the oral mucosa in particular.

HPV is associated with a variety of benign, potentially malignant, and malignant epithelial lesions, but most infected individuals are asymptomatic and lack clinically evident disease. Based upon oncogenic potential, mucosal HPV types are categorized as either *low-risk* (e.g., types 6, 11, 13, 32, 40, 42, 43, 44, 54, 55, 61, 62, 64, 67, 69, 70, 71, 72, 81, and others) or *high-risk* (e.g., types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68, 73, and others).

The reported prevalence of asymptomatic oral HPV infection varies considerably, likely due to differences in sampling techniques, detection methods, and study cohorts. Many studies have analyzed shed epithelial cells in oral rinses, although such samples do not discriminate between oral cavity and oropharyngeal infection. Notwithstanding, meta-analyses and systematic reviews of the literature suggest that oral HPV infection is present in approximately 5%–8% of normal, healthy individuals worldwide. Most studies report a male predilection, although reported gender distribution is variable. In the United States, a population-based study conducted as part of the National Health and Nutrition Examination Survey (NHANES) for 2011–2014 estimated the prevalence of oral HPV infection among individuals 18–69 years old to be 11.5% among men and 3.2% among women. In this study, the age distribution for men with oral HPV infection exhibited a bimodal pattern, with peaks at 35–39 and 50–54 years. Notably, the prevalence of oral infection with high-risk HPV types was substantially greater among men compared to women (7.3% vs 1.4%, respectively). Also, there was an increased frequency of oral HPV infection among men with concurrent genital infection.

Factors associated with an increased prevalence of oral HPV infection include tobacco smoking, an increased number of lifetime sexual partners, an increased number of recent sexual partners, and human immunodeficiency virus (HIV) infection. In addition, some investigators have suggested possible associations with periodontitis, gingivitis, or poor oral hygiene, although the significance of these findings is uncertain.

Proposed modes of transmission for oral HPV infection include sexual and nonsexual person-to-person contact, salivary transfer, contaminated objects, autoinoculation, breast-feeding, perinatal transmission, and, possibly, prenatal transmission. In particular, orogenital transmission of the virus seems to be higher from women to men than from men to women. Among newborns, some studies have detected oral and nasopharyngeal HPV in as many as 23% and 37%, respectively, although most of these infections are cleared within the first few years of life. The exact route of transmission to newborns is uncertain, although exposure via the birth canal, umbilical cord blood, or amniotic fluid has been postulated.

The natural history of oral HPV infection is not well characterized. It appears that in most people the infection clears quickly, whereas in some individuals the infection persists. However, reported clearance rates are highly variable (range 0%–80%), probably due to differences in study design and methods. Factors associated with persistent oral infection include male gender, older age, human immunodeficiency virus (HIV) infection, and cigarette smoking.

HPV may enter the epithelium via microabrasion or trauma and initially infects the basal epithelial cells. Host cell entry occurs by endocytosis, and the episomal viral DNA (i.e., circular extrachromosomal molecule) is transported to the nucleus. In normal-appearing skin or mucosa, the virus may remain in a latent state within the nuclei of basal epithelial cells; in such cases, the episomal viral DNA is present in low copy numbers. In contrast, in benign and low-grade premalignant HPV-associated lesions, episomal HPV DNA typically is present within the various epithelial cell layers in increased copy numbers, with shedding of mature virions from the superficial cells. With division of each infected basal epithelial cell, one daughter cell remains in the basal layer to maintain a viral reservoir; the other daughter cell migrates into the suprabasal layers, interferes with cell cycle regulation, and uses the host cell machinery to synthesize proteins needed for viral replication. In the presence of high episomal numbers, viral DNA may become integrated into the host genome,

TABLE 10.1 Human Papillomavirus Types for Select Lesions

Site Predilection	Lesion	Major HPV Types	Other Reported HPV Types
Oral/head and neck mucosa	Oral squamous papilloma	6, 11	5, 12, 16, 18, 22–24, 35, 51, 96, 110, 120, 121, 123, 130, 131, 156, 161
	Recurrent respiratory papillomatosis	6, 11	8, 16, 18, 31, 33, 35, 44, 45, 55, 70, 76, 84
	Exophytic sinonasal papilloma	6, 11	16, 57, 91
	Inverted sinonasal papilloma	6, 11, 16, 18	42, 57, 58, 83
	Multifocal epithelial hyperplasia	13, 32	1, 6, 11, 16, 18, 31, 39, 40, 51, 52, 55, 58, 66, 68, 69, 71, 74, 90
	Oropharyngeal squamous cell carcinoma	16	18, 26, 33, 35, 45, 52, 58, 67, 69
	Conjunctival papilloma	6, 11	5, 13, 16, 20, 23, 33, 45
Skin	Verruca vulgaris	2	1, 4, 6, 7, 10, 11, 26, 27, 29, 41, 57, 65, 75–77
	Verruca plana	3, 10	2, 5, 26–29, 38, 41, 49, 75, 76
	Palmoplantar wart	1, 4	2, 27, 41, 45, 57, 60, 63, 65, 66
	Butcher's wart	2, 7	1, 3, 4, 10, 28
Anogenital region	Condyloma acuminatum	6, 11	1, 2, 4, 6, 7, 9, 16, 18, 27, 31, 33, 35, 38–45, 51–59, 65, 66, 68, 70, 81
	Intraepithelial neoplasia	6, 11, 16, 18, 31, 33	26, 35, 39, 42, 43, 45, 51, 52, 53, 56, 58, 59, 66, 68, 70, 73, 81–83
	Cervical squamous cell carcinoma	16, 18	6, 11, 31, 33, 35, 39, 42, 45, 51, 52, 56, 58, 59, 66, 68, 73

HPV, Human papillomavirus.

leading to expression of oncoproteins and inactivation of tumor suppressor genes. Integrated HPV DNA often is found in HPV-associated malignancies and high-grade premalignant lesions, but it is not an absolute requirement for development of such lesions. Compared with HPV infection, HPV-induced malignant transformation is relatively rare. The incubation period for benign HPV disease is estimated to range from 3 weeks to 2 years, whereas the latency for development of HPV-associated malignancy may be 1 to several decades.

In the United States, routine HPV vaccination was introduced in 2006, with various modifications in vaccine policy, design, and licensing over the years. In current use is a 9-valent recombinant vaccine (Gardasil 9) targeting HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58. The Advisory Committee on Immunization Practices recommends routine HPV vaccination for adolescents 11–12 years of age and catch-up HPV vaccination for individuals through 26 years of age. In addition, HPV vaccination may be considered for inadequately vaccinated adults 27 through 45 years of age in consultation with a clinician. Two doses typically are administered 6–12 months apart for immunocompetent individuals under 15 years of age; three doses over 6 months are recommended for individuals 15 years of age or older and for immunocompromised patients at any age. The vaccine is indicated for prevention of genital warts; precancers and cancers of the uterine cervix, vulva, vagina, and anus; and oropharyngeal and other head and neck cancers. The latter indication was granted accelerated approval based on surrogate efficacy data for HPV-related anogenital disease and is subject to post-approval confirmatory studies currently underway.

The following sections discuss benign HPV-associated lesions of the oral cavity and other head and neck sites. HPV-associated malignancies are addressed later in this chapter. Examples of HPV-related lesions and their corresponding virus types are listed in Table 10.1.

SQUAMOUS PAPILLOMA

The **squamous papilloma** is a benign proliferation of stratified squamous epithelium, resulting in a papillary or verruciform mass. In the upper aerodigestive tract, squamous papillomas most often involve the oral cavity, oropharynx, and larynx. The lesion generally is considered to be induced by HPV, with HPV types 6 and 11 identified most commonly. However, HPV detection rates vary considerably across studies, likely due to differences in detection methods and viral types assayed. HPV can be demonstrated in most laryngeal papillomas (approximately 90%–95% as per more recent studies) but in only a minority of oral cases. HPV testing typically is not needed for routine diagnosis and management of papillomas in the oral cavity, oropharynx, and larynx.

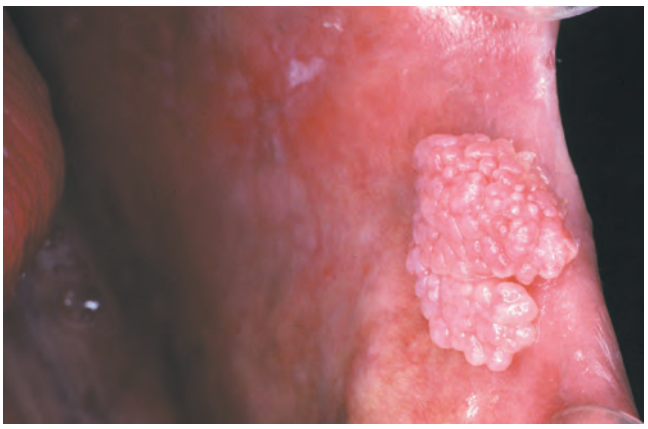
Oral squamous papillomas are relatively common and comprise approximately 3% of all oral lesions submitted for biopsy. In addition, researchers have estimated that

dentlearn.ir

squamous papillomas comprise 7%–8% of all oral masses or growths in children.

Clinical Features

Most studies have reported either no significant gender predilection or a slight male predominance. Some authors have asserted that the oral squamous papilloma develops predominantly in children; however, the lesion can arise at any age and, in fact, is diagnosed most often in persons 30–50 years old. Sites of predilection include the palate, tongue, and lips, but any oral surface may be affected. This lesion is the most common soft tissue mass arising from the soft palate.

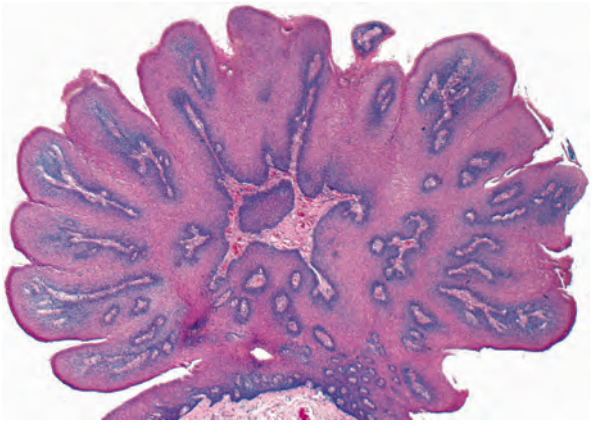


The squamous papilloma is a soft, painless, usually pedunculated, exophytic nodule with numerous fingerlike surface projections that impart a "cauliflower" or wartlike appearance (Fig. 10.1). Projections may be pointed or blunted (Figs. 10.2 and 10.3), and the lesion may be white, slightly red, or normal in color, depending on the amount of surface keratinization. The papilloma is usually solitary and enlarges rapidly to a maximum size of about 0.5 cm, with little or no change thereafter. However, lesions as large as 3.0 cm in greatest diameter have been reported.

• **Fig. 10.1 Squamous Papilloma.** An exophytic lesion of the soft palate with multiple short, white surface projections.

• **Fig. 10.2 Squamous Papilloma.** A pedunculated lingual mass with numerous long, pointed, and white surface projections. Note the smaller projections around the base of the lesion.

• **Fig. 10.3 Squamous Papilloma.** A pedunculated mass of the buccal commissure, exhibiting short or blunted surface projections and minimal white coloration.



It is sometimes difficult to distinguish this lesion clinically from verruca vulgaris (see page 357), condyloma acuminatum (see page 358), verruciform xanthoma (see page 365), multifocal epithelial hyperplasia (see page 360), or giant cell fibroma (see page 514). In addition, extensive coalescing papillary lesions **(papillomatosis)** of the orofacial region may be seen in several syndromes and skin disorders, including nevus unius lateris, acanthosis nigricans, focal dermal hypoplasia (Goltz-Gorlin) syndrome, Costello syndrome, and Down syndrome.

Also attributed mainly to HPV 6 and 11 infection, **recurrent respiratory papillomatosis (RRP)** is a rare and potentially devastating disease of the respiratory tract with a predilection for the larynx. RRP includes two distinct types: (1) **juvenile-onset** and (2) **adult-onset.** Hoarseness is the usual presenting feature, and rapidly proliferating papillomas in the juvenile-onset type may obstruct the airway. The strongest risk factor for juvenile-onset RRP is a maternal history of anogenital warts during pregnancy; HPV transmission via the birth canal, the placenta, or amniotic fluid has been hypothesized.

Histopathologic Features

The papilloma is characterized by a proliferation of keratinized stratified squamous epithelium arranged in fingerlike projections with fibrovascular connective tissue cores (Fig. 10.4). The connective tissue may show inflammation. The keratin layer is thickened in lesions with a white clinical appearance, and the epithelium typically exhibits a normal maturation pattern. However, some papillomas demonstrate basilar hyperplasia and mitotic activity, which can be mistaken for mild epithelial dysplasia. **Koilocytes** (virus-altered epithelial cells with crenated, pyknotic [small and dark] nuclei surrounded by clear halos) sometimes are evident high in the spinous cell layer. Similarities in microscopic features may make distinction of squamous papilloma from verruca vulgaris and condyloma acuminatum difficult.

dentlearn.ir

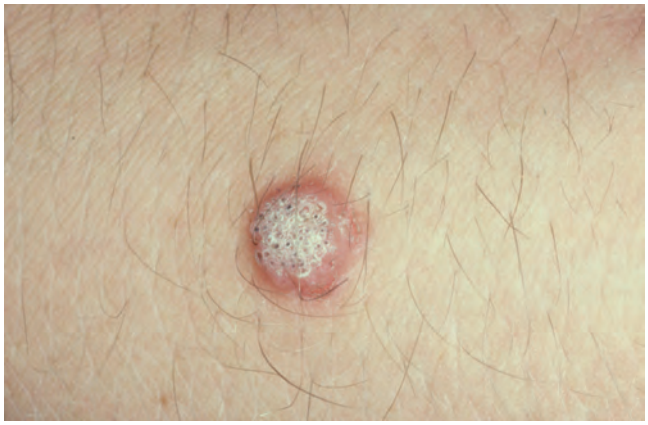
• **Fig. 10.4 Squamous Papilloma.** Low-power view showing a pedunculated squamous epithelial proliferation. There are multiple papillary projections with fibrovascular connective tissue cores.

Treatment and Prognosis

Conservative surgical excision, including the base of the lesion, is adequate treatment for the oral squamous papilloma, and recurrence is unlikely. Frequently, lesions have been left untreated for years with no reported malignant transformation, continuous enlargement, or dissemination to other parts of the oral cavity or orohparynx.

Although spontaneous remission is possible, juvenile-onset RRP tends to be continuously proliferative, sometimes leading to death by asphyxiation. Some investigators have noted especially aggressive behavior among cases associated with HPV 11 infection. The papillomatosis is treated by repeated surgical debulking procedures to relieve airway obstruction. Use of a microdebrider may decrease the risk for postsurgical scarring and loss of vocal cord function. Adjuvant therapy with interferon-alpha, cidofovir, bevacizumab, or other agents has yielded variable results. Adult-onset RRP typically is less aggressive and more localized. Conservative surgical removal may be necessary to eliminate hoarseness from vocal cord involvement. A few studies suggest that HPV vaccination may be beneficial for prevention and adjuvant treatment of RRP, although further investigation is needed. Transformation of RRP into squamous cell carcinoma is rare (occurring in <1% of juvenile-onset cases and about 3%–6% of adult-onset cases).

VERRUCA VULGARIS (COMMON WART)



Verruca vulgaris is a focal, benign, HPV-induced hyperplasia of stratified squamous epithelium. HPV 2 is present most often, although other HPV types may be found as well (see Table 10.1). Verruca vulgaris is contagious and can spread to other parts of a person's skin or mucosa by autoinoculation. It infrequently develops on oral mucosa but is extremely common on the skin.

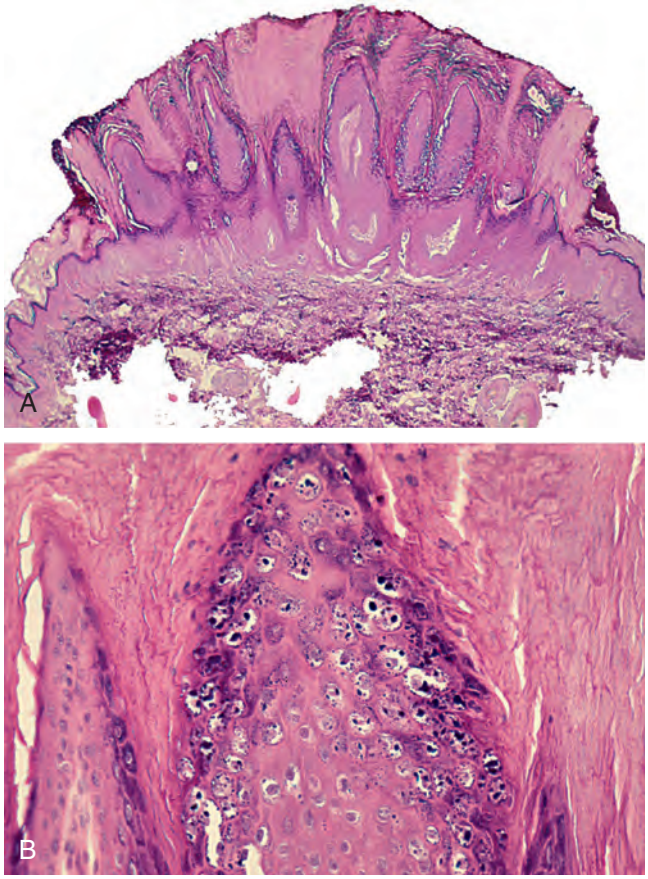
Clinical Features

Verruca vulgaris most often arises in children but occasionally may develop even into middle age. The skin of the hands is the most commonly involved site (Fig. 10.5). Oral mucosal lesions usually are found on the vermilion border, labial mucosa, or anterior tongue.

• **Fig. 10.5 Verruca Vulgaris.** Several warts on the finger, exhibiting a rough, papillary surface.

• **Fig. 10.6 Verruca Vulgaris.** Nodular lesion of the skin exhibiting numerous short papillary projections.

• **Fig. 10.7 Verruca Vulgaris.** White, papillary lesion on the upper lip vermilion. (Courtesy of Dr. Laura Summers.)



Typically, the verruca appears as a painless papule or nodule with papillary projections or a rough, pebbly surface (Figs. 10.6 and 10.7). It may be pedunculated or sessile. Cutaneous lesions may be pink, yellow, or white; oral lesions are almost always white. Verruca vulgaris enlarges rapidly to its

dentlearn.ir

maximum size (usually <5 mm), and the size remains constant for months or years thereafter unless the lesion is irritated. Multiple or clustered lesions are common. On occasion, extreme accumulation of compact keratin may result in a hard surface projection, termed a **cutaneous horn** or **keratin horn.** Other cutaneous lesions, including seborrheic keratosis (see page 366), actinic keratosis (see page 396), and squamous cell carcinoma, also may create a cutaneous horn.

Histopathologic Features

Verruca vulgaris is characterized by a proliferation of hyperkeratotic stratified squamous epithelium arranged in fingerlike, pointed projections with connective tissue cores (Fig. 10.8). Chronic inflammatory cells often infiltrate the supporting connective tissue. Elongated rete ridges tend to converge toward the center of the lesion, producing a "cupping" effect. A prominent granular cell layer (hypergranulosis) exhibits coarse, clumped keratohyaline granules. Abundant koilocytes often are seen in the superficial spinous layer. Koilocytes are HPV-altered epithelial cells with perinuclear clearing and crenated, pyknotic nuclei. Eosinophilic intranuclear viral inclusions sometimes are noted within the cells of the granular layer.

• **Fig. 10.8 Verruca Vulgaris. A,** Numerous papillary projections are covered by hyperkeratotic stratified squamous epithelium. Elongated rete ridges at the edge of the lesion converge toward the center. **B,** High-power view showing clear koilocytes in the upper epithelial layers.

Treatment and Prognosis

Verrucae often resolve spontaneously over time in immunocompetent individuals. Approximately two-thirds will disappear without treatment within 2 years, especially in children. However, removal may be considered for lesions that persist, spread, cause cosmetic concern, or produce discomfort. Commonly used treatments for cutaneous verrucae include topical salicylic acid, topical lactic acid, and cryotherapy. Surgical excision is indicated only for cases with an atypical clinical presentation in which the diagnosis is uncertain. Skin lesions that recur or are resistant to standard therapy may be treated by alternative methods, such as intralesional bleomycin, topical or intralesional 5-fluorouracil, cantharidin, immunotherapy with contact sensitizers (e.g., diphenylcyclopropenone, squaric acid dibutylester), intralesional immunotherapy (e.g., with *Candida* or mumps skin antigen, purified protein derivative), topical imiquimod, trichloroacetic acid, pulsed dye laser therapy, or photodynamic therapy.

Oral lesions usually are excised surgically, or they may be destroyed by laser, cryotherapy, or electrosurgery. Cryotherapy induces a subepithelial blister that lifts the infected epithelium from the underlying connective tissue, allowing it to slough away. All destructive or surgical treatments should extend to the base of the lesion.

Recurrence is seen in a small proportion of treated cases. There is no potential for malignant transformation.

CONDYLOMA ACUMINATUM (VENEREAL WART)

Condyloma acuminatum is a HPV-induced proliferation of stratified squamous epithelium of the anogenital region, mouth, and larynx. Approximately 90% of cases are attributed to HPV 6 and 11, although coinfection with various other types—including the high-risk types 16 and 18—is frequent (see Table 10.1).

Condyloma acuminatum represents a common sexually transmitted disease (STD), affecting about 1% of the sexually active population. However, since the introduction of HPV vaccination, significant reductions in incidence have been reported in many regions. Condyloma may be an indicator of sexual abuse when diagnosed in young children. In addition, studies of oral cavity and pharyngeal HPV infection in infants have suggested that vertical transmission from mothers with genital HPV infection may occur perinatally or perhaps *in utero*. Spread via contaminated environmental surfaces has been postulated as well. Oral and anogenital condylomata may be present concurrently. The incubation period is about 1–3 months, and autoinoculation of additional mucosal sites is possible.

Clinical Features

Condylomata usually are diagnosed in teenagers and young adults, but people of all ages are susceptible. Oral lesions most frequently occur on the labial mucosa and lingual

dentlearn.ir

frenum; the soft palate often is involved as well. The typical condyloma appears as a sessile, pink, well-demarcated, nontender, exophytic mass with short, blunted surface projections (Fig. 10.9). The condyloma tends to be larger than the papilloma and characteristically is clustered with other condylomata. The average size is 1.0–1.5 cm, but oral lesions as large as 3 cm have been reported.

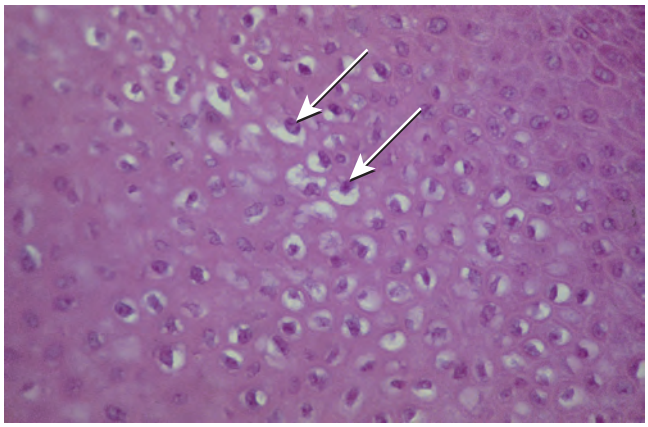
Histopathologic Features

Condyloma acuminatum appears as a benign proliferation of acanthotic stratified squamous epithelium with mildly keratotic, papillary surface projections (Fig. 10.10). Thin connective tissue cores support the papillary projections, which are more blunted and broader than those of squamous papilloma and verruca vulgaris. Keratin-filled crypts often are seen between the papillary projections. In some cases, lesions may extend from the surface mucosa to involve the underlying salivary ductal epithelium; such lesions should be distinguished from salivary ductal papillomas (see page 492).

• **Fig. 10.9 Condyloma Acuminatum.** Two lesions of the upper lip mucosa exhibit short, blunted projections. (Courtesy of Dr. Brian Blocher.)

• **Fig. 10.10 Condyloma Acuminatum.** Medium-power photomicrograph showing acanthotic stratified squamous epithelium forming a blunted projection.

The surface epithelium is mature and differentiated, but within the spinous cell layer, there are often **koilocytes** (HPV-altered cells with pyknotic, crinkled [or "raisin-like"] nuclei) (Fig. 10.11). Koilocytes may be less prominent in oral lesions compared with genital lesions, in which case distinction from squamous papilloma may be difficult. Ultrastructural examination reveals virions within the cytoplasm or nuclei of koilocytes, and the virus also can be demonstrated by immunohistochemical analysis, *in situ* hybridization (ISH), and polymerase chain reaction (PCR).



Treatment and Prognosis

Oral condylomata usually are treated by conservative surgical excision. Cryotherapy and laser ablation also may be used. However, there is some concern regarding the potential for laser therapy to produce an infectious plume that exposes the surgical team and patient to airborne HPV.

For anogenital condylomata, patient-applied topical agents (such as, imiquimod, podophyllotoxin, and sinecatechins) are becoming the mainstay of treatment. However, such treatments typically are not used for oral lesions. Anogenital warts that do not completely resolve with patient-applied treatment may be ablated by cryotherapy, laser, or electrosurgery. Additional treatment options include trichloroacetic acid, systemic, or intralesional interferon, and topical cidofovir. Interestingly, there are a few anecdotal reports of regression following HPV vaccination.

Regardless of the method used, condylomata should be treated because they are contagious and can spread by autoinoculation or to other persons. Notwithstanding, available treatments do not completely eradicate HPV infection or the potential for future viral transmission; recurrence has been reported in approximately 20%–50% of anogenital cases. Therefore, clinical follow-up is recommended.

Anogenital condylomata infected with HPV 16 or 18 are associated with an increased risk for malignant transformation to squamous cell carcinoma, but such transformation has not been well documented in oral lesions. Interestingly, a recent population-based study of Danish patients with

• **Fig. 10.11 Condyloma Acuminatum.** High-power photomicrograph demonstrating koilocytes *(arrows)* in the spinous layer.

dentlearn.ir

genital condylomata reported a long-term, increased risk for not only anogenital but also head and neck cancer. Proposed explanations for this observation include an immunologic predisposition to persistent HPV infection (resulting in increased risk for HPV-related head and neck cancer) and behavioral cofactors (e.g., tobacco and alcohol consumption, male homosexual behavior).

HPV vaccination (see page 355) is useful for the prevention of anogenital condylomata; vaccination would be expected to aid in preventing oral lesions as well, although the impact of HPV vaccination on oral condylomata requires study.

MULTIFOCAL EPITHELIAL HYPERPLASIA (HECK DISEASE; MULTIFOCAL PAPILLOMA VIRUS EPITHELIAL HYPERPLASIA; FOCAL EPITHELIAL HYPERPLASIA)

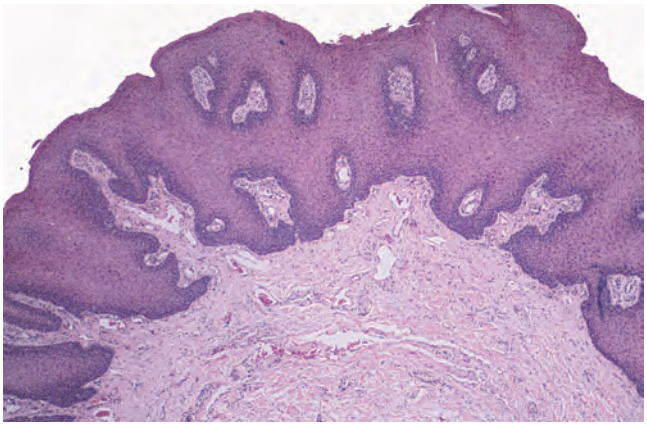
Multifocal epithelial hyperplasia is a squamous epithelial proliferation primarily attributed to HPV 13 and 32. However, infection or co-infection with various other HPV types occasionally has been reported (Table 10.1). The condition initially was described in Native Americans and Inuits but subsequently has been noted in many populations and ethnic groups. A high proportion of reported cases have been from the Americas and Europe. In some populations, nearly 40% of children are affected. Multifocal epithelial hyperplasia often affects multiple members of a given family; this familial tendency may be related to either genetic susceptibility or HPV transmission between family members. An association with the HLA-DR4 (DRB1*0404) allele has been described, and transmission via saliva has been postulated (possibly through shared use of eating utensils or toothbrushes). Lower socioeconomic status, crowded living conditions, poor hygiene, malnutrition, and HIV infection or other immunodeficiency states appear to be additional risk factors. Although originally reported as "focal epithelial hyperplasia," the term *multifocal epithelial hyperplasia* is preferred because patients usually exhibit multiple lesions.

Clinical Features

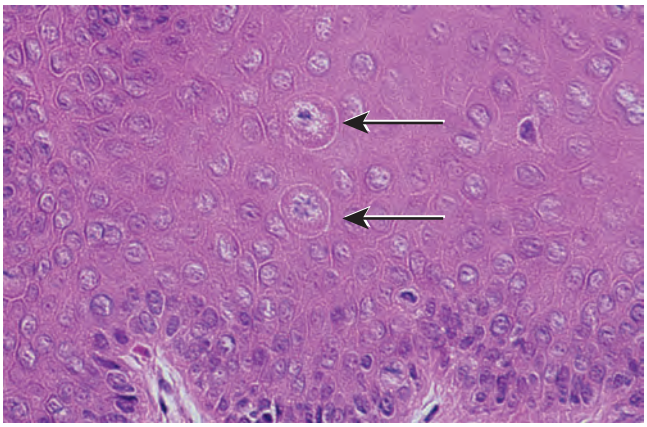
Multifocal epithelial hyperplasia predominantly arises in young individuals, with a mean age of 23 years and a broad age range of 3–92 years. There is a slight female predilection. The most common sites of involvement include the labial, buccal, and lingual mucosa, but gingival, palatal, oral floor, and tonsillar lesions also are possible. In addition, involvement of the conjunctiva has been described very rarely.

There are two major clinical variants: papulonodular and papillomatous. The more common papulonodular variant is characterized by pink, smooth-surfaced papules and nodules, with a predilection for the buccal mucosa, labial mucosa, and commissure (Fig. 10.12). The papillomatous variant appears as white to pale pink, pebbly nodules on the tongue and attached gingiva (Fig. 10.13). In both variants, the individual lesions are usually small (0.1–1.0 cm), discrete, and well-demarcated; however, they may coalesce to produce a cobblestone or fissured appearance, and individual lesions up to 3 cm in diameter are also possible. According to some authors, the lesions tend to be smaller, fewer in number, and less exophytic among older patients compared to younger patients; this observation may reflect spontaneous regression over time.

• **Fig. 10.12 Multifocal Epithelial Hyperplasia.** Multiple, flat-topped papules and nodules of normal coloration are seen on the lower lip of a child. (Courtesy of Dr. Mark Casafrancisco.)



• **Fig. 10.13 Multifocal Epithelial Hyperplasia.** The lesions may demonstrate a papillary surface change and paleness, as demonstrated on this child's tongue. (Courtesy of Dr. Román Carlos.)



Histopathologic Features

The hallmark of multifocal epithelial hyperplasia is an abrupt and sometimes considerable acanthosis of the surface epithelium (Fig. 10.14). Because the thickened mucosa extends upward, the lesional rete ridges are at the same depth as the adjacent, normal rete ridges. The rete ridges are widened, often confluent, and sometimes club-shaped. Some superficial keratinocytes show koilocytic change similar to that seen in other HPV infections. Others occasionally demonstrate an altered nucleus that resembles a mitotic figure

dentlearn.ir

• **Fig. 10.14 Multifocal Epithelial Hyperplasia.** Prominent acanthosis of the epithelium with broad and elongated rete ridges. The slightly papillary surface alteration noted here may or may not be present.

• **Fig. 10.15 Multifocal Epithelial Hyperplasia.** Mitosoid cells *(arrows)* contain altered nuclei in this otherwise mature and well-differentiated stratified squamous epithelium.

(mitosoid cell) (Fig. 10.15). Viruslike particles have been noted ultrastructurally within both the cytoplasm and the nuclei of cells within the prickle cell layer, and the presence of HPV has been demonstrated by DNA *in situ* hybridization, immunohistochemistry, and polymerase chain reaction (PCR).

Treatment and Prognosis

Spontaneous regression has been reported after months or years and is inferred from the rarity of the disease in adults. Conservative surgical excision may be performed for diagnostic or aesthetic purposes or for lesions subject to recurrent trauma. Lesions also can be removed by cryotherapy, carbon dioxide (CO_2) laser, or electrocoagulation. Alternative treatments include trichloroacetic acid, topical interferon-beta, systemic or intralesional interferon-alpha, and topical imiquimod. Recurrence (after either treatment or spontaneous regression) is possible. There seems to be no malignant transformation potential.

SINONASAL PAPILLOMAS (SCHNEIDERIAN PAPILLOMAS)

Sinonasal papillomas are benign, localized proliferations of the sinonasal mucosa and include three histomorphologically distinct types:

1. Exophytic
2. Inverted
3. Oncocytic

Lesions exhibiting features of both the inverted and the oncocytic types may be termed *mixed* or *hybrid* papillomas. In addition, a keratinizing **squamous papilloma,** similar to the oral squamous papilloma (see page 355), rarely may occur in the nasal vestibule.

Collectively, sinonasal papillomas represent 10%–25% of all sinonasal tumors. About half of sinonasal papillomas arise from the lateral nasal wall; the remainder predominantly involves the maxillary and ethmoid sinuses and the nasal septum. Multiple lesions may be present.

The etiopathogenesis of sinonasal papillomas remains unclear. Historically, numerous contributory factors—such as allergy, chronic sinusitis, nasal polyps, organic solvents, and tobacco smoke or other airborne pollutants—have been proposed but remain unsubstantiated. A variable association with HPV infection has been reported, with the strongest association noted for the exophytic type. According to a meta-analysis of studies using various HPV detection methods, approximately 39% of sinonasal papillomas are HPV-positive, with HPV prevalence rates for the exophytic, inverted, and oncocytic types of 65%, 38%, and 23%, respectively.

EXOPHYTIC (SEPTAL; SQUAMOUS; FUNGIFORM) SINONASAL PAPILLOMA

The **exophytic sinonasal papilloma** bears some similarity to the oral squamous papilloma, although it has a somewhat more aggressive biologic behavior and more varied epithelial types. It represents approximately 20%–25% of all sinonasal papillomas. The majority of cases are positive for HPV 6 or 11.

Clinical Features

The exophytic sinonasal papilloma arises almost exclusively on the nasal septum and is more common in men than women (2:1 to 10:1 male-to-female ratio). It occurs primarily in people 20–50 years of age. Typically, it causes unilateral nasal obstruction or epistaxis and appears as a pink or tan, broad-based nodule with papillary or warty surface projections (Fig. 10.16). Most lesions measure less than 2 cm in maximum diameter.

Histopathologic Features

The exophytic sinonasal papilloma has a microscopic appearance similar to that of the oral squamous papilloma, although the stratified squamous epithelium covering the fingerlike

dentlearn.ir

projections seldom is keratinized. Respiratory epithelium or "transitional" epithelium (intermediate between squamous and respiratory) may be seen in some lesions. Mucous (goblet) cells and intraepithelial microcysts containing mucus often are present. Intraepithelial neutrophils occasionally may be evident as well, and focal koilocytic changes may be noted in the superficial epithelial layers. Mitoses are infrequent, and dysplasia is rare. The lamina propria consists of delicate fibrous tissue with a minimal inflammatory component, unless it is irritated.

Treatment and Prognosis

Complete surgical excision is the treatment of choice for the exophytic sinonasal papilloma. Recurrence has been reported in approximately 20%–30% of cases; however, some of these cases may reflect incomplete excision rather than true recurrence. Most authorities consider this lesion to have minimal or no potential for malignant transformation.

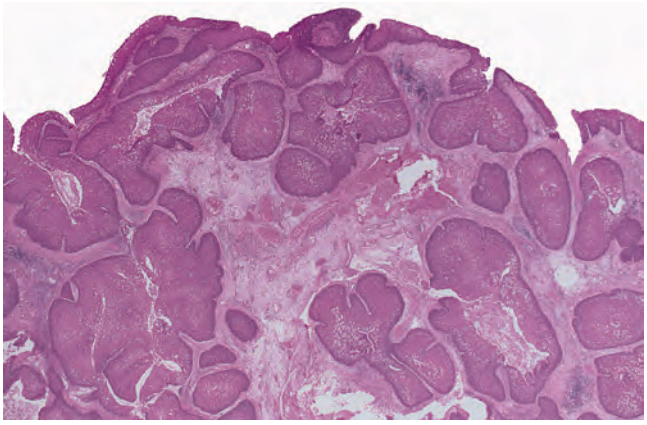
INVERTED SINONASAL PAPILLOMA (INVERTED SCHNEIDERIAN PAPILLOMA; ENDOPHYTIC SINONASAL PAPILLOMA)

The **inverted sinonasal papilloma** is the most common sinonasal papilloma variant, comprising approximately 65%–75% of cases. It is also the variant with the greatest potential for local destruction and malignant transformation. The estimated incidence is 0.2–1.5 cases per 100,000 persons per year. As many as approximately 38% of cases are HPV-positive, with HPV 6, 11, 16, and 18 representing the most prevalent types.

Molecular genetic studies support that inverted papillomas represent true neoplasms of monoclonal origin (i.e., arising from a single progenitor cell). Investigators have identified activating *EGFR* mutations in a majority of cases examined, including lesions with or without malignant transformation; such mutations have not been found in exophytic or oncocytic sinonasal papillomas. Interestingly, *EGFR* mutations and HPV tend to occur within inverted sinonasal papillomas in a mutually exclusive manner, which suggests the possibility of alternative mechanisms for lesion development and carcinogenesis. Furthermore, *TP53* and *CDKN2A* alterations may be early events in malignant transformation.

• **Fig. 10.16 Exophytic Sinonasal Papilloma.** Erythematous, papillary growth on the nasal septum.

Clinical and Radiographic Features



The average age at presentation is 53 years, with a peak in the fifth and sixth decades. There is a male predilection (2:1 to 3:1 male-to-female ratio). Inverted sinonasal papillomas arise predominantly from the lateral nasal wall or a paranasal sinus, usually the antrum. Typical signs and symptoms include unilateral nasal obstruction, epistaxis, purulent discharge, hyposmia, headache, or local deformity. The lesion appears as a soft, pink-tan to reddish gray, polypoid, or nodular growth, often with a "mulberry-like" or cerebriform surface. Multiple lesions may be present. Bilateral involvement occurs in only about 5% of cases. The lesion has significant growth potential and, if neglected, may extend into the nasopharynx, middle ear, orbit, or cranial base.

Pressure erosion of the underlying bone often is evident radiographically. Primary sinus lesions may appear only as a soft tissue radiodensity or mucosal thickening on radiographs; sinus involvement generally represents extension from the nasal cavity. Focal hyperostosis demonstrated by computed tomography (CT) scan may indicate the site of lesion attachment, which is important for surgical planning. In addition, magnetic resonance imaging (MRI) can help to identify the extent of the lesion and often reveals a convoluted, cerebriform pattern (Fig. 10.17). Focal loss of this characteristic pattern may indicate malignant transformation.

• **Fig. 10.17 Inverted Papilloma.** Magnetic resonance image (MRI) showing a tumor with a characteristic convoluted, cerebriform pattern. (Courtesy of Dr. Zoran Rumboldt.)

dentlearn.ir

• **Fig. 10.18 Inverted Papilloma.** Low-power photomicrograph showing a squamous epithelial proliferation, with multiple "inverting" islands of epithelium extending into the underlying connective tissue.

Histopathologic Features

The inverted sinonasal papilloma microscopically exhibits downward proliferation of squamous or transitional epithelium into the stroma (Fig. 10.18). The basement membrane remains intact, and the epithelium appears to "push" into the underlying connective tissue. Goblet (mucous) cells, mucin-filled microcysts, transmigrating neutrophils, and neutrophilic microabscesses frequently are noted within the epithelium. Keratin production is uncommon, but thin surface keratinization may be seen. Mitoses often are noted within the basilar or parabasilar cells, and varying degrees of epithelial atypia may be evident. Papillary surface projections separated by deep clefts may be observed. The stroma consists of dense or myxomatous connective tissue with or without inflammatory cells. Destruction of underlying bone frequently is noted. Marked surface keratinization and moderate to severe dysplasia are worrisome histopathologic findings that warrant careful microscopic examination to rule out malignancy. Nonetheless, there are no histopathologic features that are reliably predictive of malignant transformation. Some studies suggest that the presence of HPV 16 or 18 may be associated with an increased risk for malignant transformation; however, RNA *in situ* hybridization for detection of transcriptionally active high-risk HPV has yielded mostly negative or minimal results in inverted sinonasal papillomas with or without associated carcinoma. Interestingly, a recent study suggests that there may be an increased risk for malignancy in a subset of nasal cavity inverted papillomas with transcriptionally active low-risk HPV infection, condyloma-like morphology, and no *EGFR* mutations. However, further studies are needed.

Treatment and Prognosis

Over the past few decades, the preferred treatment has shifted from traditional open surgery (i.e., medial maxillectomy with ethmoidectomy via a lateral rhinotomy or midfacial degloving approach) to transnasal endoscopic surgery. Depending upon the extent and accessibility of disease, endoscopic and external surgical approaches may be combined. Average recurrence rates among studies conducted within the past few decades are approximately 11%–13% for patients treated by endoscopic or combined surgery and 18% for those treated by open surgery. Recurrences usually are noted within 2 years of treatment but can happen much later. Hence, long-term follow-up is essential. Frontal sinus involvement and continued tobacco smoking are associated with an increased risk for recurrence.

Approximately 5%–15% of inverted sinonasal papillomas transform into malignancy (usually squamous cell carcinoma). Malignancy may be synchronous or metachronous. When malignancy is present, treatment typically consists of radical surgery, with or without adjunctive radiotherapy. According to a recent systematic review and meta-analysis, the overall 5-year survival rate is higher for inverted papilloma-associated sinonasal squamous cell carcinoma compared to *de novo* sinonasal squamous cell carcinoma (65% vs 56%, respectively).

ONCOCYTIC SINONASAL PAPILLOMA (ONCOCYTIC SCHNEIDERIAN PAPILLOMA; CYLINDRICAL CELL PAPILLOMA)

The **oncocytic sinonasal papilloma** accounts for less than 7% of sinonasal papillomas. Some authorities consider this lesion to be a variant of the inverted type because of the similarity in clinicopathologic features and a similarly low frequency of HPV. Recent studies have detected activating *KRAS* mutations in the majority of cases examined, including a few associated with malignant transformation; such mutations have not been found in inverted or exophytic sinonasal papillomas.

Clinical Features

The oncocytic sinonasal papilloma most often occurs in adults older than 50 years. Most authors report either a male predominance or no significant gender bias. There is a predilection for the lateral nasal wall, maxillary antrum, and ethmoid sinus. The most common presenting symptom is unilateral nasal obstruction, and the lesion appears as a beefy-red or brown mass with a multinodular surface.

Histopathologic Features

Microscopically, the oncocytic sinonasal papilloma demonstrates both endophytic and exophytic growth. Surface papillary projections have a fibrovascular connective tissue core and are covered by a multilayered epithelium of tall columnar cells with small, dark nuclei and eosinophilic, occasionally granular cytoplasm. The lesional epithelial cell is similar to an oncocyte. Cilia may be seen on the surface, and there are numerous intraepithelial microcysts filled with mucin, neutrophils, or both.

dentlearn.ir

Treatment and Prognosis

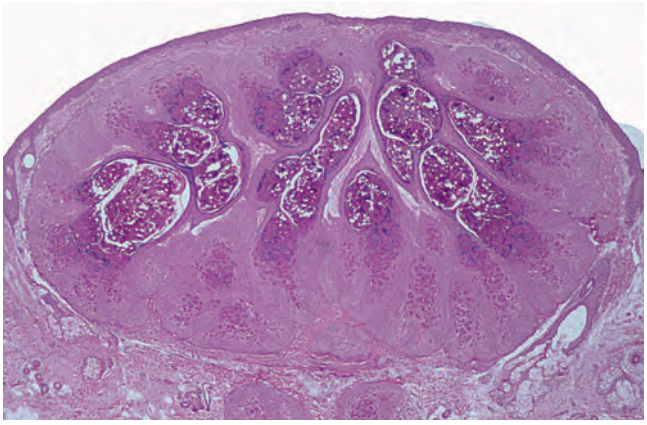
The treatment and recurrence potential for oncocytic sinonasal papilloma and inverted sinonasal papilloma (see previous topic) are similar. Reported malignant transformation rates for oncocytic sinonasal papilloma range from 4% to 17%.

◆ MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is an epithelial lesion induced by the molluscum contagiosum virus (MCV), a member of the DNA poxvirus group. At least 6% of the population (more in older age groups) has antibodies to this virus, although few ever develop lesions. In adults and adolescents, molluscum contagiosum is caused predominantly by MCV-2 via sexual contact, whereas in children it is caused mainly by MCV-1 via nonsexual contact (e.g., wrestling, sharing clothing, or towels). Autoinoculation of the virus is also possible. Warm, humid environments, such as communal baths or swimming pools, may encourage disease spread. Although infrequent, cases of molluscum contagiosum in infants have been reported, apparently resulting from vertical transmission of the virus from mother to infant.

After an incubation period of 14–50 days, multiple umbilicated papules may develop on the skin or, rarely, mucous membranes. The disease exhibits a predilection for warm portions of the skin and sites of recent injury. The lesions usually remain small for months or years and then spontaneously involute. However, florid cases have been reported in immunocompromised patients. Patients with atopic dermatitis and Darier disease also are at risk for developing severe, prolonged disease.

Clinical Features



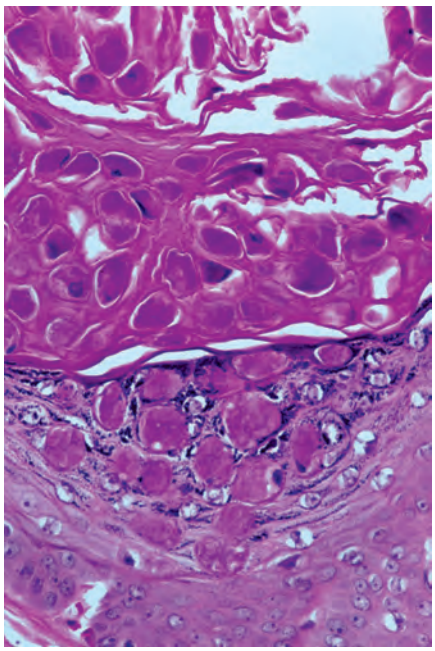
Molluscum contagiosum mainly arises in children and young adults. There is no significant gender predilection. The lesions occur predominantly on the skin of the neck, face (particularly eyelids), trunk, and genitalia. Infrequently, oral involvement occurs, usually on the lips, buccal mucosa, palate, or gingiva. Congenital lesions may involve the scalp in a halo-like distribution.

The lesions typically appear as multiple clustered, pink or pearly white, smooth-surfaced, sessile papules measuring 2–4 mm in diameter (Fig. 10.19). Many show a small central indentation or plug from which a curd-like substance containing viral particles can be expressed. Most lesions are asymptomatic, although slight tenderness or pruritus is possible. Erythema and swelling may result from trauma or may be indicative of the host's immune response and ensuing spontaneous regression. In addition, eczematous eruptions occasionally may develop in the vicinity of molluscum contagiosum, particularly in patients with atopic dermatitis. Other possible secondary complications include bacterial superinfection and conjunctivitis.

In immunocompromised patients, the lesions may be unusually large, verrucous, or markedly hyperkeratotic.

• **Fig. 10.19 Molluscum Contagiosum.** Multiple, smooth-surfaced papules, with several demonstrating small keratin-like plugs, are seen on the neck of a child.

• **Fig. 10.20 Molluscum Contagiosum.** Well-defined epidermal proliferation demonstrating a central craterlike depression filled with virally altered keratinocytes.



Histopathologic Features

Molluscum contagiosum appears as a localized, lobular proliferation of surface stratified squamous epithelium (Fig. 10.20). The central portion of each lobule is filled with bloated keratinocytes that contain large, intranuclear, basophilic viral inclusions called **molluscum bodies** (or **Henderson-Paterson bodies**) (Fig. 10.21). These bodies begin as small, eosinophilic structures in cells just above the basal layer and enlarge as they approach the surface. A central crater is formed at the surface as stratum corneum cells disintegrate to release their molluscum bodies.

Treatment and Prognosis

Most cases of molluscum contagiosum undergo spontaneous remission, with a mean duration of 6.5–13 months. For immunocompetent patients, there is ongoing debate as to whether the disease should be treated or allowed to resolve on its own. Treatment may be performed to decrease the risk of disease transmission, prevent autoinoculation, provide symptomatic relief, or address cosmetic concerns.

dentlearn.ir

• **Fig. 10.21 Molluscum Contagiosum.** Higher-power photomicrograph showing keratinocytes with large, basophilic viral inclusions (molluscum bodies) being sloughed into the central crater *(top)*.

Although there are few controlled studies of treatment efficacy, the lesions most commonly are removed by curettage or cryotherapy. Chemical destruction with cantharidin may be a preferable alternative for lesions in children. Additional treatment options include laser therapy, electrodesiccation, chemical destructive agents (e.g., salicylic acid, lactic acid, trichloroacetic acid, benzoyl peroxide, potassium hydroxide, and podophyllotoxin), topical tretinoin, topical imiquimod, intralesional injection of *Candida* antigen (which may stimulate a local immune response and MCV clearance), and oral cimetidine (most effective for lesions not involving the facial skin).

In immunosuppressed patients with recalcitrant lesions, interferon-alpha or cidofovir may be effective. Moreover, in HIV-infected patients, antiretroviral therapy indirectly counteracts MCV infection by increasing CD4+ T cell counts and improving the immune response.

Recurrence after initial clearing has been reported in up to one-third of patients. There is no apparent malignant transformation potential.

◆ VERRUCIFORM XANTHOMA

Verruciform xanthoma is a hyperplastic condition of the epithelium, with a characteristic subepithelial accumulation of lipid-laden histiocytes. It is primarily an oral disease, but skin and anogenital lesions also are possible. The cause is unknown. Although verruciform xanthoma is a papillary lesion, HPV has been identified in only a small number of cases, and no definitive pathogenetic role for this virus has been established. The lesion probably represents an unusual reaction or immune response to localized epithelial trauma or

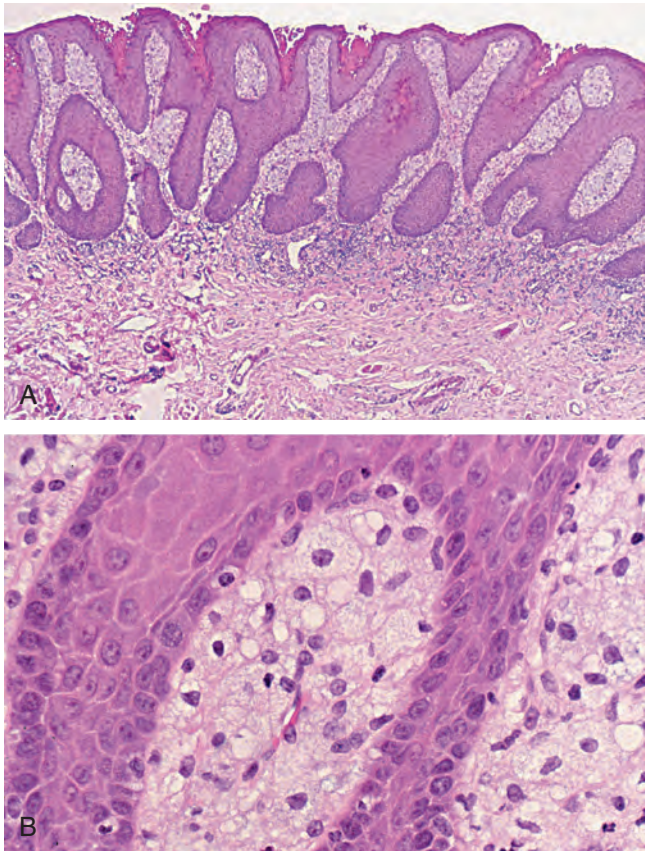
• **Fig. 10.22 Verruciform Xanthoma.** A well-demarcated, slightly elevated lesion of the hard palate that demonstrates a roughened or papillary surface.

damage. This hypothesis is supported by cases of verruciform xanthoma that have developed in association with disturbed epithelium (e.g., lichen planus, lupus erythematosus, epidermolysis bullosa, epithelial dysplasia, squamous cell carcinoma, pemphigus vulgaris, warty dyskeratoma, graft-vs-host disease [GVHD], candidiasis) and by a tendency for oral examples to involve the masticatory mucosa. The lesion is histopathologically similar to other dermal xanthomas, but it is not closely associated with diabetes or hyperlipidemia. Interestingly, in a few cutaneous and oral cases, investigators have identified somatic mutations in the *NSDHL* gene encoding 3-beta-hydroxysteroid dehydrogenase (an enzyme essential for cholesterol biosynthesis). Germline mutations in this gene are associated with CHILD (congenital hemidysplasia with ichthyosiform nevus and limb defects) syndrome.

Clinical Features

Verruciform xanthoma typically is seen in middle-aged to older adults but has been reported over a broad age range (2–94 years). There is a slight male predilection. Approximately half of intraoral lesions occur on the gingiva, but any oral site may be involved.

The lesion appears as a well-demarcated, soft, painless, sessile, slightly elevated mass with a white, yellow-white, pink, or red color and a papillary or roughened (verruciform) surface (Figs. 10.22 and 10.23). Rarely, flat-topped nodules are seen without surface projections. Most lesions are asymptomatic and smaller than 2 cm in greatest diameter, although large or "giant" examples have been reported infrequently. Multiple lesions occasionally have been described as well. Clinically, verruciform xanthoma may appear similar to squamous papilloma, verruca vulgaris, condyloma acuminatum, or early carcinoma.



Histopathologic Features

Verruciform xanthoma typically demonstrates papillary, acanthotic surface epithelium covered by a thickened layer of parakeratin. On routine hematoxylin and eosin (H&E)

dentlearn.ir

• **Fig. 10.23 Verruciform Xanthoma.** A gingival lesion with a papillary surface. (Courtesy of Dr. Ashleigh Briody.)

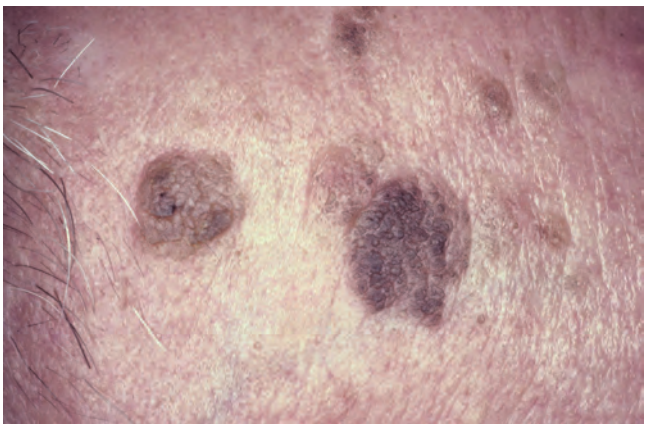
• **Fig. 10.24 Verruciform Xanthoma. A,** A slight papillary appearance is produced by hyperparakeratosis, and the rete ridges are elongated to a uniform depth. Note the parakeratin plugging between the papillary projections. **B,** The connective tissue papillae are composed almost exclusively of xanthoma cells—large macrophages with foamy cytoplasm.

staining, the keratin layer often exhibits a distinctive pinkish orange color (Fig. 10.24). Clefts or crypts between the epithelial projections are filled with parakeratin, and rete ridges are elongated to a uniform depth. However, some cases may exhibit a relatively flat surface with minimal keratinization. The most important diagnostic feature is the accumulation of numerous large macrophages with foamy cytoplasm, which typically are confined to the connective tissue papillae. These foam cells, also known as **xanthoma cells,** contain lipid and periodic acid-Schiff (PAS)-positive, diastase-resistant granules. With immunohistochemical stains, the xanthoma cells are positive for markers consistent with monocyte-macrophage lineage, including CD68, CD63, CD163, and cathepsin B.

Treatment and Prognosis

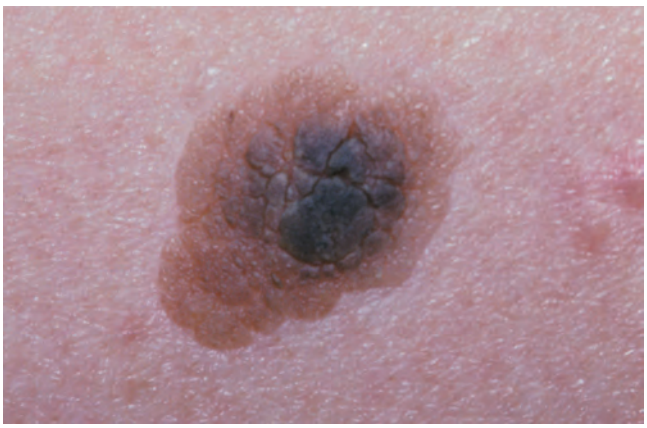
The verruciform xanthoma is treated with conservative surgical excision. Recurrence after removal is rare, and no malignant transformation has been reported. However, there are a few reported cases of verruciform xanthoma arising in association with carcinoma *in situ* or squamous cell carcinoma. This observation does not necessarily imply that verruciform xanthoma is a potentially malignant lesion; however, it may indicate that hyperkeratotic or dysplastic oral lesions can undergo degenerative changes to form a verruciform xanthoma.

◆ SEBORRHEIC KERATOSIS



Seborrheic keratosis is an extremely common skin lesion of older people and represents an acquired, benign proliferation of epidermal basal cells. This lesion frequently affects the facial skin but does not occur in the mouth. The cause is unknown, although there is a positive correlation with chronic sun exposure, sometimes with a hereditary (autosomal dominant) tendency. In addition, somatic mutations in the *fibroblast growth factor receptor 3 (FGFR3)* and *phosphatidylinositol 3-kinase, catalytic subunit alpha (PIK3CA)* genes may contribute to the pathogenesis of these lesions. In some cases, HPV DNA or Merkel cell polyomavirus DNA has been detected, but these findings may be coincidental. Investigators recently have suggested that overexpression of amyloid precursor protein is a marker of aging, sun-damaged skin and may promote the development of seborrheic keratoses.

Clinical Features

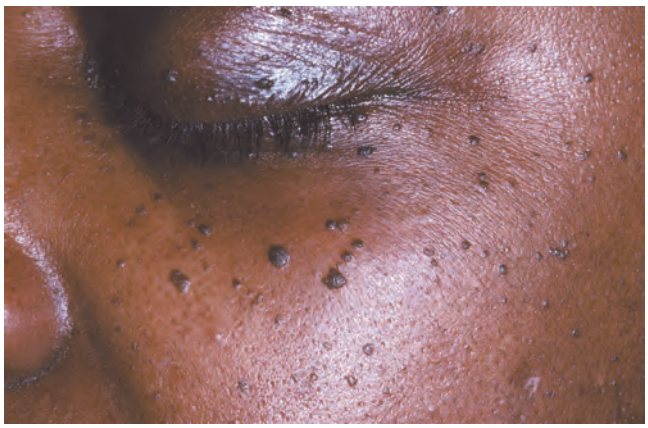


Seborrheic keratoses begin to develop on the skin of the face, neck, trunk, and extremities during the fourth decade of life, and they become more prevalent with each passing decade. Lesions are usually multiple, beginning as small, tan to brown macules that are clinically indistinguishable from **actinic lentigines** (see page 369). Subsequently, the lesions gradually enlarge and elevate to form sharply demarcated plaques, with finely fissured, pitted, verrucous, waxy, or smooth surfaces (Figs. 10.25 and 10.26). The plaques appear "stuck onto" the skin and are usually less than 2 cm in diameter. Most examples are asymptomatic, although secondarily inflamed lesions may cause pain, discomfort, or pruritus.

Dermatosis papulosa nigra is a form of seborrheic keratosis that occurs in approximately 30%–77% of blacks and frequently has an autosomal dominant inheritance pattern.

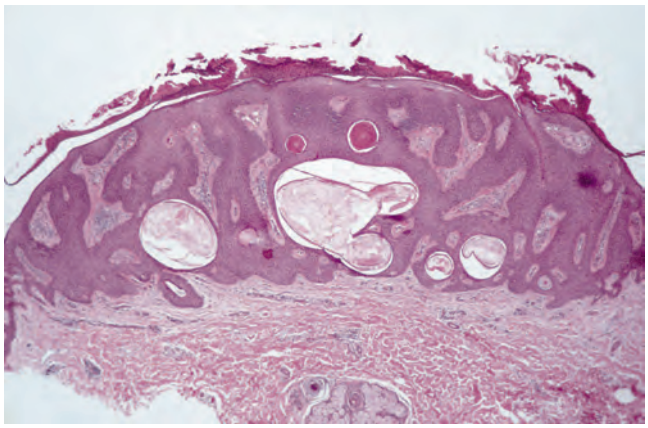
dentlearn.ir

• **Fig. 10.25 Seborrheic Keratosis.** Multiple brown plaques on the face of an older man exhibit a fissured surface. They had been slowly enlarging for several years.



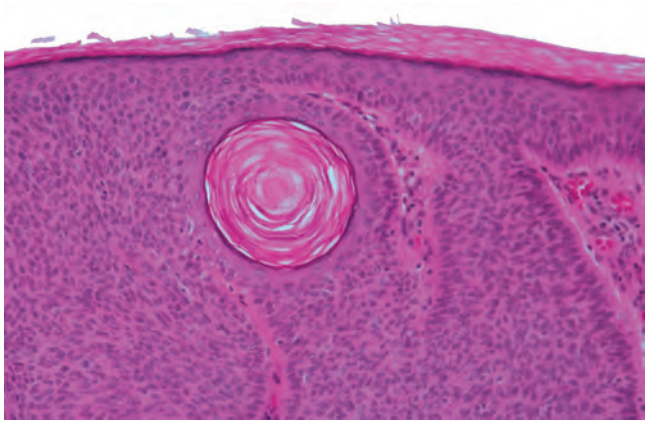
• **Fig. 10.26 Seborrheic Keratosis.** Crusted and pigmented epidermal plaque.

This condition typically appears as multiple small (1–4 mm), dark-brown to black papules scattered about the zygomatic and periorbital region (Fig. 10.27).



The sudden appearance of numerous seborrheic keratoses with pruritus may be associated with internal malignancy. This rare phenomenon is called the **Leser-Trélat sign.** In a similar phenomenon termed **pseudo-sign of Leser-Trélat**, there is drug-induced development of inflamed seborrheic keratoses; implicated medications include various biologic or antineoplastic agents (e.g., adalimumab, docetaxel, cytarabine, 5-fluorouracil, cisplatin).

Histopathologic Features



Seborrheic keratosis consists of an exophytic proliferation of basilar epithelial cells that exhibit varying degrees of surface keratinization, acanthosis, and papillomatosis (Fig. 10.28). Characteristically, the epithelial hyperplasia extends upward, above the normal epidermal surface. The lesion usually exhibits deep, keratin-filled invaginations that appear cystic on cross-section; hence, they are called **horn cysts** or **pseudo-horn cysts** (Fig. 10.29). Melanin pigmentation often is seen within the basal layer.

• **Fig. 10.27 Dermatosis Papulosa Nigra.** Multiple small pigmented papules of the malar area.

• **Fig. 10.28 Seborrheic Keratosis.** The acanthotic form demonstrates considerable acanthosis, surface hyperkeratosis, and numerous pseudocysts. The epidermal proliferation extends upward, above the normal epidermal surface.

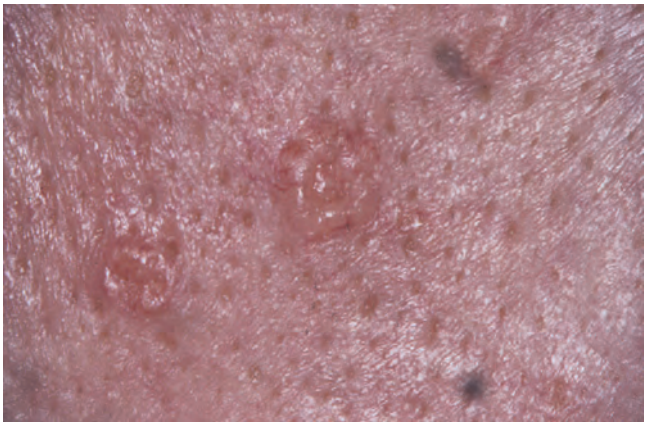
• **Fig. 10.29 Seborrheic Keratosis.** Pseudocysts are actually keratin-filled invaginations, as seen toward the left in this high-power photomicrograph. The surrounding epithelial cells are basaloid in appearance.

Several histopathologic patterns may be seen in seborrheic keratoses. The most common is the **acanthotic** form, which exhibits little papillomatosis and marked acanthosis with minimal surface keratinization. The **hyperkeratotic** form is characterized by prominent papillomatosis and hyperkeratosis

dentlearn.ir

with minimal acanthosis. The **adenoid** form consists of anastomosing trabeculae of lesional cells with little hyperkeratosis or papillomatosis. The lesions of dermatosis papulosa nigra are predominantly of the adenoid and acanthotic types.

Chronic trauma may alter these histopathologic features to produce an **irritated seborrheic keratosis** (or **inverted follicular keratosis of Helwig**). This lesion shows a mild degree of proliferation into the connective tissue and an associated chronic inflammatory cell infiltrate. Squamous metaplasia of the lesional cells results in whorled epithelial patterns called **squamous eddies.** Inflamed seborrheic keratosis may exhibit enough nuclear atypia and mitotic activity to cause confusion with squamous cell carcinoma, but enough of the basic attributes of seborrheic keratosis typically remain to allow a proper diagnosis.



Treatment and Prognosis

Except to address aesthetic concerns or secondary irritation, seborrheic keratoses seldom are removed. Cryotherapy, electrodesiccation, curettage, and shave excision are the most common methods for removal. Laser therapy is more costly than traditional treatment methods but may be preferable for removal of a large number of lesions. Investigational treatments include various topical agents (e.g., nitric-zinc complex solution, 40% hydrogen peroxide, trichloroacetic acid).

The lesion exhibits no appreciable malignant potential. However, there are isolated reports of malignant skin lesions developing within or adjacent to seborrheic keratoses; it is unclear whether such cases are coincidental. Rarely, melanomas or other skin cancers may resemble seborrheic keratoses clinically; dermoscopy (a noninvasive *in vivo* imaging technique for visualization of subsurface skin structures) may aid in differentiating seborrheic keratoses from other lesions. It is important for a dermatologist or other qualified clinician to perform such evaluation and determine whether it is appropriate to treat a lesion by cryotherapy or to excise and submit it for histopathologic confirmation.

◆ SEBACEOUS HYPERPLASIA

Sebaceous hyperplasia is a localized proliferation of sebaceous glands, with a predilection for the facial skin. The exact cause is unknown, although investigators hypothesize that hormonal and genetic factors may be important. In addition, some reported cases have developed in association with cyclosporine administration in transplant recipients or with antiretroviral therapy for HIV-infected patients. It is uncertain whether such cases result from immunosuppression or direct medication effects. Furthermore, sebaceous hyperplasia may arise in association with *Muir-Torre syndrome* (a rare autosomal dominant disorder characterized by visceral malignancies, sebaceous adenomas and carcinomas, and keratoacanthomas) or X-linked hypohidrotic ectodermal dysplasia (see page 747). The major significance of sebaceous hyperplasia is its clinical similarity to more serious facial tumors, such as basal cell carcinoma.

• **Fig. 10.30 Sebaceous Hyperplasia.** Multiple soft papules of the midface are umbilicated and small. Sebum can often be expressed from the central depressed area.

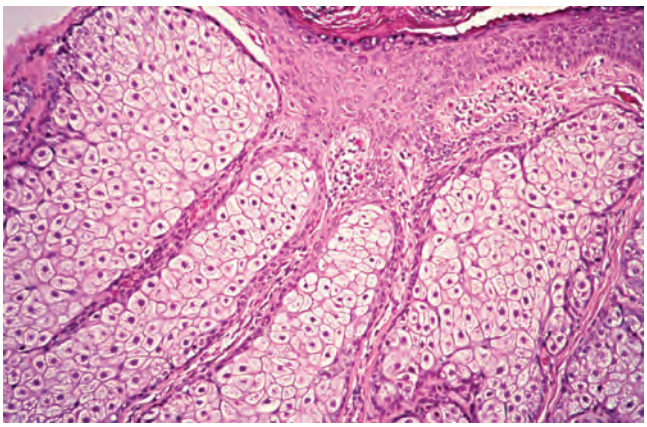
Clinical Features

Cutaneous sebaceous hyperplasia usually affects adults older than 40 years. It occurs most commonly on the skin of the face, especially the nose, cheeks, and forehead. Less commonly, lesions may involve the genital area, chest, and areola. The condition is characterized by one or more soft, nontender papules with white, yellow, or normal color (Fig. 10.30). Most lesions grow slowly and are smaller than 5 mm in greatest diameter. The lesions usually exhibit central umbilication, representing the area where the ducts of the involved sebaceous lobules terminate. The ability to express sebum (the thick, yellow-white product of the sebaceous gland) from this small, central depression aids in clinical distinction of sebaceous hyperplasia from basal cell carcinoma.

An oral counterpart, which probably has no relation to the skin lesion, appears as a white to yellow papule or nodular mass with a "cauliflower" appearance, usually involving the buccal mucosa or retromolar pad.

Histopathologic Features

Histopathologically, sebaceous hyperplasia is characterized by a collection of enlarged but otherwise normal sebaceous gland lobules grouped around one or more centrally located sebaceous ducts (Fig. 10.31).



Treatment and Prognosis

No treatment is necessary for sebaceous hyperplasia except for cosmetic reasons or unless basal cell carcinoma cannot be eliminated from the clinical differential diagnosis. Excisional biopsy is curative. Cryosurgery, electrodesiccation, laser therapy, photodynamic therapy, and isotretinoin are alternative treatment methods.

◆ EPHELIS (FRECKLE)

An **ephelis** is a common, small, hyperpigmented macule of the skin. The lesion results from increased melanin deposition in the epidermis, without an increase in the number

dentlearn.ir

• **Fig. 10.31 Sebaceous Hyperplasia.** Sebaceous glands are enlarged and more numerous than normal, but they demonstrate no other pathologic changes.

• **Fig. 10.32 Ephelides.** Multiple brown macules over the bridge of the nose.

of melanocytes. Ephelides may become more pronounced after sun exposure and are associated closely with a history of painful sunburns in childhood. There is a genetic predilection (autosomal dominant), and studies have demonstrated a strong relationship with certain variants of the *melanocortin 1 receptor (MC1R)* gene.

Clinical Features

Ephelides arise most often on the face, arms, and back of fair-skinned, blue-eyed, red- or blond-haired individuals. There is no gender predilection. The macules usually develop during the first decade of life, seldom arise after the teenage years, and become less prominent in adulthood.

Each lesion appears as a sharply demarcated, uniformly light brown, round or oval macule, measuring less than 3 mm in diameter (Fig. 10.32). There is great variability in the number of lesions present. Many individuals have less than 10, whereas some have hundreds. The brown color is not as dark as that seen in lentigo simplex (see page 370), and there is never elevation above the skin surface, as may occur in a melanocytic nevus (see page 374).

Histopathologic Features

The ephelis exhibits abundant melanin deposition in the basal cell layer of the epidermis. Despite increased melanin, the number of melanocytes is normal or slightly reduced. In contrast to lentigo simplex, there is no elongation of rete ridges.

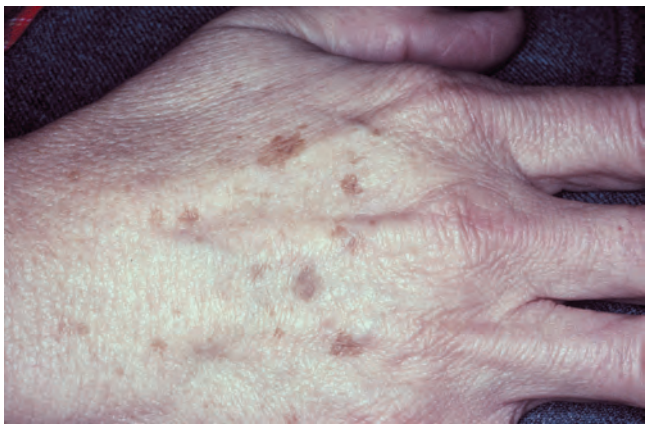
Treatment and Prognosis

No treatment is necessary for ephelides. Cosmetically unpleasing lesions may be treated by cryotherapy, hydroquinone, chemical peels, or laser therapy. Sunscreens can prevent the appearance of new freckles and help prevent the darkening of existing lesions.

◆ ACTINIC LENTIGO (LENTIGO SOLARIS; SOLAR LENTIGO; AGE SPOT; LIVER SPOT; SENILE LENTIGO)

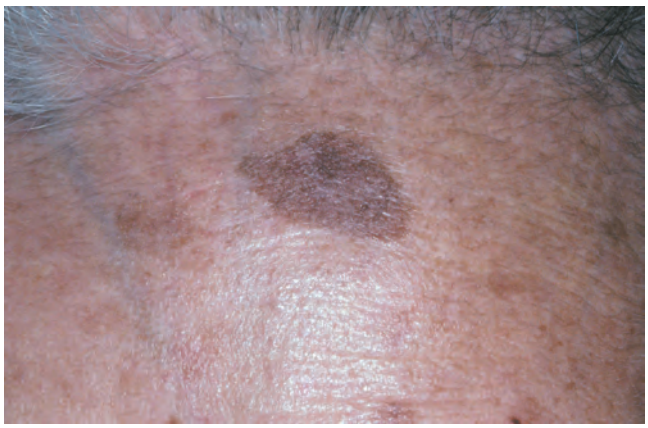
Actinic lentigo is a benign, brown macule that is considered a hallmark of photodamaged skin. The lesion is associated with both chronic and intermittent ultraviolet (UV) light exposure. A potential association with air pollutants also has been suggested. The lesion frequently arises on the facial skin but does not occur in the mouth. Actinic lentigo affects more than 90% of whites older than 70 years. The lesion rarely develops before age 40, although young adults with a history of severe sunburns may develop multiple large actinic lentigines on the upper back. Persons who have facial ephelides (freckles) in childhood are prone to developing actinic lentigines later in life.

Some authorities have proposed that actinic lentigo represents a precursor to adenoid seborrheic keratosis (see page 366). Interestingly, investigators have noted that at least some cases of both actinic lentigo and seborrheic keratosis exhibit mutations in the *FGFR3* and *PIK3CA* genes.



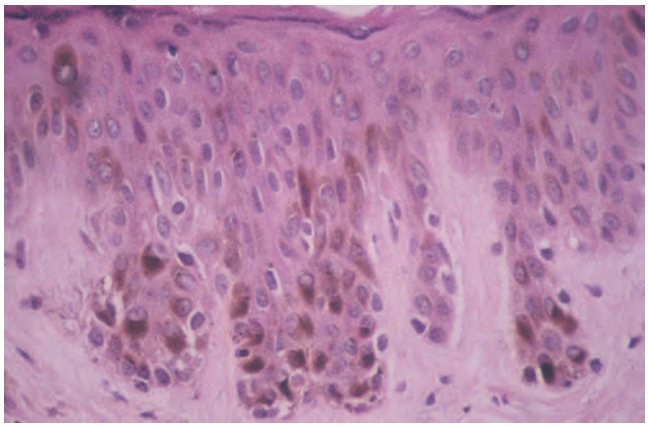
Clinical Features

Multiple lesions typically develop in older whites on sun-exposed skin, especially on the face, dorsa of the hands, forearms, shoulders, and upper back (Figs. 10.33 and 10.34). The lesions may appear more prominent and at a somewhat younger age among Asians compared to whites. The individual lesions appear as uniformly pigmented, brown to tan macules with well-demarcated but irregular borders. Most examples are smaller than 5 mm in diameter, although some lesions may measure more than 1 cm. Adjacent lesions may coalesce, and new ones continuously arise with age. Unlike ephelides, no change in color intensity is seen after UV light exposure.



Histopathologic Features

The rete ridges are elongated and club-shaped, with thinning of the epithelium above the connective tissue papillae



dentlearn.ir

• **Fig. 10.33 Actinic Lentigines.** Multiple lesions on the sun-exposed skin of the hand of an older adult. Lesions are brown macules with irregular borders.

• **Fig. 10.34 Actinic Lentigo.** Large, flat, evenly pigmented lesion on the forehead of an older adult man.

• **Fig. 10.35 Actinic Lentigo.** Rete ridges are elongated and occasionally intertwining. Pigmented melanocytes (with clear cytoplasm) are excessive and commingled with melanin-laden basilar cells.

(Fig. 10.35). The ridges sometimes coalesce with one another. Within each rete ridge, melanin-laden basilar cells are intermingled with excessive numbers of heavily pigmented melanocytes. Prominent solar elastosis typically is seen within the dermis.

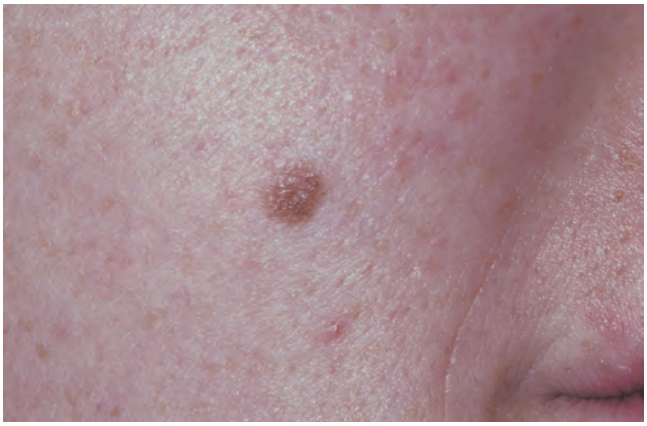
Treatment and Prognosis

No treatment is required for actinic lentigo, except for aesthetic reasons. Ablative treatment methods include cryotherapy, laser therapy, intense pulsed light, and chemical peels. In addition, there is a wide range of topical therapies available, including hydroquinone, tretinoin, tazarotene, adapalene, and combined mequinol and tretinoin. Generally, sunscreens are recommended as preventive treatment and for maintenance of treatment success. Lesions rarely recur after removal, although new lesions may arise. Actinic lentigo does not undergo malignant transformation; however, the lesion represents a clinical marker of photodamage and may indicate an increased risk for developing skin cancer.

◆ LENTIGO SIMPLEX

Lentigo simplex is one of several forms of benign cutaneous melanocytic hyperplasia of unknown cause. In contrast to the ephelis (see page 368), lentigo simplex typically is found on skin that is not exposed to sunlight, appears somewhat darker in color, does not darken with sun exposure, and represents an increase in both local melanin production and the number of melanocytes. Oral lesions have been reported, but they are rare and may be examples of the oral melanotic macule (see page 372).

Some investigators believe that lentigo simplex represents the earliest stage of another common skin lesion, the melanocytic nevus (see page 374). However, lentigo simplex appears to lack *BRAF* mutations that are commonly found in conventional acquired melanocytic nevi. In addition, lentigo simplex does not appear to harbor *FGFR3* and *PIK3CA* mutations, which are frequently present in actinic lentigo.



Clinical Features

Lentigo simplex usually is seen in children, although it may occur at any age. The typical lesion is a sharply demarcated, uniformly tan to dark-brown macule smaller than 5 mm in diameter (Fig. 10.36). It is usually solitary, although some patients may have several lesions scattered on the skin of the trunk and extremities. Lentigo simplex reaches its maximum size in a matter of months and may remain unchanged indefinitely thereafter.

Clinically, individual lesions of lentigo simplex are indistinguishable from the nonelevated melanocytic nevus. With multiple lesions, conditions such as lentiginosis profusa, Peutz-Jeghers syndrome (see page 758), and LEOPARD[a] syndrome must be considered as diagnostic possibilities.

[a]**L**entigines (multiple), **e**lectrocardiographic abnormalities, **o**cular hypertelorism, **p**ulmonary stenosis, **a**bnormalities of genitalia, **r**etardation of growth, and **d**eafness (sensorineural).

dentlearn.ir

• **Fig. 10.36 Lentigo Simplex.** A sharply demarcated lesion of uniform brown coloration is seen on the midface.

• **Fig. 10.37 Melasma.** Diffuse hyperpigmentation of the facial skin in a pregnant woman.

Histopathologic Features

Lentigo simplex shows an increased number of benign melanocytes within the basal layer of the epidermis. These melanocytes often are clustered at the tips of slightly to moderately elongated rete ridges. Abundant melanin is distributed among the melanocytes and basal keratinocytes, as well as within the papillary dermis in association with melanophages **(melanin incontinence).**

Treatment and Prognosis

Lentigo simplex may fade spontaneously after many years, but most lesions remain constant over time. Treatment is not required, except for cosmetic reasons. Treatment methods include conservative surgical excision, cryotherapy, and laser therapy. No malignant transformation potential has been documented.

◆ MELASMA (MASK OF PREGNANCY; CHLOASMA)

Melasma is an acquired, symmetrical hyperpigmentation of the sun-exposed skin of the face and neck. The exact etiopathogenesis is unknown, but UV light exposure, hormonal influences, and an underlying genetic predisposition appear to be important factors. The condition traditionally has been thought to arise primarily from the stimulatory effects of UV light on melanocytes; however, emerging evidence suggests that visible light, keratinocytes, dermal mast cells, extracellular matrix alterations, and angiogenesis may play important roles in disease development as well. Melasma classically is associated with pregnancy. In addition, an association with oral contraceptives, hormone replacement therapy, ovarian or thyroid disorders, liver dysfunction, malnutrition, phototoxic medications, antiepileptic agents, cosmetics, and air pollutants has been described. The condition most commonly affects medium- to dark-complexioned persons—particularly females of Asian, Hispanic, and Mediterranean descent. In some study populations it affects as many as 30%–40% of women. In the United States, melasma affects more than 5 million individuals.

Clinical Features

Melasma most often develops in females between the ages of 11–49 years, with an average age of approximately 30–38 years. Men are affected infrequently. The condition typically appears as bilateral brown or grayish cutaneous macules that range from a few millimeters to more than 2 cm in diameter (Fig. 10.37). The borders of the lesion tend to be ill-defined and irregular. Lesions develop slowly with sun exposure and primarily involve the skin of the midface, forehead, upper lip, chin, temporal, and mandibular ramus region. The condition only rarely affects extrafacial sites, such as the arms, sternal region, and back. The pigmentation may remain faint or darken over time.

Histopathologic Features

Melasma is characterized by increased melanin deposition and, possibly, an increased number of melanocytes in the epidermis. The melanocytes typically are plump, full of pigment, and highly dendritic. In addition, numerous melanophages (melanin-laden macrophages) may be seen in the dermis, especially around blood vessels. Some authors have noted that hallmarks of photoaging (including solar elastosis, increased numbers of dermal mast cells, increased vascularization, and basement membrane disruption) are more prominent in lesional skin compared to adjacent normal-appearing skin.

Treatment and Prognosis

Melasma is difficult to treat. In the United States, first-line therapy typically consists of topical triple-combination cream (Tri-Luma) containing 4% hydroquinone, 0.05% tretinoin, and 0.01% fluocinolone acetonide. Alternative treatments include dual-ingredient topical agents (e.g., hydroquinone combined with a retinoid, corticosteroid, or kojic acid) or single-ingredient topical agents (e.g., hydroquinone, retinoids, or azelaic acid). Recent studies suggest that microneedling may be a useful adjuvant to topical therapies. Oral tranexamic acid may be helpful for refractory cases.

dentlearn.ir

Variable results have been reported with laser therapy, light therapy, chemical peels, or microdermabrasion. Because sun exposure is an important etiologic factor, sun avoidance, protective clothing, and the use of sunscreens containing zinc oxide or titanium dioxide are crucial for effective management. The lesions may resolve after parturition or after discontinuing oral contraceptives. There is no potential for malignant transformation.

◆ ORAL MELANOTIC MACULE (FOCAL MELANOSIS)

The **oral melanotic macule** is a flat, brown, mucosal discoloration produced by a focal increase in melanin deposition and, possibly, a concomitant increase in the number of melanocytes. The cause remains unclear. Unlike the cutaneous ephelis (freckle), the melanotic macule is not dependent on sun exposure. Some authorities have questioned the purported lack of an association with actinic irradiation for the melanotic macule located on the vermilion border and prefer to consider it a distinct entity **(labial melanotic macule).** Oral and labial melanotic macules are the most common oral melanocytic lesions submitted to oral pathology laboratories for histopathologic examination.

Clinical Features

The oral melanotic macule occurs over a broad age range, with a mean age at diagnosis of 42 years and a 2:1 female-to-male ratio. The lower lip vermilion is the most commonly involved site (33% of cases), followed by the buccal mucosa, gingiva, and palate. Rare examples have been reported on the tongue in newborns.

The typical lesion appears as a solitary (17% are multiple), well-demarcated, uniformly tan to dark-brown, asymptomatic, round or oval macule with a diameter less than 1 cm (Figs. 10.38–10.40). Occasional lesions may be blue or black. The maximum dimension is achieved rather rapidly and remains constant thereafter.

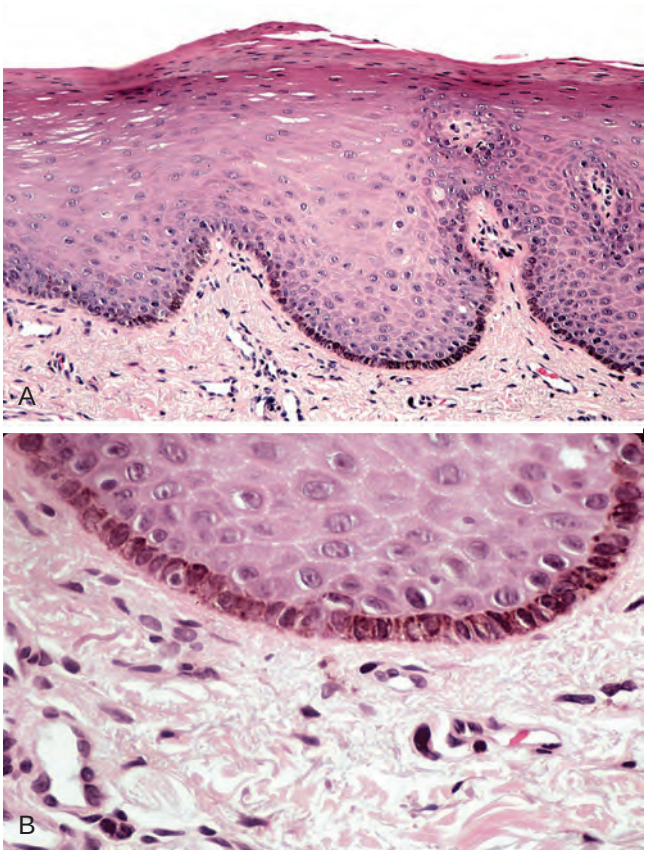
• **Fig. 10.38 Oral Melanotic Macule.** A single small, uniformly pigmented brown macule on the lower lip vermilion.

Histopathologic Features

The oral melanotic macule is characterized by an increase in melanin (and perhaps melanocytes) in the basal and parabasal layers of an otherwise normal stratified squamous epithelium (Fig. 10.41). Melanin also may be seen free **(melanin incontinence)** or within melanophages in the subepithelial connective tissue. Unlike actinic lentigo (see page 369), the melanotic macule typically does not show elongated rete ridges.

Treatment and Prognosis

The oral melanotic macule generally is considered a benign lesion with no malignant potential. However, a single case of apparent malignant transformation of an oral melanotic macule has been reported, and early melanoma can have a similar clinical appearance. Therefore, all oral pigmented macules of recent onset, large size, irregular pigmentation, unknown duration, or recent enlargement should be submitted for



• **Fig. 10.39 Oral Melanotic Macule.** A well-demarcated brown macule of the gingival mucosa.

• **Fig. 10.40 Oral Melanotic Macule.** A brown macule on the soft palate. Smoker's melanosis may exhibit a similar clinical appearance and could be a consideration in the clinical differential diagnosis, although this patient denied any history of tobacco use.

dentlearn.ir

• **Fig. 10.41 Oral Melanotic Macule. A,** Low-power view showing increased melanin pigmentation distributed along basal epithelial layer. **B,** High-power view showing granular brown melanin pigment in the basilar cells.

microscopic examination. In addition, because oral melanoma exhibits a predilection for the palatal and maxillary alveolar mucosa, it is advisable to submit pigmented macules in these locations for histopathologic examination. Furthermore, removal may be desirable for melanotic macules involving aesthetic areas. Excisional biopsy is the preferred treatment method. Electrocautery, laser ablation, or cryosurgery is effective, but no tissue remains for histopathologic examination after these procedures.

On occasion, flat pigmented lesions that are clinically and microscopically similar to the melanotic macule may occur in association with a systemic disease, a genetic disorder, chronic trauma/irritation, or certain medications. A list of these conditions is shown in Box 10.1.

◆ ORAL MELANOACANTHOMA (MELANOACANTHOSIS)

Oral melanoacanthoma is an uncommon, benign, acquired pigmentation of the oral mucosa characterized by dendritic melanocytes dispersed throughout the epithelium. The lesion appears to be a reactive process; in some cases an association with trauma or local irritation has been reported. Oral melanoacanthoma appears to be unrelated to the melanoacanthoma of skin, which most authorities believe represents a variant of seborrheic keratosis.

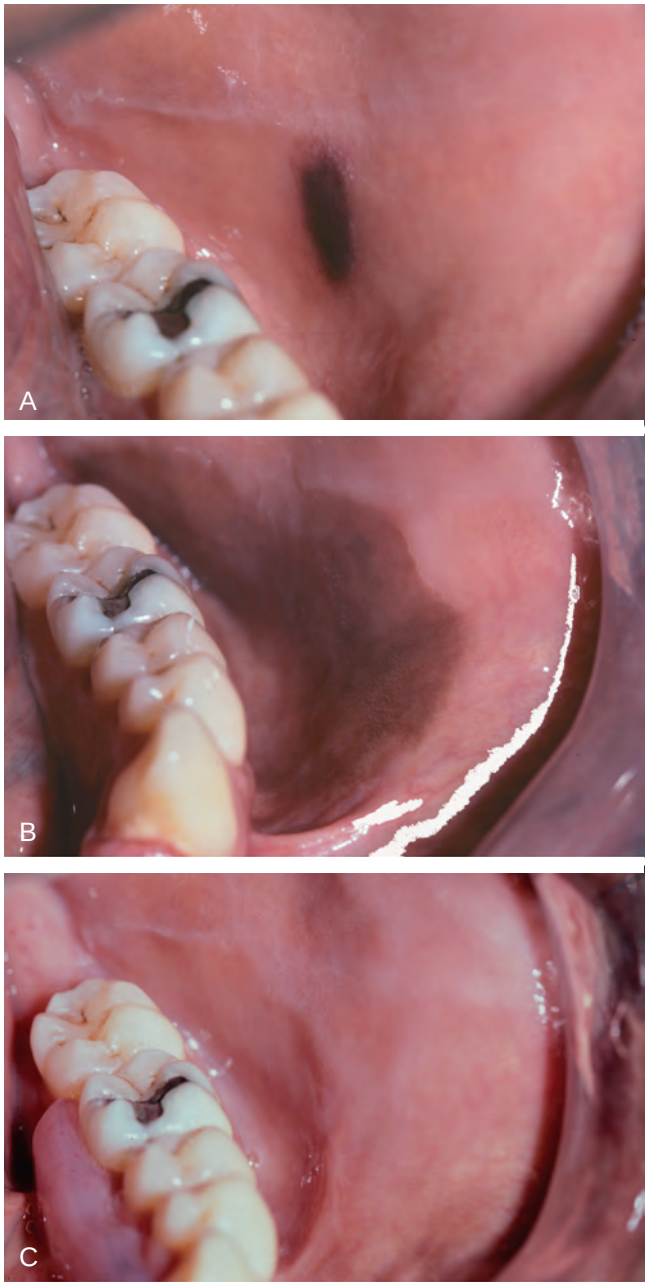
• BOX 10.1 Associations With Melanin Pigmentation of Oral Mucosa

Physiologic or Syndromic Associations

- Racial or physiologic pigmentation
- Peutz-Jeghers syndrome
- McCune-Albright syndrome
- LEOPARD syndrome (lentiginosis profusa, no intraoral melanosis)
- Laugier-Hunziker syndrome
- Cronkhite-Canada syndrome
- Bloom syndrome
- Dunnigan syndrome
- Dyskeratosis congenita
- Endocrine candidiasis syndrome
- Incontinentia pigmenti
- Oculo-cerebro-cutaneous syndrome
- Rothmund-Thomson syndrome
- Trisomy 14 mosaicism
- Unusual facies, vitiligo, spastic paraplegia syndrome
- Xeroderma pigmentosum
- Addison disease
- Neurofibromatosis type I
- Carney complex

Chronic Trauma or Irritation or Environmental Pollutant

- Chronic mucosal trauma or irritation (chronic cheek bite)
- Chronic autoimmune disease (erosive lichen planus, pemphigoid)
- Smoker's melanosis
- Yusho (chronic exposure to high levels of polychlorinated biphenyls [PCBs])

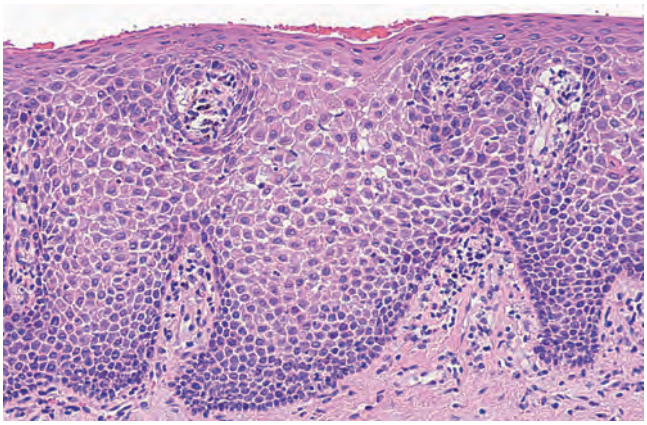


Systemic Medications

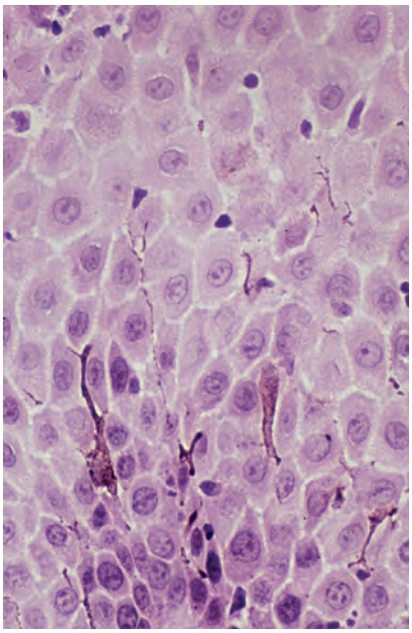
- Chloroquine and other quinine derivatives
- Phenolphthalein
- Estrogen
- AIDS-related medications

Clinical Features

Oral melanoacanthoma is seen primarily in blacks, although some cases also have been reported in Caucasians, Hispanics, and Asians. The lesion exhibits a female predilection and most commonly arises during the third and fourth decades of life. The buccal mucosa is the most common site of occurrence. The lips, palate, gingiva, and alveolar mucosa also may be involved. Most patients exhibit solitary lesions, although bilateral or multifocal involvement is possible. Oral melanoacanthomas typically are asymptomatic; however, pain, burning, and pruritus have been reported in a few cases. The lesion appears smooth, flat or slightly raised, and dark-brown to black (Fig. 10.42). Lesions often rapidly increase in size, and they occasionally reach a diameter of several centimeters within a few weeks.



dentlearn.ir



• **Fig. 10.42 Oral Melanoacanthoma. A,** Smooth, darkly pigmented macule of the buccal mucosa in a young adult. **B,** Appearance of the lesion 2 months later showing dramatic enlargement. **C,** Resolution of the lesion 3 months after incisional biopsy. (From Park SK, Neville BW: AAOMP case challenge: rapidly enlarging pigmented lesion of the buccal mucosa, *J Contemp Dent Pract* 3:69–73, 2002.)

Histopathologic Features

The oral melanoacanthoma is characterized by numerous benign dendritic melanocytes (cells that normally are confined to the basal layer) scattered throughout the lesional epithelium (Figs. 10.43 and 10.44). Basal layer melanocytes are also present in increased numbers. Spongiosis and mild acanthosis typically are evident. In addition, the underlying connective tissue often contains a mild to moderate chronic inflammatory cell infiltrate that may include eosinophils.

• **Fig. 10.43 Oral Melanoacanthoma.** Medium-power photomicrograph showing acanthosis of the epithelium. Spongiosis is demonstrated by intercellular spaces between the keratinocytes.

• **Fig. 10.44 Oral Melanoacanthoma.** High-power view showing numerous dendritic melanocytes extending between the spinous epithelial cells.

Treatment and Prognosis

Because of the alarming growth rate of oral melanoacanthoma, incisional biopsy usually is indicated to rule out melanoma. Once the diagnosis has been established, no further treatment is necessary. In several instances, lesions have undergone spontaneous resolution after incisional biopsy. Recurrence or development of additional lesions has been reported only rarely. There is no potential for malignant transformation.

◆ MELANOCYTIC NEVUS (NEVOCELLULAR NEVUS; MOLE)

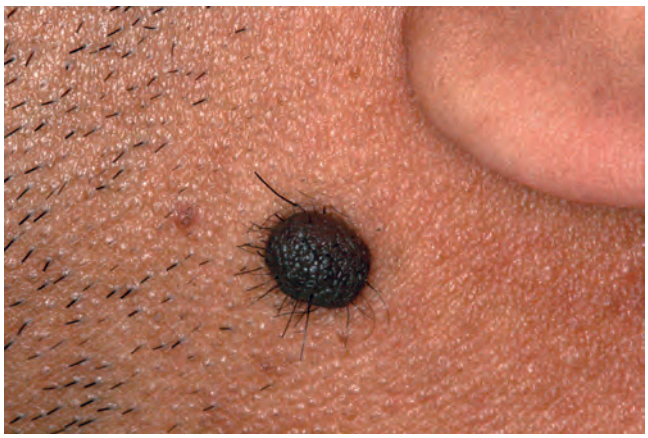
The generic term *nevus* refers to congenital or developmental malformations of the skin (and mucosa). Nevi may arise from the surface epithelium or underlying connective tissue.

dentlearn.ir

• BOX 10.2 Types of Nevi

- Melanocytic nevus
- Acquired melanocytic nevus (e.g., conventional, blue, Spitz, and other subtypes)
- Congenital melanocytic nevus
- Epidermal nevus
- Nevus sebaceus
- Nevus flammeus (see page 551)
- Basal cell nevus (nevoid basal cell carcinoma) (see page 694)
- White sponge nevus (see page 748)

Melanocytic nevi represent benign proliferations of *nevus cells* (or *nevomelanocytes*). Such proliferations develop when an initiating genetic mutation arises within a melanocyte or melanocytic precursor cell. (Melanocytes are neural crest-derived cells that produce melanin pigment and colonize the skin, mucosa, and other sites.) The natural history of melanocytic nevi typically includes a period of clonal expansion followed by inhibition of further growth by cellular safeguard mechanisms. However, progression to malignant melanoma (see page 434) is possible if additional mutations arise in oncogenes or tumor suppressor genes.



Broadly speaking, melanocytic nevi can be classified as *congenital* (developing *in utero* and present at birth) or *acquired* (developing after birth). The most commonly recognized nevus is the **conventional acquired melanocytic nevus,** or **common mole**—so much so that the simple term *nevus* often is used synonymously for this pigmented lesion. However, many other types of nevi also are recognized (Box 10.2). The following sections will discuss acquired melanocytic nevi (including conventional and other subtypes) as well as congenital melanocytic nevi.

◆ ACQUIRED MELANOCYTIC NEVUS

CONVENTIONAL ACQUIRED MELANOCYTIC NEVUS (COMMON ACQUIRED NEVUS; BANAL NEVUS; COMMON MOLE)

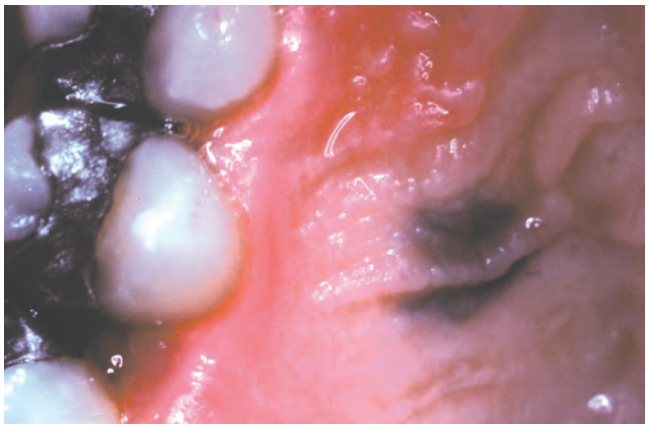
The conventional acquired melanocytic nevus is probably the most common of all human "tumors," with an average of 10–40 cutaneous nevi per white adult. In contrast, oral examples are distinctly uncommon. One study based on a national pathology registry in the Netherlands reported an annual incidence of 4.35 excised oral melanocytic nevi per 10 million population. Some investigators have noted that oral melanocytic nevi represent only about 0.01%–0.2% of biopsies accessioned by oral pathology laboratories.

Activating mutations in *BRAF* (especially *BRAF* V600E) and *NRAS* have been identified in approximately 80% and 6% of conventional acquired melanocytic nevi, respectively; such mutations also have been detected frequently in cutaneous melanomas (see page 434). These *BRAF* and *NRAS* mutations result in stimulation of the mitogen-activated protein kinase (MAPK) signaling pathway, which mediates cell proliferation and differentiation. In addition, activated *NRAS* stimulates the phosphatidylinositol 3-kinase (PI3K)/Akt pathway, which regulates cell proliferation, growth, and survival. The life cycle of conventional acquired melanocytic nevi includes four stages: initiation (mutation development in a progenitor cell), promotion (activation and proliferation of the mutated progenitor cell), senescence (growth arrest), and involution.

• Fig. 10.45 Conventional Acquired Melanocytic Nevus, Intradermal. A brown nodule on the facial skin with a papillomatous surface and protruding hairs.

Clinical Features

Conventional acquired melanocytic nevi begin to develop on the skin during childhood, and most cutaneous lesions are present before 35 years of age. Women usually have a few more nevi than men, and whites tend to have more than Asians or blacks. Most lesions are distributed above the waist, and the head and neck region commonly is involved.



Conventional acquired melanocytic nevi evolve through several developmental stages: junctional, compound, and intradermal. However, not all nevi pass through each stage. The **junctional nevus** clinically appears as a sharply demarcated, brown or black macule, typically less than 6 mm in diameter. Although this presentation may persist into adulthood, more often the nevus cells proliferate over a period of years to produce a slightly elevated, soft papule with a relatively smooth surface **(compound nevus).** The degree of pigmentation decreases; most lesions appear brown or tan. As time passes, the nevus gradually loses its pigmentation, the surface may become somewhat papillomatous, and hairs may be seen growing from the center **(intradermal nevus)** (Figs. 10.45 and 10.46). However, the nevus usually remains less than 6 mm in diameter. Ulceration is not a feature unless the lesion is traumatized. During the adult years, many conventional acquired melanocytic nevi involute and disappear; therefore, fewer lesions are detected in older persons.

Oral examples of conventional acquired melanocytic nevi are distinctly uncommon. Most arise on the palate, mucobuccal fold, lip vermilion, buccal mucosa, or gingiva, although any oral site may be affected (Fig. 10.47). Approximately two-thirds of cases are found in females, and the average

• **Fig. 10.48 Conventional Acquired Melanocytic Nevus, Intramucosal.** This intramucosal nevus of the mandibular gingiva is nonpigmented. (Courtesy of Dr. James Jacobs.)

• **Fig. 10.49 Conventional Acquired Melanocytic Nevus, Junctional.** Nests of melanocytic nevus cells along the basal layer of the epithelium.

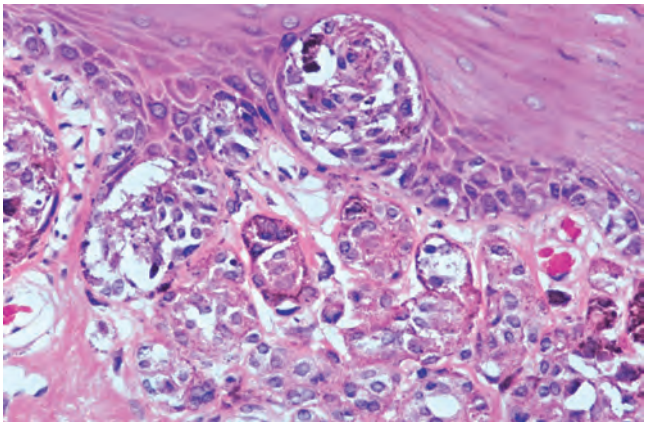
age at diagnosis is approximately 35 years. The mean lesion size is 0.9 cm in diameter. Intraoral lesions have an evolution and appearance similar to skin nevi but may not demonstrate a papillary surface as they mature. More than one in five intraoral nevi lack clinical pigmentation (Fig. 10.48).

Histopathologic Features

The conventional acquired melanocytic nevus is characterized by a benign, unencapsulated proliferation of nevus cells. Zones of differentiation often are seen among the lesional cells. Superficial nevus cells tend to be organized into small, round aggregates *(thèques)* and usually appear ovoid or epithelioid, with abundant cytoplasm and frequent intracellular melanin. Deeper nevus cells may have less cytoplasm, are seldom pigmented, and appear much like lymphocytes. The deepest nevus cells appear elongated and spindle-shaped, much like Schwann cells or fibroblasts. Some authorities classify these nevus cell variations as *types A* (epithelioid), *B*(lymphocyte-like), and *C* (spindle-shaped). Nevus cells typically lack the dendritic processes that melanocytes possess.

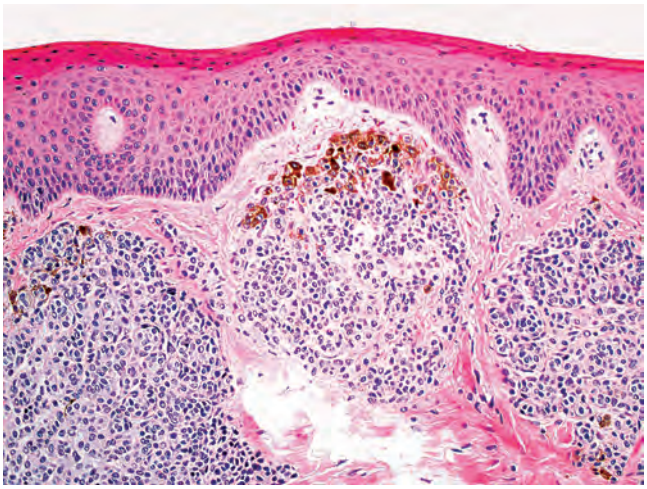
Melanocytic nevi are classified histopathologically according to their stage of development. The **junctional nevus** represents an early stage, in which thèques of nevus cells are confined to the junction of the epithelium and connective tissue (Fig. 10.49), especially at the tips of the rete ridges. As the nevus cells proliferate, they begin to drop off into the underlying dermis or lamina propria. When nevus cells are present along the junctional area and within the connective tissue, the lesion is called a **compound nevus** (Fig. 10.50). In later stages, the nevus cells are found only within the connective tissue. In the skin, this stage is called an **intradermal nevus;** the intraoral counterpart is called an **intramucosal nevus** (Fig. 10.51). At the time of diagnosis, most intraoral melanocytic nevi are classified as intramucosal nevi.

Treatment and Prognosis



No treatment is indicated for a conventional acquired melanocytic nevus on the skin unless it is cosmetically unacceptable, is chronically irritated by clothing, or changes in size or

dentlearn.ir



color. By midlife, cutaneous melanocytic nevi tend to regress; by age 90, very few remain. If removal is elected, then conservative surgical excision is the treatment of choice; recurrence is unlikely.

The lifetime risk of malignant transformation of an individual conventional acquired melanocytic nevus into cutaneous melanoma is low (approximately one in 3200 for men to one in 10,800 for women). Nevertheless, patients with a large number (>100) of cutaneous nevi are at increased risk for developing melanoma and should be monitored closely. According to a meta-analysis, about 30% of cutaneous melanomas arise in association with preexisting nevi, and the majority of nevus-associated melanomas occur on the skin of the trunk.

There is no definitive evidence that oral melanocytic nevi are a marker of increased risk for developing oral mucosal melanoma. However, early oral mucosal melanomas may appear clinically similar to oral melanocytic nevi or other benign pigmented lesions. Therefore, biopsy of all unexplained pigmented oral lesions generally is advised.

• **Fig. 10.50 Conventional Acquired Melanocytic Nevus, Compound.** High-power view showing nests of pigmented nevus cells within the epithelium and the superficial lamina propria.

• **Fig. 10.51 Conventional Acquired Melanocytic Nevus, Intramucosal.** Collections of melanocytic nevus cells within the lamina propria.

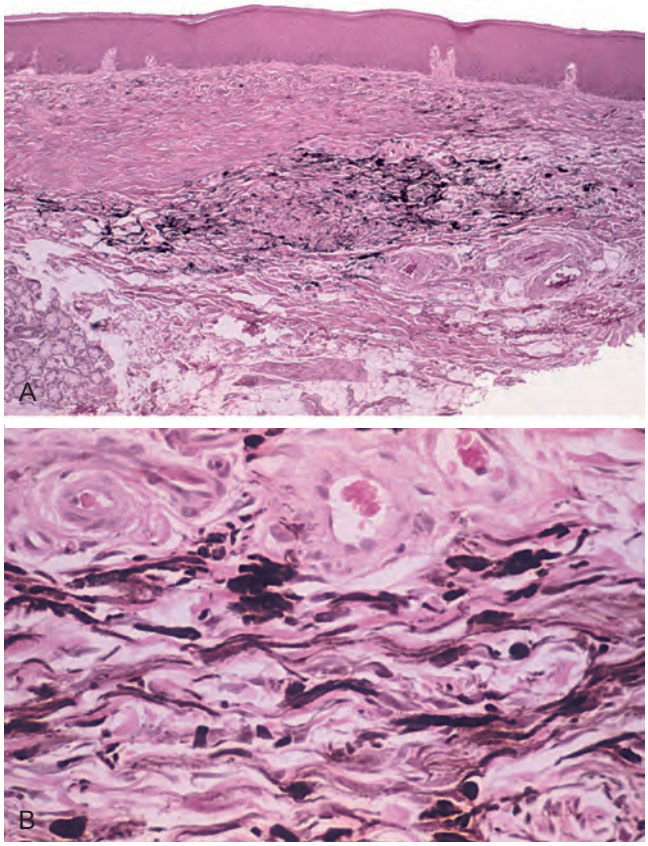
BLUE NEVUS (DERMAL MELANOCYTOMA; JADASSOHN-TIÈCHE NEVUS)

The **blue nevus** is an uncommon, benign proliferation of dermal melanocytes, usually deep within the connective tissue. Two major types are recognized: (1) the **common** blue nevus and (2) the **cellular** blue nevus. The common blue nevus is the second most frequently encountered type of melanocytic nevus in the mouth. The blue color of this melanin-producing lesion can be explained by the **Tyndall effect**, which relates to the interaction of light with particles in a colloidal suspension. In the case of a blue nevus, the melanin particles are deep to the surface, so that light reflected back has to pass through the overlying tissue. Colors with long wavelengths (reds and yellows) tend to be absorbed more readily by the tissue; the shorter-wavelength blue light is more likely to be reflected back to the observer's eyes.

Most blue nevi are acquired, although congenital lesions are possible. Unlike conventional acquired melanocytic nevi, blue nevi only rarely harbor *BRAF* mutations. Instead, blue nevi tend to exhibit activating mutations in *GNAQ* or, to a lesser extent, *GNA11*; these genes encode G-protein alpha subunits important for signal transduction from cell-surface receptors. *GNAQ* or *GNA11* mutations in blue nevi and *BRAF* mutations in acquired melanocytic nevi both result in constitutive activation of the MAPK signaling pathway.

Clinical Features

The common blue nevus may affect any cutaneous or mucosal site, but it has a predilection for the hands and feet (mainly the dorsal aspect), the scalp, and the face. Mucosal lesions may involve the oral cavity, the conjunctiva, and, rarely, the sinonasal region. Oral examples almost always are found on the palate. The lesion exhibits a female predilection and usually occurs in children and young adults. It typically appears as a macular or dome-shaped, blue or blue-black lesion smaller than 1 cm in diameter (Fig. 10.52).



• **Fig. 10.52 Blue Nevus.** A well-circumscribed, deep-blue macular lesion on the palatal mucosa.

dentlearn.ir

The cellular blue nevus is encountered much less frequently than the common type. It usually develops during the second to fourth decades of life but may be congenital. More than 50% of cellular blue nevi arise in the sacrococcygeal or buttock region, although other cutaneous or mucosal surfaces may be involved as well. Clinically, the lesion typically appears as a slow-growing, blue-black papule or nodule that sometimes attains a size of 2 cm or more. Occasional examples remain macular.

Histopathologic Features

Histopathologically, the common blue nevus consists of a collection of elongated, slender melanocytes with dendritic extensions and numerous melanin granules. These cells are located deep within the dermis or lamina propria (Fig. 10.53) and usually align themselves parallel to the surface epithelium. The cellular blue nevus appears as a well-circumscribed, highly cellular aggregate of plump, melanin-producing spindle cells within the dermis or submucosa. More typical pigmented dendritic spindle cells are seen at the periphery of the lesion. Occasionally, a blue nevus is found in conjunction with an overlying conventional acquired melanocytic nevus, in which case the term **combined nevus** is used.

• **Fig. 10.53 Blue Nevus. A,** Abundant melanin is seen within spindle-shaped melanocytes located relatively deep within the lamina propria and parallel to the surface epithelium. **B,** High-power view showing heavily pigmented spindle-shaped cells.

Treatment and Prognosis

If clinically indicated, conservative surgical excision is the treatment of choice for blue nevi. Recurrence is minimal with such treatment. Malignant transformation of cutaneous or oral blue nevi to melanoma is rare but has been reported. Because an oral blue nevus clinically can mimic an early melanoma, biopsy of intraoral pigmented lesions is usually advisable.

SPITZ NEVUS (BENIGN JUVENILE MELANOMA; SPINDLE AND EPITHELIOID CELL NEVUS)

Spitz tumors represent a group of uncommon melanocytic lesions characterized by large, spindled and/or epithelioid melanocytes. Although initially described by Spitz in 1948 as "juvenile melanoma," these tumors currently are recognized as a spectrum of lesions ranging from benign to malignant. Herein we will focus on the **Spitz nevus**—a benign acquired melanocytic nevus variant, which accounts for about 1% of all cutaneous melanocytic nevi in children. Additional entities within this spectrum include the **atypical Spitz tumor** (an intermediate lesion with uncertain biologic behavior) and **Spitz melanoma** (a rare subset of malignant melanoma). Diagnosis of Spitz tumors can be challenging and represents an ongoing area of controversy.

Characteristic genetic findings in Spitz nevi include activating point mutations in *HRAS* (often accompanied by copy number gain in mutant *HRAS* due to chromosome 11p amplification), rearrangements involving the serine/threonine kinases *BRAF* and *MAP3K8*, and rearrangements of receptor tyrosine kinases (including *ROS1, NTRK1, ALK*, and others). These alterations result in activation of the MAPK signaling pathway. Whereas melanomas and conventional acquired melanocytic nevi tend to exhibit MAPK signaling activation via *BRAF* V600E and *NRAS* mutations, Spitz nevi demonstrate such mutations only infrequently.

Clinical Features

The Spitz nevus typically develops on the skin of the face, neck, or lower extremities during childhood. Oral examples have been reported rarely. White individuals are affected more often than blacks or Asians. The tumor usually appears as a solitary, dome-shaped, pink to reddish-brown papule smaller than 6 mm in greatest diameter. The young age at presentation and relatively small size help distinguish the Spitz nevus from melanoma. Spitz nevi may grow rapidly at first but usually stabilize after about 6 months.

Histopathologic Features

Most Spitz nevi are compound in architecture, with zonal differentiation from the superficial to deep aspects and good symmetry. Lesional cells are either spindle-shaped or plump (epithelioid), and the two cell types often are intermixed.

dentlearn.ir

The epithelioid cells may be multinucleated and may appear somewhat bizarre, often lacking cohesiveness. Solitary or coalescent eosinophilic globules shown to be masses of basement membrane material (Kamino bodies) may be seen within the epidermis or at the junction of the epidermis and dermis. Ectatic blood vessels (imparting the reddish color of some lesions) and normal mitotic figures may be present in the superficial aspects of the lesion. Immunohistochemistry may show expression of various melanocytic antigens, such as S-100 protein, HMB-45 (usually positive in superficial areas of the tumor), and melan-A (MART-1).

Treatment and Prognosis

Conservative surgical excision is the most common treatment, and there is little chance of recurrence after removal. However, for lesions exhibiting typical clinical and dermoscopic features of Spitz nevus in children younger than 12 years, some authorities advocate close monitoring. Untreated lesions eventually may undergo involution or conversion to another nevus type.

HALO NEVUS (SUTTON NEVUS; LEUKODERMA ACQUISITUM CENTRIFUGUM)

The **halo nevus** is a melanocytic nevus with a hypopigmented border, apparently resulting from the destruction of nevus cells and melanocytes by the immune system. The cause of the immune attack is unknown, but regression of the nevus usually results. Most cases develop from preexisting acquired melanocytic nevi, although development from congenital nevi is possible as well. Some reports have suggested a possible association with vitiligo. Interestingly, multiple halo nevi may develop in patients who have had a recent excision of a melanoma. Infrequently, melanomas and basal cell carcinomas also may exhibit halo phenomena.

Clinical Features

Halo nevi most commonly occur on the skin of the trunk during the second decade of life. The lesion typically appears as a pigmented papule or macule, surrounded by a hypopigmented zone measuring 2–3 mm or wider (Fig. 10.54).

Histopathologic Features

Histopathologically, the halo nevus differs from the routine acquired melanocytic nevus only in the presence of an intense chronic inflammatory cell infiltrate.

Treatment and Prognosis

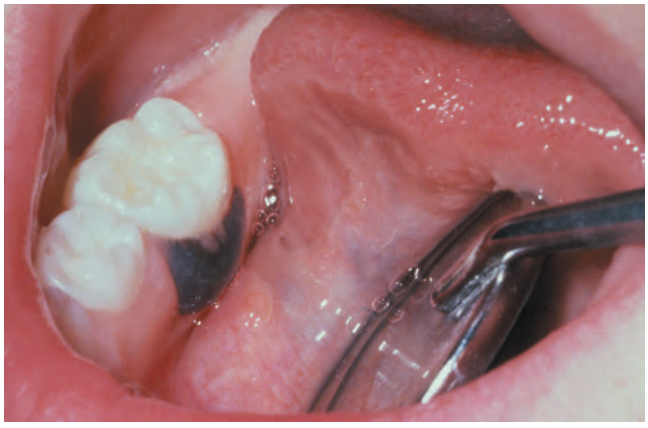
Most halo nevi regress and do not require treatment. If treatment is elected, then conservative surgical removal is curative and recurrence is unlikely.

• **Fig. 10.54 Halo Nevus.** Elevated brown lesion of the skin showing surrounding depigmentation.

◆ CONGENITAL MELANOCYTIC NEVUS

The **congenital melanocytic nevus** affects approximately 1% of newborns in the United States. The trunk and extremities are involved most commonly, although about 15% of lesions arise in the head and neck area. Intraoral involvement is rare. Congenital melanocytic nevi usually are classified according to projected adult size as follows: small (<1.5 cm in diameter), medium (1.5–20 cm in diameter), or large (>20 cm in diameter). Especially large lesions may be termed "giant." Small to medium congenital melanocytic nevi are relatively common and often exhibit *BRAF* mutations, whereas large to giant lesions occur in only about 1 in 20,000–500,000 births and often harbor *NRAS* mutations. Growth of congenital nevi tends to mirror growth of the affected child; unlike conventional acquired melanocytic nevi, congenital lesions tend to persist into adulthood without regression.

Clinical Features



Small congenital melanocytic nevi may appear similar to acquired melanocytic nevi. However, most lesions are medium to large—appearing as light tan macules that over time develop into dark brown to black, rough-surfaced plaques or multinodular lesions (Figs. 10.55 and 10.56). A common feature is **hypertrichosis** (excess hair) within the lesion, which may become more prominent with age **(giant hairy nevus).** A very large congenital nevus sometimes may give the appearance that the patient is wearing an article of clothing and, thus, may be termed a **bathing trunk nevus** or **garment nevus**.

Patients with large, giant, or multiple congenital nevi are at risk for *neurocutaneous melanosis*. This rare and potentially fatal syndrome is characterized by congenital nevi in conjunction with melanotic neoplasms of the central nervous system (CNS), including leptomeningeal melanocytosis and melanoma. Associated findings may include seizures, paralysis, learning disorders, intellectual deficit, hydrocephalus, and brain malformations. MRI in early infancy may aid in screening at-risk patients for this condition.

dentlearn.ir

• **Fig. 10.55 Congenital Melanocytic Nevus.** Pigmented lesion of the skin showing hypertrichosis.

• **Fig. 10.56 Congenital Melanocytic Nevus.** Deeply pigmented lesion of the lingual mandibular gingiva in a 3-year-old child.

Histopathologic Features

The histopathologic appearance of the congenital melanocytic nevus is similar to that of the acquired melanocytic nevus, and some small congenital nevi cannot be distinguished microscopically from acquired nevi. Both congenital and acquired types are composed of nevus cells, which may have a junctional, compound, or intradermal pattern. The congenital nevus is usually of the compound or intradermal type. In contrast to the acquired melanocytic nevus, the congenital nevus often extends into deeper levels of the dermis, with "infiltration" of nevus cells between collagen bundles. In addition, congenital nevus cells often intermingle with neurovascular bundles in the reticular dermis and surround normal adnexal skin structures (e.g., hair follicles, sebaceous glands). Large congenital melanocytic nevi may extend into the subcutaneous fat.

Treatment and Prognosis

Many congenital melanocytic nevi are excised for aesthetic purposes. Systematic reviews of the literature suggest that approximately 2%–3% of large congenital nevi transform into malignant melanoma. However, the efficacy of excision in reducing this slightly elevated risk for melanoma is unknown and remains controversial. Also, complete excision may not be feasible for large lesions. Alternative treatment options include partial surgical removal, dermabrasion, laser therapy, cryotherapy, and chemical peels. Close clinical follow-up is recommended regardless of whether or not treatment has been rendered.

†Oral lesions with lichenoid features but lacking the typical clinical or histopathologic appearances of oral lichen planus.

◆ ORAL POTENTIALLY MALIGNANT DISORDERS

As defined by the World Health Organization, **oral potentially malignant disorders** represent "a heterogeneous group of clinically defined conditions associated with a variable risk of progression to oral squamous cell carcinoma." The true prevalence of these disorders is difficult to determine because of the limited availability of population-based data. However, a recent meta-analysis reported an estimated worldwide prevalence of 4.5%. Box 10.3 lists major types of oral potentially malignant disorders, and Box 10.4 provides definitions for various terms related to our discussion of these disorders. Most widely recognized among oral potentially malignant disorders is *leukoplakia*, with an estimated worldwide prevalence of 4.1%. In contrast, its counterpart, *erythroplakia*, is relatively rare (global prevalence <1%) but associated with a very high risk for harboring or transforming into malignancy. The following oral potentially malignant disorders are discussed in greater detail in the sections below:

dentlearn.ir

• BOX 10.4 Terminology Related to Oral Potentially Malignant Disorders

- **Oral potentially malignant disorders.** A heterogeneous group of clinically defined conditions associated with a variable risk of progression to oral squamous cell carcinoma.
- **Malignant transformation potential.** The risk of cancer being present in a potentially malignant disorder, either at initial diagnosis or in the future (usually expressed in percentages).
- **Relative risk.** A specific epidemiologic measure of the association between exposure to a particular factor and the risk of acquiring a disease, expressed as a ratio of the incidence or prevalence of a disease among those exposed and those not exposed to the factor.
- **Hazard ratio.** A measure of how often an event (such as, cancer) occurs over time in one group compared to another group (e.g., patients in the treatment group vs the control group in a clinical trial, individuals exposed to a particular carcinogen compared to those not exposed).

leukoplakia, erythroplakia, smokeless tobacco keratosis, oral submucous fibrosis, and actinic cheilosis.

The phrase *potentially malignant* refers to the fact that the risk for cancer development is increased but not inevitable. In fact, the majority of patients with oral potentially malignant disorders do not progress to malignancy, although some will develop cancer or already may have cancer at initial presentation. According to a meta-analysis of the literature, the overall malignant transformation rate of oral potentially malignant disorders is approximately 8%. However, estimated malignant transformation rates vary considerably by disorder type (e.g., proliferative verrucous leukoplakia 44%–100%, leukoplakia 4%–22%, oral submucous fibrosis 4%–6%). With regard to erythroplakia, at least half of cases already represent carcinoma at initial presentation; after excluding the already malignant cases, the remainder mostly exhibit *high-grade dysplasia* (epithelial microscopic features associated with a high risk for progression to carcinoma), with estimated malignant transformation rates mostly in the range of 14%–50%.

There is some uncertainty regarding the malignant potential of lichen planus (see page 787) and other lichenoid pathoses, and their inclusion within the category of oral potentially malignant disorders has been debated. Considerable variation in reported malignant transformation rates for these conditions likely reflects difficulties with establishing definitive clinical and histopathologic criteria; however, the malignant transformation risk generally appears to be low (best estimates are less than 1%–3% for lichen planus and slightly higher for so-called oral lichenoid lesions). Some studies also suggest that the erosive form of lichen planus has greater potential for malignant progression compared to other subtypes.

◆ LEUKOPLAKIA (LEUKOKERATOSIS; ERYTHROLEUKOPLAKIA)

As defined by the World Health Organization, oral **leukoplakia** (*leuko* = white; *plakia* = patch) represents a white plaque that is of questionable risk for oral cancer and only can be diagnosed once having excluded other known diseases. The term is strictly a clinical one and does not imply a specific histopathologic tissue alteration. (As with most oral white lesions, the clinical color results from a thickened surface *keratin* layer, which appears white when wet, or a thickened *spinous* layer, which masks the normal vascularity [redness] of the underlying connective tissue.) Nonetheless, both clinical and microscopic examination may aid in ruling out other conditions that may appear as oral white plaques, such as lichen planus, morsicatio buccarum (chronic cheek nibbling), frictional keratosis, smokeless tobacco keratosis, nicotine stomatitis, leukoedema, and white sponge nevus. Thus, leukoplakia is somewhat unusual in that it represents a *diagnosis of exclusion*.

Prevalence

Based on pooled, weighted data from various studies, the worldwide prevalence of leukoplakia has been estimated to fall within a range of 1.5%–4.3%. Similarly, a recent meta-analysis of studies with clinical assessment and histopathologic confirmation reported an estimated worldwide prevalence of 4.1%.

Etiology

The cause of leukoplakia remains unknown, although hypotheses abound.

Tobacco

Among the various proposed contributory factors, tobacco smoking appears to be the most closely associated with leukoplakia. More than 80% of patients with leukoplakia are smokers, and smokers are much more likely to have leukoplakia than nonsmokers. Heavier smokers have greater numbers of lesions and larger lesions than do light smokers, especially after many years of tobacco use. In addition, leukoplakias often disappear or become smaller within the first year of smoking cessation.

Smokeless tobacco use frequently causes a clinically distinctive white oral plaque called **smokeless tobacco keratosis** (see page 391), which generally exhibits a very low malignant transformation risk. This lesion is considered an orally potentially malignant disorder but should not be classified as a true leukoplakia. In contrast, betel quid use (see page 393)—with or without smokeless tobacco—is associated with true leukoplakia; this habit is common in parts of Asia.

Alcohol

Alcohol exerts a strong synergistic effect with tobacco in oral cancer development. Nevertheless, there is conflicting evidence as to whether alcohol is associated independently with leukoplakia. People who excessively use mouth rinses with alcohol content greater than 25% may have grayish buccal mucosal plaques, but these lesions are not considered true leukoplakias.

Sanguinaria

Persons who use toothpaste or mouth rinses containing the herbal extract, sanguinaria, may develop a true leukoplakia

dentlearn.ir

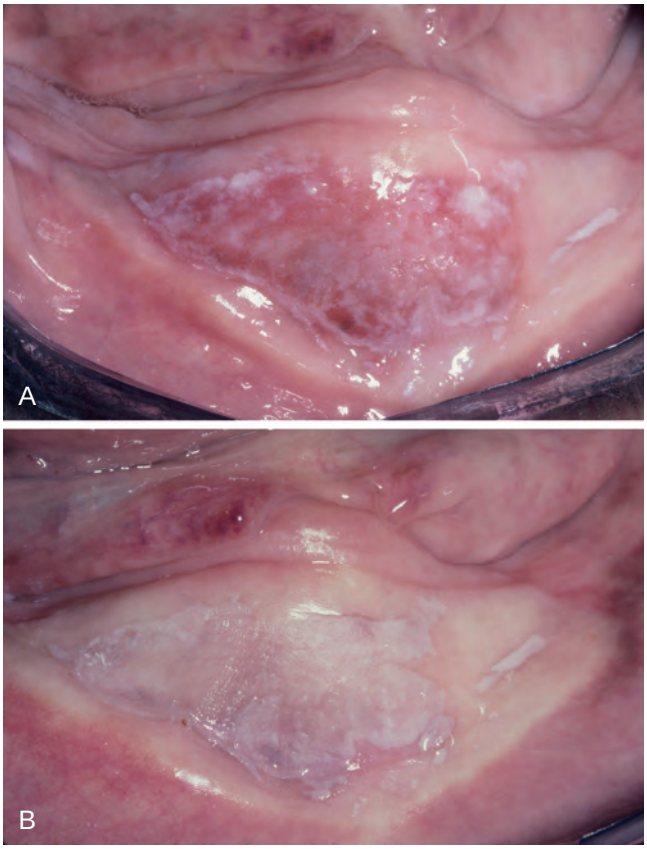
• **Fig. 10.57 Sanguinaria-associated Keratosis.** Thin white plaque on the maxillary alveolar mucosa.

called **sanguinaria-associated keratosis.** This lesion usually arises in the maxillary vestibule or on the maxillary alveolar mucosa (Fig. 10.57). More than 80% of individuals with maxillary vestibular or alveolar leukoplakia have a history of using products that contain sanguinaria, compared with 3% of the normal population.

The affected epithelium may demonstrate dysplasia identical to that seen in other leukoplakias, although the potential for cancer development is uncertain. The white plaque may persist for years even after the patient stops using the product.

Ultraviolet Radiation

UV radiation is a causative factor for leukoplakia of the lower lip vermilion. Such lesions typically represent actinic cheiloses (see page 395). Immunocompromised persons, such as transplant patients, are especially prone to developing leukoplakia and squamous cell carcinoma of the lower lip vermilion.



Microorganisms

Several microorganisms have been implicated in the etiology of leukoplakia. *Treponema pallidum,* for example, produces glossitis in the late stage of syphilis, with or without the arsenic therapy in popular use before the advent of modern antibiotics. The tongue is stiff and frequently has extensive dorsal leukoplakia.

Tertiary syphilis is rare today, but oral infection by *Candida albicans* is not. *C. albicans* can colonize the keratin layer of the oral mucosa, often producing a thick, granular, red and white plaque (Fig. 10.58). The terms **candidal leukoplakia** and **candidal hyperplasia** have been used to describe such a lesion, and biopsy may show epithelial dysplasia or hyperplasia. It is unknown whether this yeast produces dysplasia or secondarily infects previously altered epithelium; however, some of these lesions disappear, shrink, or become less severely dysplastic after antifungal therapy. In some cases, tobacco smoking may cause the leukoplakia and also may predispose the patient to develop candidiasis.

Some studies have detected HPV DNA about two to four times more often in oral leukoplakias than in clinically normal oral mucosa; in addition, recent meta-analyses have reported HPV DNA in about 20% of oral leukoplakias and 27% of oral epithelial dysplasias. However, the presence of HPV DNA alone cannot exclude the possibility of coincidental (or "bystander") infection. Additional investigations have identified a subset of dysplastic oral leukoplakias (and, more rarely, erythroplakias) positive for p16 by immunohistochemistry and positive for high-risk HPV DNA or mRNA by *in situ* hybridization (see page 405 for further discussion of these assays). These findings suggest that a small proportion of oral leukoplakias may be HPV-driven, although further studies are needed.

Recent advances in high-throughput sequencing technologies have enabled researchers to investigate the oral microbiome of patients with leukoplakia. Although results across studies have been variable, some researchers have noted decreased levels of commensal organisms (such as streptococci) and increased levels of anaerobic bacteria (such as *Fusobacterium nucleatum*, *Prevotella intermedia*, and *Porphyromonas gingivalis*) in patients with oral leukoplakia compared to healthy controls. Research in this field is still in its infancy, however, and more standardized studies are needed.

• **Fig. 10.58 Candidal Leukoplakia. A,** Well-circumscribed red and white plaque on the anterior floor of mouth, which showed candidal infestation on cytology smears. **B,** After antifungal therapy, the erythematous component resolved, resulting in a homogeneous white plaque.

dentlearn.ir

Chronic Trauma or Irritation

Several keratotic lesions, which until recently had been viewed as variants of leukoplakia, are now considered not to be precancers. Nicotine stomatitis is a generalized white palatal alteration that seems to be a hyperkeratotic response to the heat generated by tobacco smoking (usually a pipe), rather than a response to the carcinogens within the smoke (see page 397). Its malignant transformation potential is so low as to be about the same as that of normal palatal mucosa.

In addition, chronic mechanical irritation can produce a white lesion with a roughened keratotic surface, termed **frictional keratosis.** Although this lesion clinically appears similar to true leukoplakia, it is now thought to be no more than a normal hyperplastic response (similar to a callus on the skin). Keratoses of this type are readily reversible after elimination of the trauma, and obviously traumatic lesions—such as linea alba (see page 272), morsicatio (see page 272), and toothbrush gingival "abrasion"—have not been documented to transform into malignancy. **Alveolar ridge keratoses** (Fig. 10.59)—involving the retromolar pad or crest of an edentulous alveolar ridge—represent another form of frictional keratosis caused by masticatory function or denture trauma. Frictional keratosis should be differentiated from oral precancers.

Interestingly, a recent study noted an association between gingival white plaques and the presence of silicon-containing foreign particles. Potential sources of such particles include oral hygiene products and dental materials. Most of these leukoplakias exhibited a verrucous growth pattern; other frequent findings included chronic inflammation and hyperorthokeratosis. Epithelial dysplasia was evident in some cases as well. The clinicopathologic features resemble those seen in early stages of proliferative verrucous leukoplakia (see page 384).

• **Fig. 10.59 Frictional Keratosis.** There is a rough, hyperkeratotic change to the posterior mandibular alveolar ridge ("alveolar ridge keratosis"), because this area is now edentulous and becomes traumatized from mastication. Such frictional keratoses should resolve when the source of irritation is eliminated and should not be mistaken for true leukoplakia.

Clinical Features

Oral leukoplakia exhibits a male predilection, with approximately 60%–80% of cases overall arising in men. However, there is a female predilection in some regions where women use tobacco products more than men. Oral leukoplakia usually affects persons older than 40 years, and prevalence increases rapidly with age. The average age (60 years) is similar to that for patients with oral cancer; however, in some studies, leukoplakia has been found to occur about 5 years earlier (on average) than oral squamous cell carcinoma.

Approximately 70% of oral leukoplakias are found on the lip vermilion, buccal mucosa, and gingiva. Lesions on the tongue, lip vermilion, and oral floor, however, account for more than 90% of those that show dysplasia or carcinoma. Among betel quid users, the buccal mucosa and commissure are the major sites for leukoplakia harboring carcinoma. Leukoplakia presents as a white plaque that cannot be wiped or scraped away. The inability to wipe the lesion away is a clinical finding that aids in distinguishing leukoplakia from other conditions, such as pseudomembranous candidiasis, chemical or thermal burns, and toothpaste-related allergic contact stomatitis.

Individual lesions may have a varied clinical appearance, and their features may change over time. **Homogeneous leukoplakia** refers to individual lesions with a relatively uniform appearance throughout. An early or mild lesion may present as **homogeneous thin leukoplakia**—a white to gray-white macule or plaque, which may be somewhat translucent, fissured, or wrinkled (Fig. 10.60). Such lesions usually are soft with sharply demarcated borders, but occasionally they may blend gradually into normal mucosa. Homogeneous thin leukoplakias may disappear or continue unchanged, and they seldom show dysplasia on biopsy. For tobacco smokers who do not reduce their habit, however, as many as two-thirds of

• **Fig. 10.60 Homogeneous Thin Leukoplakia.** A thin, white plaque on the right ventral tongue.

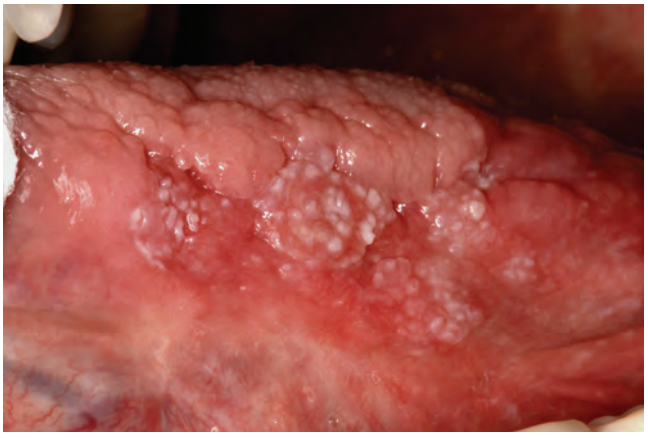
dentlearn.ir

such lesions enlarge and progress to a stage called **homogeneous thick leukoplakia**, characterized by a thickened, leathery, distinctly white plaque with deepened fissures (Figs. 10.61 and 10.62). Most remain indefinitely at this stage, and as many as one-third regress or disappear. However, some lesions may progress to develop a nonhomogeneous appearance.

Nonhomogeneous leukoplakia refers to leukoplakia with a granular (Fig. 10.63), nodular, verrucous/verruciform, ulcerated, or red component. Notably, nonhomogeneous leukoplakia has a significantly greater risk for malignant transformation (or already harboring malignancy) compared to homogeneous leukoplakia. A nonhomogeneous leukoplakia with a mixture of red and white areas may be termed **erythroleukoplakia** or **speckled leukoplakia** (Fig. 10.64). The red areas tend to exhibit high-grade dysplasia or microinvasive carcinoma upon microscopic examination. The erythema may result from epithelium that is so immature that it no longer produces keratin and/or atrophic epithelium that allows underlying vascularity to be readily apparent. Lesions that become entirely red in appearance are known as **erythroplakias** (see page 390).

A special high-risk form of leukoplakia, **proliferative verrucous leukoplakia (PVL)** (or **proliferative leukoplakia**), is characterized by the development of multiple, slowly spreading, keratotic plaques with rough surface projections (Figs. 10.65–10.67). The gingiva frequently is involved, but other sites may be affected as well. Although the lesions typically begin as simple, flat hyperkeratoses that are indistinguishable from ordinary homogeneous leukoplakia, PVL exhibits persistent growth, with lesions eventually becoming exophytic and verrucous. As the lesions progress, they may go through a stage indistinguishable from **verrucous carcinoma** (see page 421), but they later usually develop dysplasia and transform into full-fledged **squamous cell carcinoma** (often within 8 years of initial PVL diagnosis). These lesions rarely regress despite therapy. PVL is unusual among the leukoplakia variants in having a strong female predilection (1:4 male-to-female ratio) and minimal association with tobacco use.

Many leukoplakic lesions are a mixture of the previously mentioned phases or subtypes. Figs. 10.68 and 10.69



• **Fig. 10.61 Homogeneous Thick Leukoplakia.** A diffuse, corrugated white plaque on the right ventral surface of the tongue and floor of mouth.

• **Fig. 10.62 Homogeneous Thick Leukoplakia.** Left buccal mucosa exhibiting an extensive thick, white plaque with associated fissures. Moderate epithelial dysplasia was noted on histopathologic evaluation, and squamous cell carcinoma later developed in this area.

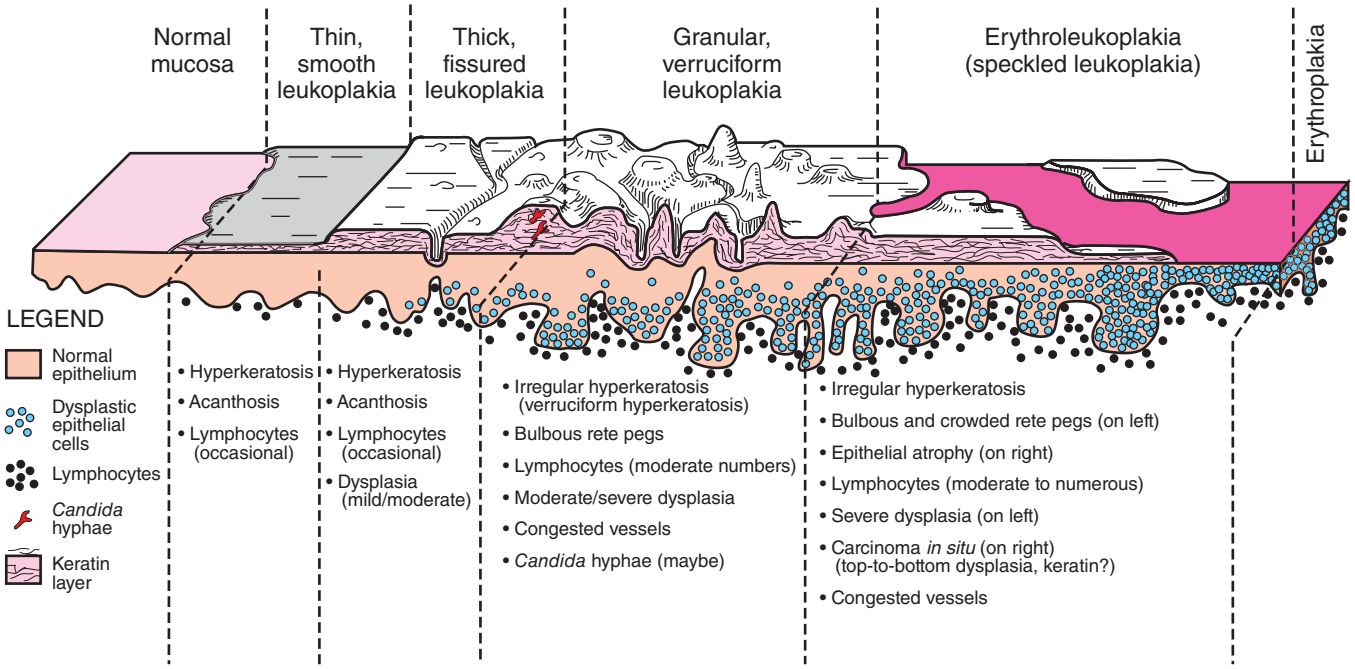
provide a clinical and graphic representation of such a lesion. Biopsies should be taken from areas of a lesion most likely to harbor dysplasia or carcinoma (i.e., areas with a clinical appearance similar to those toward the right in Fig. 10.69).

Over the years, several techniques (e.g., vital dyes, brush cytology, chemiluminescence, autofluorescence, salivary biomarker assays, *in vivo* microscopy) have been proposed to aid in the identification or diagnosis of premalignant and malignant oral lesions. However, there is currently insufficient evidence to support the use of such technologies in routine practice, and careful clinical evaluation with directed conventional biopsy remains the gold standard for assessment of oral leukoplakia (see Fig. 10.101).

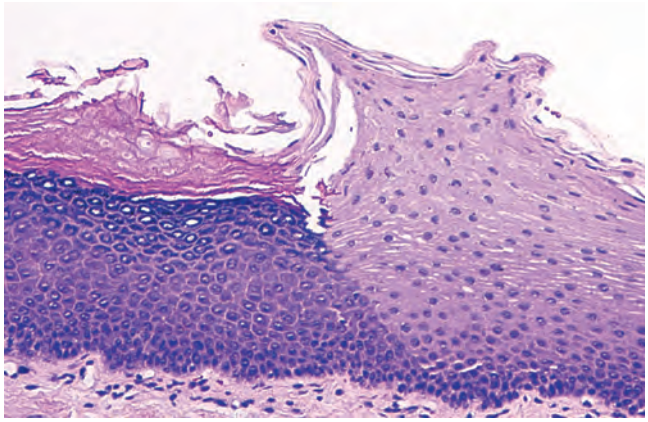
Histopathologic Features

Microscopically, leukoplakia is characterized by a thickened keratin layer of the surface epithelium **(hyperkeratosis),** with or without a thickened spinous layer **(acanthosis).** Some leukoplakias demonstrate surface hyperkeratosis but show atrophy or thinning of the underlying epithelium.

• **Fig. 10.67 Proliferative Verrucous Leukoplakia (PVL). A,** An elderly white female developed extensive leukoplakia with rough surface projections on the buccal mucosa and mandibular alveolar ridge. **B,** After failing to comply with a recommendation for biopsy, the same patient returned 2 years later with a verrucous carcinoma.



• **Fig. 10.68 Leukoplakia.** Extensive ventral and lateral tongue lesion with areas representing various possible phases or clinical appearances (compare with Fig. 10.69).



Frequently, variable numbers of chronic inflammatory cells are noted within the subjacent connective tissue.

The keratin layer may consist of parakeratin **(hyperparakeratosis)**, orthokeratin **(hyperorthokeratosis)**, or a combination of both (Fig. 10.70). With parakeratin, there is no granular cell layer, and the epithelial nuclei are retained in the

dentlearn.ir

• **Fig. 10.69 Leukoplakia.** Composite representation of the various phases or clinical appearances of oral leukoplakia, with anticipated underlying histopathologic changes. Lesions have increasing malignant transformation potentials as their appearances approach those toward the right. (From Bouquot JE, Gnepp DR: Laryngeal precancer—a review of the literature, commentary and comparison with oral leukoplakia, *Head Neck* 13:488–497, 1991.)

• **Fig. 10.70 Hyperorthokeratosis.** This medium-power photomicrograph demonstrates hyperorthokeratosis with a well-defined granular cell layer on the left side. The right side shows normal parakeratinized epithelium without a granular cell layer.

keratin layer. With orthokeratin, the epithelium demonstrates a granular cell layer, and the nuclei are lost in the keratin layer.

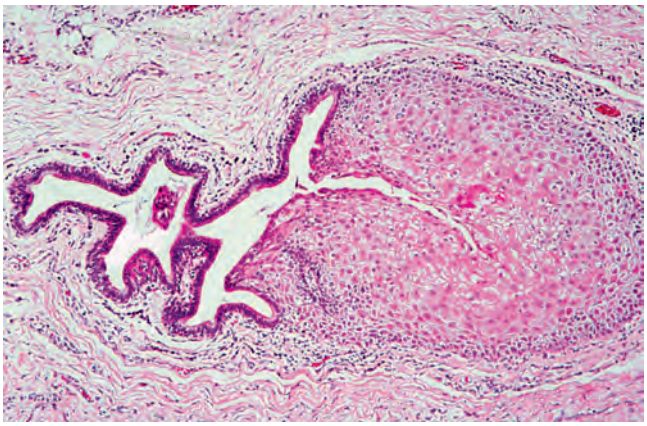
Oral epithelial dysplasia represents a spectrum of cytologic and architectural changes in oral epithelium that are associated with a risk for transformation into squamous cell carcinoma. These changes are evident at the light microscopic level and apparently result from accumulation of underlying genetic and epigenetic alterations. Epithelial dysplasia can be found in leukoplakia, erythroplakia (see next section), and other types of oral potentially malignant disorders. The exact proportion of oral leukoplakias exhibiting dysplasia is difficult to determine due to variation in study design/bias, case definitions, and interobserver evaluation. In prior studies, epithelial dysplasia or carcinoma has been reported in only about 5%–25% of oral leukoplakias, although more recent analyses, with refined case definitions, have noted such changes in as many as 40%–46% of cases.

The histopathologic alterations of dysplastic epithelial cells are similar to those of squamous cell carcinoma and may include the following:

- Abnormal variation in size of nuclei and cells
- Abnormal variation in shape (pleomorphism) of nuclei and cells
- Increased nuclear-to-cytoplasmic ratio
- Increased nuclear size
- Hyperchromatic (excessively dark-staining) nuclei
- Increased number and size of nucleoli
- Dyskeratosis (premature keratinization of individual cells)
- Increased mitotic activity (excessive numbers of mitoses)
- Atypical mitotic figures (e.g., tripolar or star-shaped mitoses)
- Apoptotic mitoses

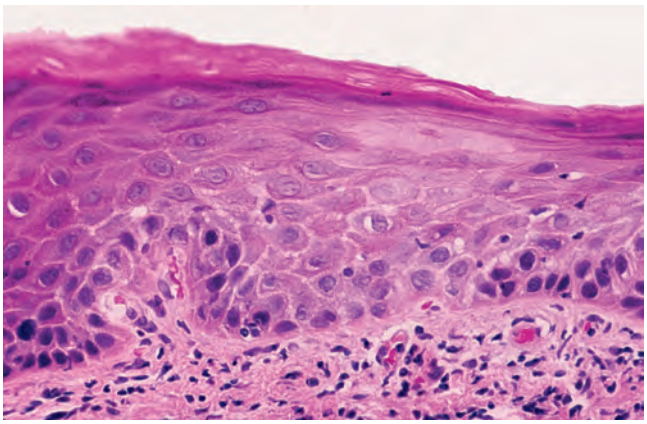
In addition, dysplastic epithelium may exhibit architectural alterations, including the following:

- Drop-shaped rete ridges
- Irregular epithelial stratification
- Basal cells exhibiting disorganization or loss of polarity
- Basal cell clustering or nesting
- Mitoses high in the epithelium; mitoses in maturing cells



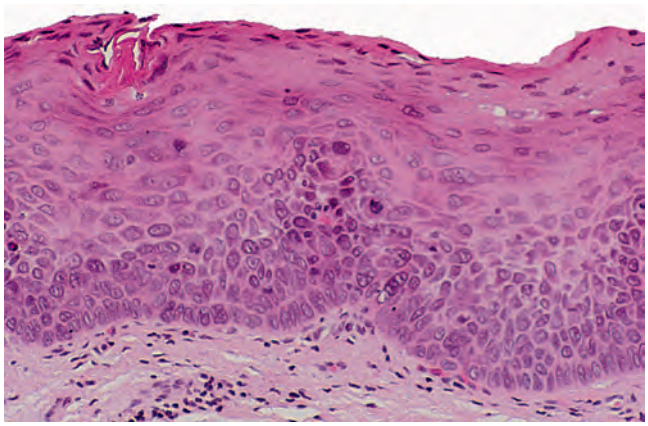
dentlearn.ir

- Keratin pearls (focal, round collections of concentrically layered keratinized cells) within rete ridges
- Generalized premature keratinization
- Altered keratin pattern for oral subsite
- Reduced keratinocyte cohesion
- Verrucous or papillary architecture
- Multifocal or "skip" lesions (areas of thick keratosis alternating with normal-appearing nonkeratinized epithelium)
- Sharply defined margins (between microscopically altered and "normal-appearing" epithelium)
- Extension of dysplastic changes into minor salivary gland ducts (Fig. 10.71) (This feature often is seen in the floor of mouth and is associated with an increased risk for recurrence.)
- Multiple different patterns of dysplasia

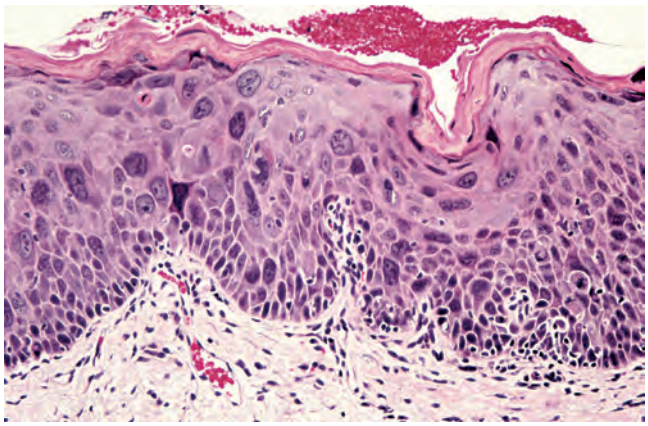


The grade of epithelial dysplasia refers to its "severity" or intensity. Traditionally, a 3-tier grading system has been applied as follows: (1) **mild epithelial dysplasia** (with alterations limited principally to the basal and parabasal layers) (Fig. 10.72), (2) **moderate epithelial dysplasia** (with alterations from the basal layer to the midportion of the spinous layer) (Fig. 10.73), and (3) **severe epithelial dysplasia** (with alterations from the basal layer to a level above the midpoint of the epithelium) (Fig. 10.74). However, this traditional definition does not reflect the full complexity of grading oral epithelial dysplasia. For example, cytologic atypia and architectural disturbances that are limited to the basal third of the epithelium but are especially marked or concerning may constitute severe epithelial dysplasia. Also note that architectural changes with minimal to no cytologic atypia may be sufficient for assigning the presence of dysplasia.

Alternatively, some authorities advocate a binary grading system (low-grade vs high-grade dysplasia). Such a 2-tier system may exhibit improved reproducibility compared to a 3-tier system. However, further validation and outcome studies are needed.

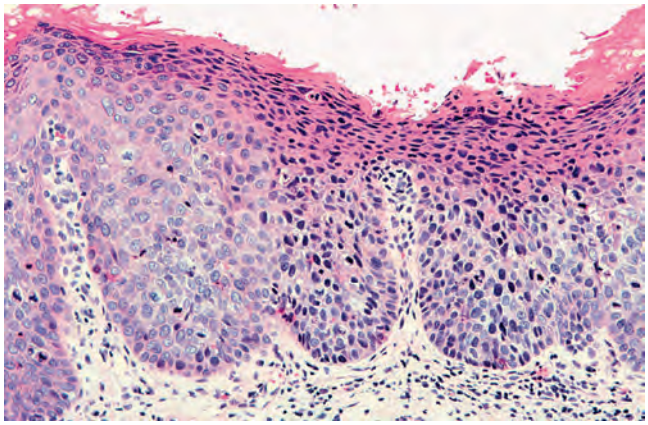


Carcinoma *in situ* is defined as dysplasia involving the entire thickness of the epithelium (i.e., extending from the basal layer to the surface or "top-to-bottom" change) (Fig. 10.75). There may or may not be a thin layer of keratin on the surface. The epithelium may be hyperplastic or



• **Fig. 10.71 Ductal Dysplasia.** Salivary gland duct exhibiting squamous metaplasia and dysplasia that originated from an overlying surface epithelial dysplasia.

• **Fig. 10.72 Mild Epithelial Dysplasia.** Hyperchromatic and slightly pleomorphic nuclei are noted in the basal and parabasal cell layers of this stratified squamous epithelium.



• **Fig. 10.73 Moderate Epithelial Dysplasia.** Dysplastic changes extend to the midpoint of the epithelium and are characterized by nuclear hyperchromatism, pleomorphism, and cellular crowding.

• **Fig. 10.74 Severe Epithelial Dysplasia.** Epithelium exhibiting marked pleomorphism, hyperchromatism, and scattered mitotic figures. Atypical cells involve most of the epithelial thickness.

dentlearn.ir

• **Fig. 10.75 Carcinoma *In Situ*.** Dysplastic changes extend throughout the entire thickness of the epithelium. Some authorities include carcinoma *in situ* within the category of severe epithelial dysplasia or high-grade dysplasia.

atrophic. Some authorities include carcinoma *in situ* within the category of severe epithelial dysplasia or high-grade dysplasia. Furthermore, some consider carcinoma *in situ* to be a precancerous lesion, whereas others believe that it represents a genuine malignancy discovered before invasion. Regardless, an important feature of carcinoma *in situ* is the absence of invasion, and without invasion, metastasis cannot occur. In this light, keratin pearl formation is rare in carcinoma *in situ* and may indicate focal invasive squamous cell carcinoma.

Proliferative verrucous leukoplakia exhibits microscopic features that vary by lesion stage. Early lesions may appear as relatively unremarkable hyperkeratoses that are indistinguishable from conventional leukoplakias. Such lesions typically lack cytologic atypia, but premature keratinization and sharply defined peripheral margins may be evident. With time, the condition progresses to form *corrugated hyperkeratotic lesions* with an architectural pattern marked by troughs/crests or undulation; alternatively, some lesions at this stage may be relatively flat with atrophic epithelium but disproportionate hyperkeratosis. Orthokeratosis usually predominates over parakeratosis. There is typically minimal to no cytologic atypia; abrupt transitions and "skip" lesions alternating between abnormal- and normal-appearing epithelium may be evident. Intermediate-stage disease is characterized by *bulky hyperkeratotic epithelial proliferation.* Such lesions exhibit a verrucous to papillary surface as well as exophytic and/or endophytic growth with broad, bulbous, and, at times, coalescing rete ridges. The total epithelial thickness may be many times greater than what is normally seen for a given oral subsite. All of the above stages may exhibit a secondary chronic inflammatory infiltrate within the superficial lamina propria; however, the presence of dysplasia (especially from an archictectural standpoint) should aid in avoiding misdiagnosis as lichen planus. Also, marked hyperorthokeratosis is a more frequent finding in proliferative verrucous leukoplakia compared to oral lichen planus. In the final stages, the epithelium becomes even more voluminous and proliferative; the lesions may develop into verrucous carcinoma, papillary squamous cell carcinoma, or frankly invasive conventional squamous cell carcinoma. Although characteristic disease stages have been described as above, individual lesions do not always progress in a stepwise manner through each stage. Overall, the diagnosis of PVL requires careful correlation of the variable clinical and microscopic findings.

Interestingly, investigators have identified a subset of oral epithelial dysplasias that harbor high-risk HPV (including HPV 16 and other types). Such lesions exhibit a predilection for the tongue and floor of mouth, and they tend to have distinctive microscopic features, including frequent apoptosis and karryorhexis. As per conventional grading criteria, the histopathologic findings often are compatible with high-grade dysplasia or carcinoma *in situ;* however, because there is a paucity of patient outcome data available at this time, some authorities advocate reporting these lesions as "HPV-associated dysplasia" without assigning a grade.

Treatment and Prognosis

The determination of management and prognosis for oral leukoplakia is guided by *histopathologic findings* (especially assessment and grading of oral epithelial dysplasia) as well as *clinical factors*. The identification of *biomarkers* predictive of malignant transformation risk represents an active area of research but remains investigational. The relevance of these factors with respect to treatment and prognosis are discussed in more detail below. Although several risk stratification models incorporating clinicopathologic parameters and/or molecular findings have been proposed, no single model has gained widespread acceptance, and further prospective clinical studies are needed.

Because leukoplakia represents a clinical term only, a biopsy is required to obtain a histopathologic diagnosis and to guide the appropriate management. Biopsies should be taken from the clinically most "severe" areas (with features toward the right of Fig. 10.69). Multiple biopsies may be needed for large or multifocal lesions.

Leukoplakia exhibiting moderate epithelial dysplasia or worse typically warrants complete destruction or removal, if feasible, and close clinical follow-up (e.g., at 1-, 3-, or 6-month intervals). Complete removal can be accomplished with equal effectiveness by surgical excision, electrocautery, cryosurgery, or laser ablation. An advantage of surgical excision is that it allows for optimal tissue preservation for histopathologic analysis, whereas the other methods may be preferable in some cases for limiting procedure-related morbidity.

The management of leukoplakia exhibiting less severe change may be guided by clinical surveillance, risk factor modification, and additional clinical factors. For example, leukoplakias with no or mild dysplasia and no adverse clinical factors (see below) often are managed conservatively by risk factor modification (e.g., tobacco counseling) and periodic clinical reevaluation (e.g., at 6- to 12-month intervals) rather than surgical excision. Some leukoplakias with no or minimal dysplasia may disappear or diminish in size within a

dentlearn.ir

few months after risk factor modification. However, if the clinical appearance of a lesion increases in severity over time, then additional biopsies may be performed. Also, for lesions with mild dysplasia plus adverse clinical predictors of outcome, surgical excision and/or short-interval clinical follow-up may be considered.

Clinical factors associated with an increased risk for malignant transformation of leukoplakia include female gender, older age, nonsmoking status, lesion persistence for several years, lesion size >200 mm^2, multifocal disease (e.g., proliferative verrucous leukoplakia), nonhomogeneous appearance, involvement of the ventrolateral tongue or floor of mouth, and a prior history of oral cancer. In particular, leukoplakias of the ventrolateral tongue and oral floor exhibit malignant transformation in 16%–39% of cases overall and in 47% of cases arising in females. Also, nonhomogeneous leukoplakia generally exhibits a greater risk for malignant transformation compared to homogeneous leukoplakia and warrants complete removal or destruction, if possible. According to one systematic review of observational studies, malignant transformation rates for nonhomogeneous and homogeneous lesions were 14.5% and 3%, respectively. Among nonhomogeneous leukoplakias, some studies have found cancer to develop in about 4%–15% of granular or verrucous lesions and 18%–47% of erythroleukoplakic lesions. In contrast, homogeneous thin leukoplakias seldom become malignant without demonstrating a clinical change, and malignant transformation occurs in only about 1%–7% of homogeneous thick leukoplakias. Notably, proliferative verrucous leukoplakia is associated with a very high risk for oral cancer development (>9% per year), and management is difficult. Patients with this condition typically are placed under close surveillance, with serial biopsies performed in an attempt to detect cancer development at an early stage.

Even after removal or apparent resolution of oral leukoplakia, reported overall recurrence rates range from 7% to 38%, and development of additional lesions is common. In particular, verruciform or granular leukoplakias exhibit an 83% recurrence rate and, thus, often undergo additional removal or destruction. There has been some disagreement in the literature regarding whether surgical excision of leukoplakia significantly reduces the risk for developing malignancy. Therefore, even after removal, long-term follow-up is extremely important.

Chemoprevention as an alternative treatment for oral leukoplakia remains experimental. Retinoid-based therapies (e.g., 13-*cis*-retinoic acid, vitamin A, beta-carotene alone or in combination with vitamin C) have reduced or eliminated some leukoplakic lesions in short-term studies. Toxic reactions to systemic retinoids are frequent, however, as is lesion recurrence after the conclusion of therapy. Additional potential chemopreventive agents of interest include nonsteroidal anti-inflammatory drugs (such as celecoxib and ketorolac), epidermal growth factor receptor (EGFR) inhibitors, immune checkpoint inhibitors, herbal extracts (such as green tea extract and freeze-dried black raspberry gel), and topical bleomycin. However, to date there is insufficient evidence to support the effectiveness of such medical therapies in preventing the progression of oral premalignant lesions to squamous cell carcinoma.

The transformation potential of oral leukoplakia is related closely to the degree of epithelial dysplasia present. According to one meta-analysis, the mean malignant progression rates for oral leukoplakia with mild/moderate dysplasia vs severe dysplasia/carcinoma *in situ* were approximately 10% and 24%, respectively. In addition, a population-based study of patients with oral leukoplakia reported overall hazard ratios of 4.9 for mild dysplasia vs 15.8 for severe dysplasia. Furthermore, a recent meta-analysis found a sixfold increased risk of malignant transformation for high-grade compared to low-grade oral epithelial dysplasia. Other large-scale studies of oral potentially malignant disorders have reported transformation rates of approximately 4%–12% for mild dysplasia, 9%–18% for moderate dysplasia, and 27%–39% for severe dysplasia. In the absence of oral epithelial dysplasia, the risk for malignant transformation is generally low but is not completely excluded.

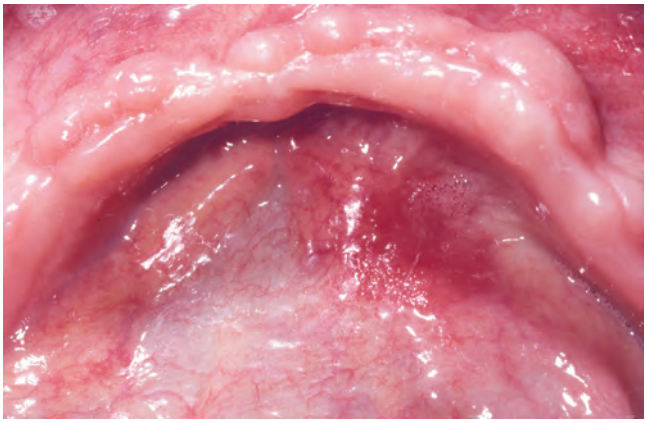
Reported overall malignant transformation rates for oral leukoplakia vary, although most studies suggest rates in the range of about 1%–3% per year. Some of this variation may be due to patient selection bias, with lower rates typically reported among community-based than hospital-based studies. Additional confounding factors include variations in case definitions, statistical methodology, patient risk profiles, clinical management, and periods of observation. Typically, the latter extend for 5–10 years, but several studies have observed patients for more than 20 years. Carcinomatous transformation usually is noted 1–4 years after leukoplakia initially is identified, but it may occur within months or after decades.

An active area of investigation is the identification of chromosomal and molecular genetic alterations that may aid in predicting the risk of malignant transformation for oral leukoplakia. Cytogenetic studies have suggested that loss of heterozygosity (LOH) of chromosome arms 3p and 9p is associated with an increased risk of malignant transformation, and additional LOH at 4q, 8p, 11q, 13q, and 17p further increases this risk. A variable association with progression to malignancy has been reported for a host of other alterations—such as DNA aneuploidy, copy number variation, DNA methylation, microsatellite instability, increased or decreased levels of micro-RNAs, increased telomerase activity (important for cellular longevity), and changes in expression of various molecular markers (e.g., p53 and other regulators of apoptosis, p16 and other markers of cell cycle regulation, epidermal growth factor receptor [EGFR], Notch1, matrix metalloproteinases, vascular endothelial growth factor, podoplanin, regulators of DNA damage repair, stem cell markers). Interestingly, some investigators have noted an increased risk for cancer development among oral premalignant lesions with a "classical" profile (including LOH at 3p14 and 17p13 [the latter locus including *TP53*]) or an "immunological" profile (including downregulation of a certain micro-RNA type and decreased infiltration by T cells, monocytes, and myeloid dendritic

dentlearn.ir

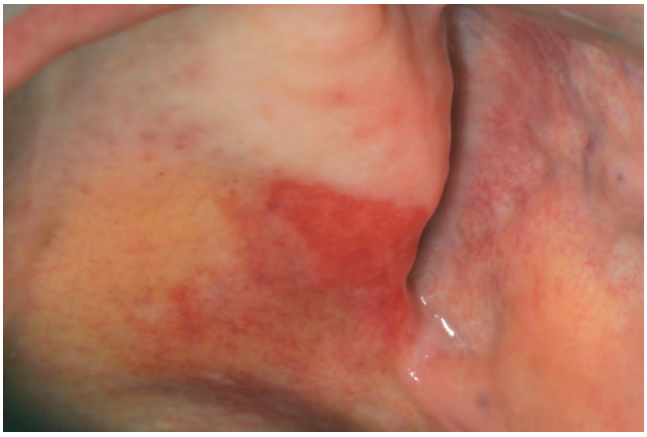
cells). Moreover, differences in transcriptome profiles for dysplastic vs nondysplastic oral leukoplakias have been identified, and an intermediate group of hyperkeratoses without conventional dysplastic histomorphology but exhibiting some genomic or transcriptomic similarities to dysplastic lesions has been noted. Despite recent advances in biomarker research and molecular profiling for patients with oral leukoplakia, the standard method for predicting the risk of progression to malignancy remains histopathologic grading of oral epithelial dysplasia, along with consideration of clinical factors.

◆ ERYTHROPLAKIA (ERYTHROPLASIA; ERYTHROPLASIA OF QUEYRAT)



Similar to leukoplakia, **erythroplakia** is defined as a red patch that cannot be characterized clinically or pathologically as any other definable lesion. Queyrat originally used the term *erythroplasia* to describe a precancerous red lesion on the penis. Oral erythroplakia is clinically and histopathologically similar to the genital process. Almost all true erythroplakias demonstrate significant epithelial dysplasia, carcinoma *in situ,* or invasive squamous cell carcinoma. The causes of erythroplakia are presumed to be the same as those associated with oral squamous cell carcinoma (see page 402). The estimated point prevalence rate (number of persons with active lesions at a given point in time) of oral erythroplakia is 1 per 2500 adults, and the reported prevalence among several large-scale epidemiologic surveys—many of which were conducted in Asia and the United States—ranges from 0.01% to 0.83%.

Erythroplakia also may occur in conjunction with leukoplakia (see page 381) and has been found concurrently with a large proportion of early invasive oral carcinomas. Although erythroplakia is less common than leukoplakia, it is associated with a much greater risk for malignancy.



Clinical Features

Erythroplakia is predominantly a disease of middle-aged to older adults with no significant gender predilection. In the United States, a peak prevalence among individuals 65–74 years old has been reported. In India, the peak prevalence is in a somewhat younger age range of 45–54 years. The floor of mouth, tongue, soft palate, and buccal mucosa are among the most frequently described sites of involvement, and multiple lesions may be present.

The lesion typically appears as a well-demarcated, erythematous patch or plaque with a soft, velvety, or granular texture (Figs. 10.76 and 10.77). It is usually asymptomatic and may be associated with an adjacent leukoplakia **(erythroleukoplakia)**. Some lesions may be somewhat depressed compared to the surrounding mucosa. Biopsy typically is required to distinguish erythroplakia from other conditions with a similar clinical appearance, such as nonspecific mucositis, candidiasis, psoriasis, or vascular lesions.

• **Fig. 10.76 Erythroplakia.** Erythematous macule on the right floor of the mouth. Biopsy showed early invasive squamous cell carcinoma.

• **Fig. 10.77 Erythroplakia.** Well-circumscribed red patch on the posterior lateral hard and soft palate. (From Neville BW, Chi AC, Jeter M: Diagnostic challenge: a red lesion on the palate, *J Am Dent Assoc* 137:1537–1538, 2006.)

Histopathologic Features

In the majority of cases, histopathologic examination exhibits severe epithelial dysplasia (see page 385), carcinoma *in situ* (see page 387), or superficially invasive squamous cell carcinoma (see page 416). The epithelium lacks keratin production and often is atrophic, thereby allowing the underlying microvasculature to show through and produce a red appearance. The underlying connective tissue frequently demonstrates chronic inflammation.

Treatment and Prognosis

Red lesions of the oral mucosa, especially those of the oral floor and ventrolateral tongue, should be viewed with suspicion, and a biopsy should be performed. If a source of irritation can be identified and removed, then biopsy may be delayed for 2 weeks to allow a clinically similar inflammatory lesion time to regress.

As with leukoplakia, the treatment of erythroplakia is guided by the histopathologic diagnosis. Moderate dysplasia

dentlearn.ir

or worse typically warrants complete excision or destruction (see treatment methods for leukoplakia on page 388). Excision often is preferred, because it allows for microscopic examination to rule out invasive carcinoma. Recurrence and multifocal involvement are common; hence, long-term follow-up is suggested.

◆ SMOKELESS TOBACCO USE AND SMOKELESS TOBACCO KERATOSIS (SNUFF POUCH; SNUFF DIPPER'S LESION; TOBACCO POUCH KERATOSIS; SPIT TOBACCO KERATOSIS)

The three main types of smokeless tobacco used in the United States include chewing tobacco, dry snuff, and moist snuff. The latter is most popular, accounting for approximately 90% of smokeless tobacco sales nationwide. Chewing tobacco often is used by men in conjunction with outdoor activities, and dry snuff is used primarily by women in the southern United States. Smokeless tobacco users frequently develop the habit during adolescence.

According to the 2020 National Health Interview Survey, approximately 2.3% of adults (or 5.7 million individuals 18 years and older) in the United States use smokeless tobacco. The highest prevalence rates are seen in some Southeastern and Midwestern states. In recent years, smokeless tobacco consumption in the United States has been declining. This trend in part may reflect the impact of an increasingly diverse tobacco product marketplace (including the introduction of electronic cigarettes as another popular mode of nicotine delivery).

Although the present discussion focuses on major types of smokeless tobacco in the United States and other Western nations, various other forms are found around the world. For example, in India and other Asian countries, smokeless tobacco may be combined in a quid, composed of areca nut, slaked lime, and other ingredients wrapped in a betel leaf. Oral lesions associated with betel quid use are described separately (see page 393). In addition, in parts of Africa and the Middle East, many individuals use varieties of snuff known as toombak (tobacco with sodium bicarbonate) and shammah (tobacco with ash and lime).

Clinical Features

Several health and addiction hazards may be associated with smokeless tobacco use because of the ready absorption of nicotine and other molecules through the oral mucosa. A variety of local oral alterations also are found in chronic users. One of the most common local changes is painless gingival recession in the area of tobacco contact (Fig. 10.78), at times accompanied by destruction of the underlying facial alveolar bone. The severity of the defect correlates with the quantity and duration of smokeless tobacco use. Although the association between smokeless tobacco and gingival recession is well known, there is some variability across studies regarding the association between smokeless tobacco and periodontal bone loss. Researchers have suggested that this variability may be related to the specific type of smokeless tobacco used or confounding by concurrent cigarette smoking.

• **Fig. 10.78 Smokeless Tobacco–related Gingival Recession.** Extensive recession of the anterior mandibular facial gingiva.

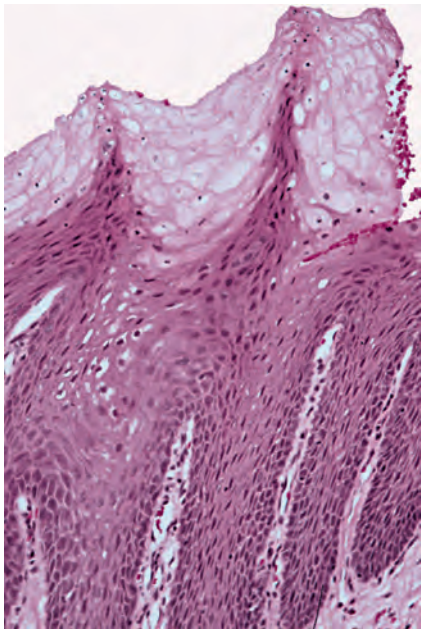
Dental caries also has been reported to be more prevalent in smokeless tobacco users, perhaps because of the high sugar content of some brands; other reports dispute caries susceptibility. Long-term use may lead to localized or generalized wear of occlusal and incisal surfaces, especially in those using the product in dusty environments. A brown-black extrinsic tobacco stain typically is found on the tooth surfaces adjacent to the tobacco. In addition, halitosis is a frequent finding.

Smokeless tobacco keratosis represents a characteristic white or gray plaque involving the mucosa in direct contact with snuff or chewing tobacco. In Western cultures, it affects 15% of chewing tobacco users and 60% of snuff users, if mild examples are included. Lesion development is influenced most strongly by habit duration and also by the brand of tobacco used, early onset of smokeless tobacco use, total hours of daily use, amount of tobacco consumed daily, and number of sites routinely used for tobacco placement. In Western populations, smokeless tobacco keratosis most often is noted in young adult men and men older than 65 years of age; however, in some subpopulations the prevalence is greatest among older women. Individual lesions begin to develop shortly after heavy tobacco use begins, and new lesions seldom arise in persons with a long history of use.

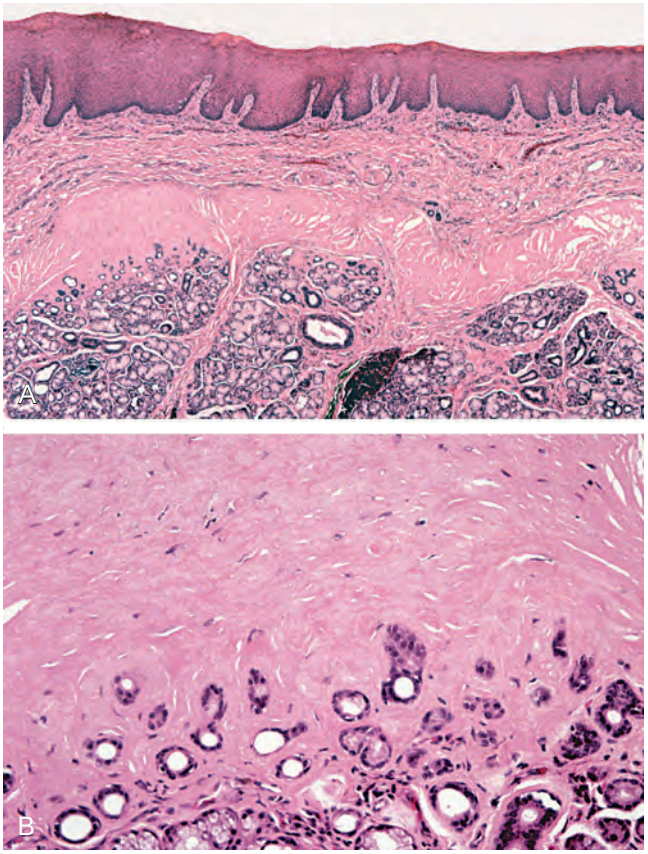
The altered mucosa typically is thin and almost translucent, with an indistinct border (Fig. 10.79). Sometimes mild peripheral erythema is present. Upon palpation, the lesion may feel soft and velvety. Stretching of the mucosa often reveals a distinct "pouch" **(snuff pouch, tobacco pouch)** caused by flaccidity in the area of chronic tobacco placement. The mucosa appears fissured or rippled, in a fashion resembling the sand on a beach after an ebbing tide. Similar alterations can occur when other bulky materials (e.g., hard candy, sunflower seeds, and beef jerky) are held chronically in the vestibule. Induration, ulceration, and pain are not associated with this lesion.

dentlearn.ir

• **Fig. 10.79 Tobacco Pouch Keratosis, Mild.** A soft, fissured, gray-white lesion of the lower labial mucosa located in the area of chronic snuff placement. The gingival melanosis is racial pigmentation and not associated with the keratosis.



• **Fig. 10.80 Tobacco Pouch Keratosis, Severe.** A somewhat leathery, white, fissured plaque of the right mandibular vestibule, which was located in the area of chronic chewing tobacco placement.



Smokeless tobacco keratosis usually takes 1–5 years to develop. Once it occurs, however, the keratosis typically remains unchanged indefinitely unless the daily tobacco contact time is altered. In some cases, the lesion gradually becomes thickened to the point of appearing leathery or nodular (Fig. 10.80).

Histopathologic Features

The histopathologic appearance of smokeless tobacco keratosis is not specific. The squamous epithelium is hyperkeratotic and acanthotic, with or without intracellular vacuolization or "edema" of glycogen-rich superficial cells. Parakeratin **chevrons** may be seen as pointed projections above or within superficial epithelial layers (Fig. 10.81. Increased subepithelial vascularity and vessel engorgement often are observed. In some cases, an unusual deposition of amorphous eosinophilic material is noted within the subjacent connective tissue and salivary glands (Fig. 10.82). Epithelial dysplasia is uncommon in smokeless tobacco keratosis and, when

• **Fig. 10.81 Tobacco Pouch Keratosis.** Epithelium exhibiting acanthosis, hyperparakeratosis, and "chevron" formation.

• **Fig. 10.82 Tobacco Pouch Keratosis. A,** Low-power view showing mild hyperkeratosis and acanthosis. Note linear deposition of amorphous, eosinophilic material in the lamina propria above the minor salivary glands. **B,** Higher-power view of the amorphous material.

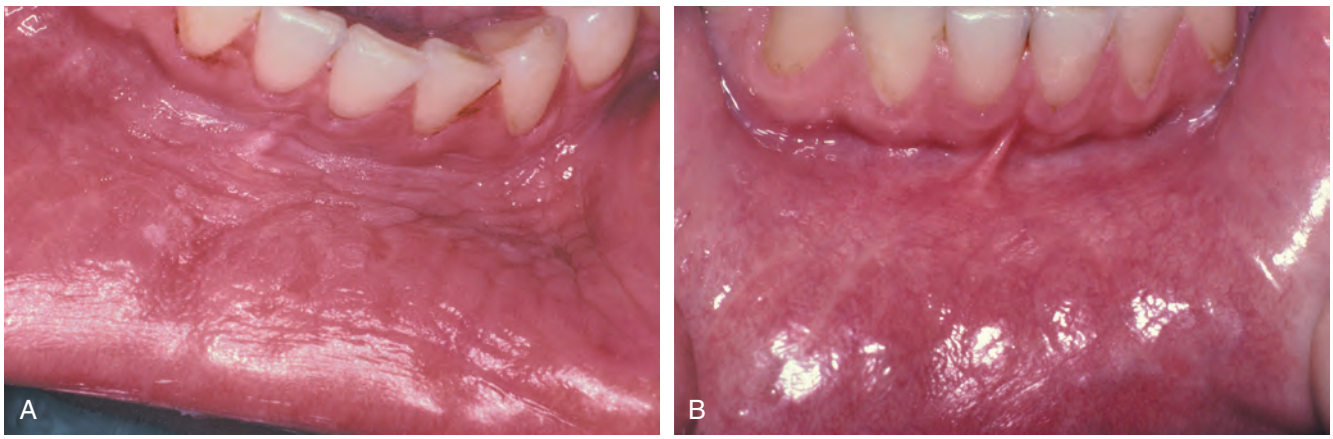
dentlearn.ir

present, is typically mild. Occasionally, however, significant dysplasia or squamous cell carcinoma may develop.

Treatment and Prognosis

Tobacco counseling should be provided. Biopsy is indicated for lesions with atypical findings (i.e., a granular or verruciform clinical appearance, ulceration, mass formation, induration, or hemorrhage) or intense whiteness. For lesions that are not atypical or intensely white, habit cessation leads to a normal mucosal appearance (usually within 2 weeks) in 98% of cases (Fig. 10.83). For patients unable to cease the habit, switching to a different tobacco-chewing site may be an alternative approach but may result in epithelial alteration or gingival and periodontal difficulties in two sites rather than one. A lesion that remains after 2 weeks without smokeless tobacco contact should be biopsied. Management depends on the histopathologic findings. Keratoses without dysplasia or malignancy may require only continued monitoring and tobacco cessation. Treatment considerations for patients with oral epithelial dysplasia or squamous cell carcinoma are discussed elsewhere (see pages 388 and 418).

Chronic use of smokeless tobacco in the United States is considered to be carcinogenic, although the risk is less than that associated with cigarette smoking and alcohol abuse. Squamous cell carcinoma (see page 391) related to smokeless tobacco use typically develops after a latency period of several decades. Most such cases represent conventional squamous cell carcinoma, although an uncommon low-grade variant known as **verrucous carcinoma ("snuff dipper's" cancer)** (see page 421) also is possible. In the United States, a pooled analysis of data from National Health Interview Surveys reported an association between current smokeless tobacco use and oral cavity cancer (approximate hazard ratio = 9) among individuals who had never used other forms of tobacco. In addition, case-control studies performed in the United States and Western Europe have noted lower risk associated with chewing tobacco and moist snuff and higher risk associated with dry snuff. In particular, many of the early reports of malignant transformation described lesions among female dry snuff users in the southern United States. Studies from Sweden, however, have failed to show an increased oral cancer risk for users of Swedish moist snuff (also known as *snus*).



◆ ORAL SUBMUCOUS FIBROSIS

Oral submucous fibrosis is an oral potentially malignant disorder characterized by chronic, progressive scarring of the oral mucosa. The condition has an estimated global prevalence of approximately 5% and is seen primarily in the Indian subcontinent, Southeast Asia, Taiwan, southern China, Polynesia, and Micronesia. Cases among Asian communities in North America, Europe, and Africa also have been reported.

The etiology is linked to the use of betel quid *(paan)* and related products—a habit among up to 20% of the world's population. The quid consists of a betel leaf wrapped around a mixture of areca nut (from the *Areca catechu* palm tree), slaked lime, possibly tobacco, and sometimes sweeteners and spices. The slaked lime releases alkaloids from the areca nut to produce a feeling of euphoria in the user. Villagers habitually chew betel quid from an early age, frequently for 16–24 hours daily.

The annual incidence of oral submucous fibrosis has been increasing—especially among young persons—due to the growing popularity of commercially freeze-dried betel quid substitutes (such as, *pan masala, gutkha,* and *mawa*), conveniently packaged in portable sachets. These products contain a higher concentration of areca nut and may cause oral submucous fibrosis more rapidly than conventionally prepared betel quid.

The fibrosis appears to be induced by areca nut, whereas the epithelial alterations and carcinogenesis appear to result mainly from tobacco. However, several studies suggest that even betel quid without tobacco may be carcinogenic, albeit probably less so than when combined with tobacco. Nutritional deficiency increases the risk and severity of fibrosis.

• **Fig. 10.83 Tobacco Pouch Keratosis. A,** Moderately severe lesion of the lower anterior vestibule and lip in a 15-year-old male. There is a gray-white, fissured surface. The patient had placed snuff in the area for several years. **B,** Two weeks after cessation of the tobacco habit, the mucosa returned to an almost normal appearance.

dentlearn.ir

Furthermore, an underlying genetic predisposition has been proposed based on associations with certain human leukocyte antigen (HLA) types and various genetic polymorphisms, as well as the fact that only a small subset of betel quid or areca nut chewers develop this condition. Autoimmunity and other immunologic factors may contribute to disease development as well.

The pathogenesis of oral submucous fibrosis is hypothesized to involve the disruption of collagen metabolism by components of the areca nut. Alkaloids (especially arecoline) and polyphenols induce various downstream effects, including increased fibroblast proliferation, increased collagen production, and decreased collagen degradation. Arecoline also may suppress or damage endothelial cells, resulting in a loss of vascularity. In addition, there are considerable amounts of copper in areca nut products. Copper upregulates lysyl oxidase, which is an enzyme involved in collagen cross-linking; this process renders collagen fibrils resistant to degradation by collagenase. Various cytokines and growth factors may promote fibrosis as well.

Clinical Features

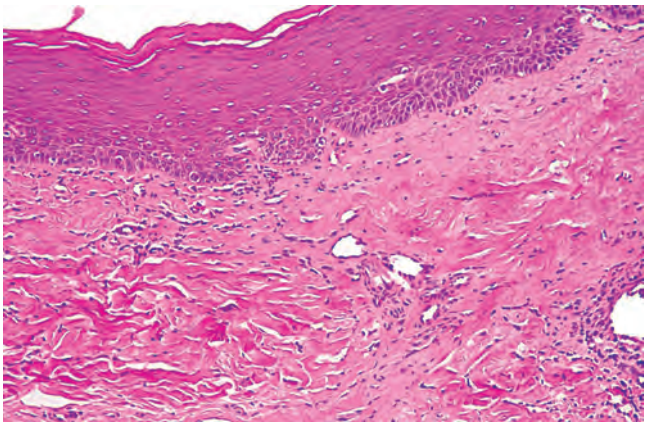
Oral submucous fibrosis often manifests in young adult users of betel quid or related areca nut products. Reported gender predilection varies by population. Typical chief complaints include an inability to open the mouth **(trismus)** and a generalized oral burning sensation **(stomatopyrosis)** with intolerance to spicy foods. An interincisal distance of less than 20 mm is considered severe; in advanced cases, the jaws may be inseparable.

Vesicles, petechiae, melanosis, xerostomia, and stomatopyrosis are usually the first signs and symptoms. The buccal mucosa, retromolar area, and soft palate are the most commonly affected sites. Subsequently, the mucosa develops a blotchy, marblelike pallor and progressive stiffness (Fig. 10.84). The tongue may become immobile, diminished in size, and devoid of papillae. Submucosal fibrous bands are palpable on the buccal mucosa, soft palate, and labial mucosa of fully developed cases. Involvement may extend to include the pharynx, larynx, and upper esophagus. **Leukoplakia** of the surface mucosa often is noted as well (see page 381).

Betel quid chewers also may exhibit a brown-red discoloration of the mucosa with an irregular surface that tends to desquamate. This particular change, known as **betel chewer's mucosa,** is not believed to be precancerous. In addition, some authors have reported **betel quid lichenoid lesions,** characterized by white, parallel, wavy striae resembling oral lichen planus (see page 787). Other possible sequelae include tooth staining, attrition, and periodontal disease.

Histopathologic Features

Oral submucous fibrosis is characterized by juxtaepithelial and submucosal deposition of densely collagenized connective tissue with variable numbers of chronic inflammatory cells (Fig. 10.85). In addition, early lesions may exhibit epithelial hyperplasia, hyperkeratosis, and dilated vessels, whereas more advanced lesions demonstrate epithelial atrophy and hypovascularity with constricted or occluded vessels. Epithelial dysplasia is found in about 10%–15% of cases submitted for biopsy, and carcinoma is found in at least 6% of sampled cases.



Betel chewer's mucosa appears histopathologically similar to morsicatio buccarum (see page 272), except the ragged keratinaceous surface is covered by encrusted betel quid ingredients.

Treatment and Prognosis

Unlike tobacco pouch keratosis, oral submucous fibrosis does not regress with habit cessation. Mild cases may be treated with intralesional corticosteroids to reduce symptoms and limit progression. Moderate to severe cases may require surgical excision or release of the fibrous bands, followed by lifelong physiotherapy; however, relapse is common. There is limited evidence for various alternative treatments, such as intralesional injection of interferon-gamma; topical or intralesional proteolytics (e.g., collagenase, hyaluronidase, chymotrypsin, papain); human placental extract; vitamins and

• **Fig. 10.85 Oral Submucous Fibrosis.** Mucosal biopsy exhibiting hyperparakeratosis, basilar hyperplasia, and fibrosis in the lamina propria.

dentlearn.ir

minerals; antioxidants (e.g., lycopene); levamisole; vasodilators (e.g., pentoxifylline); and ayurvedic remedies (e.g., turmeric).

Frequent evaluation for development of oral squamous cell carcinoma is essential. Reported malignant transformation rates vary considerably (approximately 1%–23%), likely due to differences in study design and patient cohorts. However, according to recent meta-analyses and systematic reviews of the literature, approximately 4%–6% of patients with oral submucous fibrosis develop oral cancer, with an estimated annual malignant transformation rate of 0.73%–0.98%.

◆ ACTINIC CHEILOSIS (ACTINIC CHEILITIS; SOLAR CHEILOSIS)

Actinic cheilosis is a common premalignant alteration of the lower lip vermilion that results from chronic UV light exposure. Its etiopathogenesis is similar to that of **actinic keratosis** of the skin (see next topic). The incidence of actinic cheilosis increases with proximity to the equator, and there is a predilection among middle-aged to elderly, fair-complexioned men. Outdoor occupations are associated with this condition, leading to popular terms, such as *farmer's lip* and *sailor's lip.* In addition, there is increased susceptibility among patients with certain genetic disorders (e.g., xeroderma pigmentosum, albinism, and porphyria cutanea tarda). Furthermore, cofactors—such as immunosuppression and tobacco smoking—may increase the likelihood of progression to squamous cell carcinoma.

Clinical Features

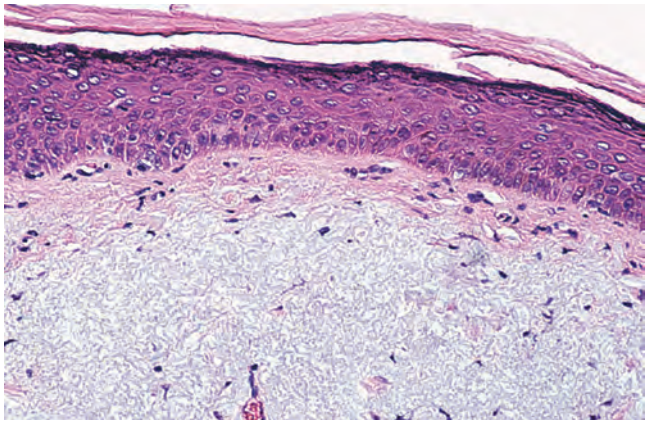
Actinic cheilosis seldom occurs in persons younger than 45 years. There is a strong male predilection (reported male-to-female ratio as high as 10:1), which may reflect more outdoor occupational activity and less frequent use of lip protective agents among men compared to women.

The lesion develops so slowly that patients often are unaware of a change. Early clinical findings include atrophy (characterized by smooth, blotchy, pale areas), dryness, and fissures of the lower lip vermilion, with blurring of the margin between the vermilion and the adjacent skin. As the lesion progresses, rough, scaly areas develop on the drier portions of the vermilion. These areas may assume a leukoplakic appearance, especially when they extend near the wet line of the lip (Fig. 10.86). The patient may peel off the scale with some difficulty, only to see it reform within a few days.

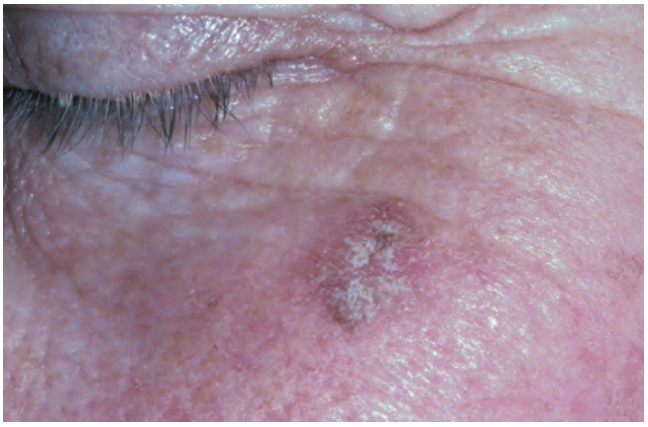
Eventually, chronic ulceration may develop (Fig. 10.87). Such ulcerations may last for months and suggest progression to squamous cell carcinoma (Fig. 10.88).

• **Fig. 10.86 Actinic Cheilosis.** Diffuse, irregular white plaque at the wet line of the lower lip vermilion.

• **Fig. 10.87 Actinic Cheilosis.** Crusted and ulcerated lesions of the lower lip vermilion.



• **Fig. 10.88 Squamous Cell Carcinoma Arising in Actinic Cheilosis.** Patient with actinic cheilosis of the lower lip, who developed a small, chronic ulceration. Biopsy revealed early invasive squamous cell carcinoma.



Histopathologic Features

The surface epithelium exhibits varying degrees of dysplasia. There is usually hyperkeratosis, and the epithelium may be either atrophic or acanthotic. The underlying connective tissue invariably demonstrates a band of amorphous, acellular, basophilic change known as **solar elastosis**, an UV light–induced alteration of collagen and elastic fibers (Fig. 10.89). A chronic inflammatory cell infiltrate and dilated blood vessels may be present as well.

dentlearn.ir

• **Fig. 10.89 Actinic Cheilosis.** Hyperorthokeratosis and epithelial atrophy. Note the striking underlying solar elastosis.

• **Fig. 10.90 Actinic Keratosis.** A plaque of the skin of the face with a rough, sandpaper-like surface.

Treatment and Prognosis

Many of the changes associated with actinic cheilosis are probably irreversible, but patients should be encouraged to reduce sun exposure, wear a wide-brimmed hat, and use sunscreen to prevent further damage. Areas of induration, thickening, ulceration, or leukoplakia should be submitted for biopsy to rule out carcinoma. In clinically severe cases without obvious malignant transformation, a lip shave procedure **(vermilionectomy)** may be performed. The vermilion mucosa is removed, and either a portion of the intraoral labial mucosa is pulled forward or the wound is allowed to heal by secondary intention. The advantage of this technique is that it provides tissue for histopathologic examination should areas of superficially invasive squamous cell carcinoma be present. Alternative treatments include CO_2 or erbium:YAG (Er:YAG) laser ablation, electrodesiccation, cryotherapy, 5-fluorouracil, topical imiquimod, topical diclofenac, and photodynamic therapy. Long-term follow-up is recommended. Of course, if a squamous cell carcinoma is identified, then the involved lip is treated accordingly.

The malignant transformation rate of actinic cheilosis is difficult to determine because of the lack of high-quality follow-up studies. However, it is estimated that actinic cheilosis more than doubles an individual's risk for developing squamous cell carcinoma of the lip. Also, the risk of malignant transformation is approximately 2.5 times greater for actinic cheilosis compared to actinic keratosis. However, it typically takes several decades for actinic cheilosis to transform into squamous cell carcinoma, and the resulting carcinoma usually is histopathologically well differentiated.

◆ ACTINIC KERATOSIS (SOLAR KERATOSIS)

Actinic keratosis is a common, cutaneous premalignant lesion that is caused by chronic, high-level exposure to UV radiation. A similar phenomenon, **actinic cheilosis,** is associated with sun damage to the lower lip vermilion (see previous section). UV light exposure can produce mutations in various genes, such as the tumor suppressor gene *TP53*. Additional risk factors for actinic keratosis include fair skin, old age, severe male baldness, immunosuppression, arsenic exposure, and certain genetic abnormalities (e.g., albinism, Rothmund-Thompson syndrome, Cockayne syndrome, xeroderma pigmentosum [see page 753], and Bloom syndrome). Recent genomic analysis suggests associations with mutations in the *IRF4*, *MC1R*, and *TYR* genes, which have functions related to pigmentation and carcinogenesis. Furthermore, recent studies suggest that HPV infection may be a cofactor in some cases, especially those arising in immunosuppressed individuals.

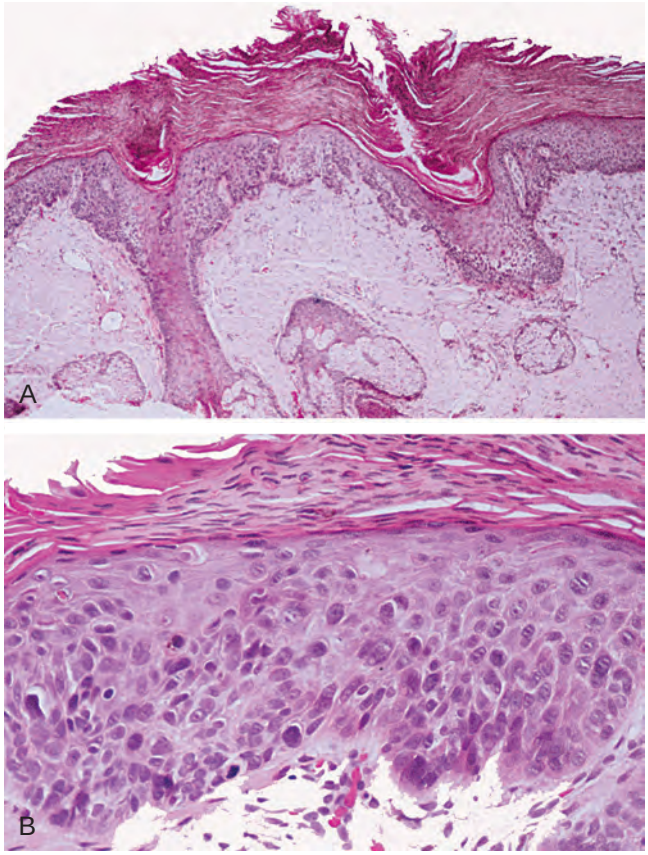
Actinic keratosis affects more than 50% of white adults with significant lifetime sun exposure. In the United States, reported prevalence rates range from 14% to 27% for men and 6% to 10% for women. According to the National Ambulatory Medical Care Survey, more than 47 million physician office visits were conducted in the United States over a 10-year period for the diagnosis of actinic keratosis. Another study reported that actinic keratosis accounts for more than 5 million physician office visits per year in the United States.

Clinical Features

Actinic keratosis seldom occurs in persons younger than 40 years. Common sites of involvement include the face, neck, dorsum of the hands, forearms, and balding scalp. The lesions most often occur in clusters (apparently due to UV-induced *field cancerization* [see page 421]), although solitary lesions also are possible. Many patients are asymptomatic, but tenderness, pain, or pruritus is possible. The lesions appear as irregular, scaly plaques, which range in color from normal to white, gray, or brown, and may be superimposed on an erythematous background (Fig. 10.90). The keratotic scale peels off with varying degrees of difficulty. Palpation reveals a rough, "sandpaper-like" texture, and some lesions can be felt more easily than they can be seen. Each lesion typically is smaller than 7 mm in diameter, but some lesions may reach a size of 2 cm or more. Most lesions are minimally elevated above the skin surface, although occasional lesions

dentlearn.ir

• **Fig. 10.91 Actinic Keratosis.** Skin lesion involving the helix of the ear. This example exhibits a prominent surface projection, termed a *cutaneous horn*, which results from an accumulation of keratin.



produce so much keratin that a central **cutaneous horn** (or **keratin horn**) may be evident (Fig. 10.91). Other skin lesions, such as verruca vulgaris or seborrheic keratosis, also may produce cutaneous horns.

Histopathologic Features

Histopathologically, actinic keratosis is characterized by hyperparakeratosis and acanthosis (Fig. 10.92). The epithelium often exhibits teardrop-shaped rete ridges, and by definition, some degree of epithelial dysplasia is present. When full-thickness dysplasia is noted, this is termed **bowenoid actinic keratosis.** Suprabasilar acantholysis may be seen, as well as melanosis and a lichenoid inflammatory infiltrate. The dermis exhibits a pale, basophilic band of sun-damaged collagen and elastic fibers **(solar elastosis).** In this band of sun-damaged connective tissue, there is a fourfold increase in the amount of elastic fibers, and band thickness increases with further exposure to actinic rays. Variable numbers of chronic inflammatory cells are typically present.

Treatment and Prognosis

Preventive measures include avoiding sun exposure, wearing protective clothing, and using sunscreen. Although studies suggest that more than half of actinic keratoses regress spontaneously, treatment is recommended because of the lesion's precancerous nature. For solitary lesions, the most common treatment is cryotherapy; additional treatment options include curettage, electrodesiccation, surgical excision, and laser therapy. Multifocal lesions or sun-damaged skin fields at risk for lesion development may be treated with topical agents (e.g., 5-fluorouracil, imiquimod, diclofenac, retinoids, and ingenol mebutate), chemical peels, laser therapy, or photodynamic therapy. Alternatively, cryotherapy may be combined with broader application of topical agents. Recurrence is rare, but fields of adjacent sun-damaged skin are at risk for development of cancer or additional actinic keratoses. Long-term follow-up, therefore, is recommended.

• **Fig. 10.92 Actinic Keratosis. A,** An extremely excessive amount of parakeratin is noted on the epidermal surface. **B,** High-power view showing hyperchromatism and pleomorphism of the epidermal cells.

The estimated malignant transformation rate for an individual lesion varies considerably (0.025%–16% per year) but generally is considered low. However, the risk increases significantly for a patient with a large number of lesions over an extended period. Longitudinal studies of larger patient groups suggest that malignancy develops on average within 2 years, and spontaneous regression may occur in about 20% of lesions within 12 months.

◆ NICOTINE STOMATITIS (NICOTINE PALATINUS; SMOKER'S PALATE)

Once a common mucosal change of the hard palate, **nicotine stomatitis** has become less common because cigar and pipe smoking have lost popularity. Although this hyperkeratotic lesion is associated with tobacco smoking, it does not appear to have a premalignant nature, perhaps because it develops in response to heat rather than the chemicals in tobacco smoke. In particular, pipe smoking appears to generate more heat on the palate than other forms of smoking. Similar changes also can be produced by the long-term use of extremely hot beverages. In addition, recent reports have suggested a potential association with electronic cigarette use.

In some South American and Asian cultures, hand-rolled cigarettes and cigars are smoked with the lit end held within

dentlearn.ir

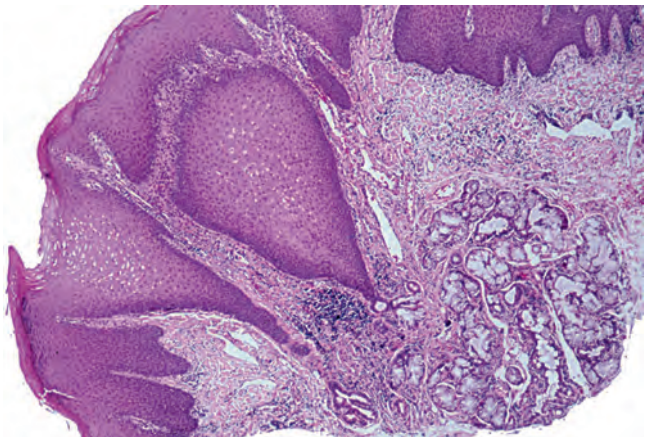
• **Fig. 10.93 Nicotine Stomatitis.** Palatal mucosa showing white change and numerous scattered papules with red punctate centers.

• **Fig. 10.94 Nicotine Stomatitis.** Close-up of the inflamed ductal openings of involved salivary glands of the hard palate. Note the white keratotic ring at the lip of many of the inflamed ducts.

the mouth. This "reverse smoking" habit produces a pronounced palatal keratosis, or **reverse smoker's palate,** which has a significant potential to develop dysplasia or carcinoma.

Clinical Features

Nicotine stomatitis most commonly affects men older than 45 years. With long-term exposure to heat, the palatal mucosa becomes diffusely gray or white; numerous slightly elevated papules are noted, usually with punctate red centers (Figs. 10.93 and 10.94). Such papules represent inflamed minor salivary glands and their ductal orifices.



The palatal keratin may become so thickened that a fissured or "dried mud" appearance is imparted. The whiteness also may involve the marginal gingiva and interdental papillae, and hyperkeratosis of the buccal mucosa occasionally is seen. A heavy brown or black tobacco stain may be present on the teeth.

Histopathologic Features

Nicotine stomatitis is characterized by hyperkeratosis and acanthosis of the palatal epithelium and mild, patchy, chronic inflammation of subepithelial connective tissue and mucous glands (Fig. 10.95). Squamous metaplasia of the excretory ducts is usually seen, and an inflammatory exudate may be noted within the duct lumina. In cases with papular elevation, hyperplastic ductal epithelium may be seen near the orifice. The degree of epithelial hyperplasia and hyperkeratosis appears to correlate positively with the duration and the level of heat exposure. Epithelial dysplasia rarely is seen.

Treatment and Prognosis

Nicotine stomatitis is completely reversible, even when it has been present for many decades. The palate usually returns to normal within 1–2 weeks of smoking cessation. Although this lesion is not precancerous and does not require treatment, the patient nevertheless should be encouraged to stop smoking (and other high-risk areas should be examined closely). Any white lesion of the palatal mucosa that persists after 1 month of habit cessation should be considered a true leukoplakia and managed accordingly (see page 388).

• **Fig. 10.95 Nicotine Stomatitis.** There is hyperkeratosis and acanthosis of the palatal epithelium. Note the squamous metaplasia of the minor salivary gland ducts.

◆ KERATOACANTHOMA ("SELF-HEALING" CARCINOMA; PSEUDOCARCINOMA; KERATOCARCINOMA; SQUAMOUS CELL CARCINOMA, KERATOACANTHOMA TYPE)

Keratoacanthoma is a self-limiting, epithelial proliferation with a strong clinical and histopathologic similarity to well-differentiated **squamous cell carcinoma.** Indeed, many dermatopathologists consider it to represent an extremely well-differentiated squamous cell carcinoma. Cutaneous lesions presumably arise from the epithelium of hair follicles. Intraoral lesions have been reported, but they are rare; in fact, some authorities do not accept keratoacanthoma as an intraoral disease.

dentlearn.ir

Ultraviolet light exposure appears to be a major risk factor, with most solitary lesions arising on sun-exposed skin in older adults. Additional potential contributing factors include x-irradiation, tar exposure, immunosuppression, certain drugs (such as, *BRAF* inhibitors, hedgehog pathway inhibitors, and PD-1 inhibitors), foreign materials (such as, tattoos and cosmetic fillers), trauma (such as, burns and surgical procedures), other skin conditions (such as, lichen planus and psoriasis), and HPV or human polyomavirus 6 infection. Keratoacanthoma-like lesions have been produced in animals by the cutaneous application of carcinogens.

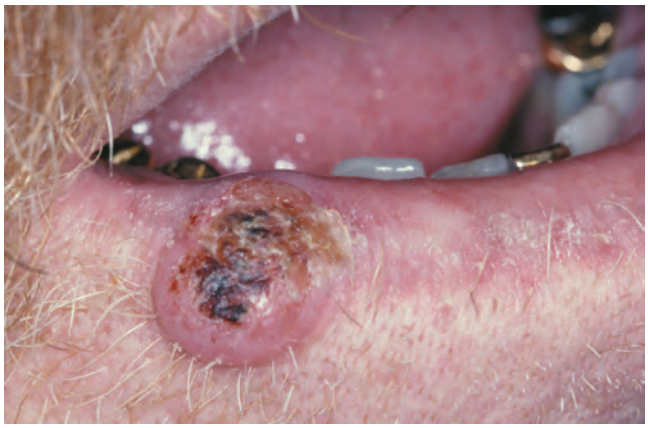
There appears to be a hereditary predisposition for multiple lesions, and the lesions occur with increased frequency in certain heritable conditions attributed to defects in DNA repair, including **Muir-Torre syndrome** (sebaceous neoplasms, keratoacanthomas, and gastrointestinal carcinomas) and **xeroderma pigmentosum** (see page 753).

Various underlying pathogenetic mechanisms have been proposed, including alterations in Wnt signaling, expression of cyclin-dependent kinase inhibitor p27, activation of the MAP kinase pathway, and *HRAS* mutations. Several studies have shown that keratoacanthomas and squamous cell carcinomas typically exhibit distinct genetic profiles.

Clinical Features

Keratoacanthoma shows a male predilection, with a peak between the ages of 65 and 71 years. Almost 95% of solitary lesions involve sun-exposed skin, and 8% of all cases involve the outer edge of the vermilion border of the lips, with equal frequency on the upper and lower lips.

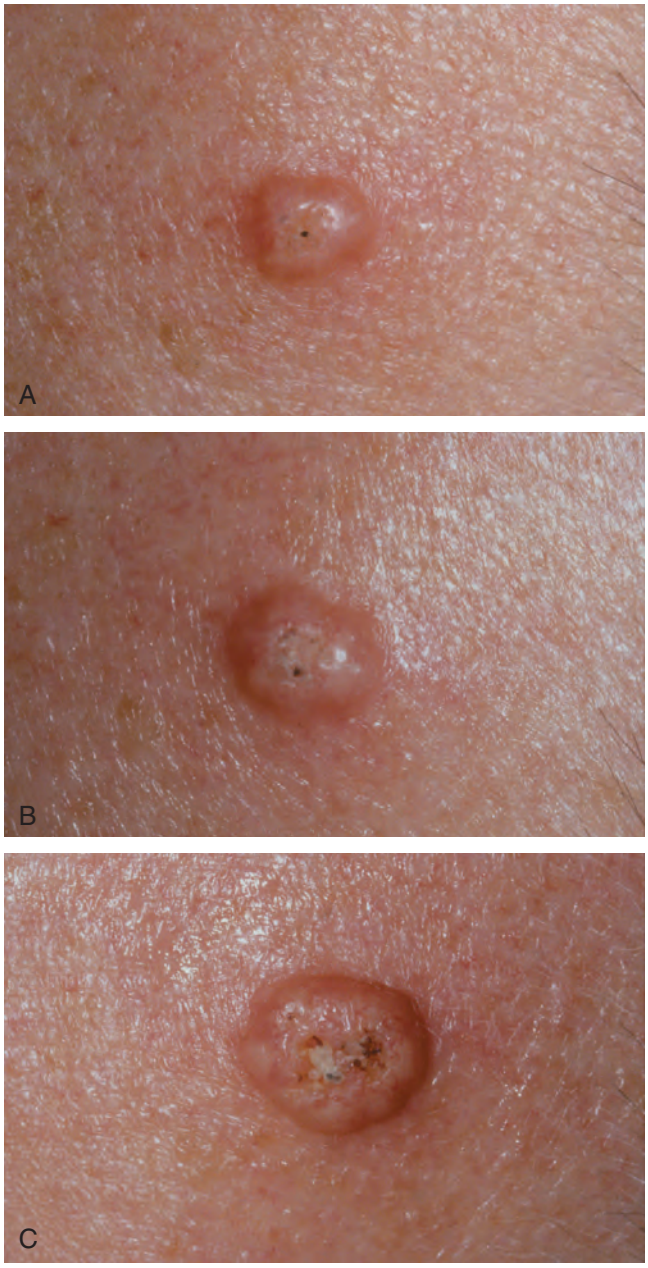
Keratoacanthoma appears as a firm, well-demarcated, sessile, dome-shaped nodule with a central plug of keratin (Figs. 10.96 and 10.97), although lesions reported as intraoral keratoacanthoma usually have lacked a central plug. The outer portion of the nodule typically has a normal texture and color but may be erythematous. The central keratin plug is yellowish, brown, or black and has an irregular, crusted, often verruciform surface. Most lesions are asymptomatic, although pruritus and mild tenderness are possible.



The evolution of keratoacanthoma can be divided into three phases: (1) growth phase, (2) stationary phase, and (3) involution phase. During the growth phase, rapid enlargement is typical, with the lesion usually attaining a diameter of 1–2 cm within 6 weeks (Fig. 10.98). This critical feature helps to distinguish it from the more slowly enlarging squamous cell carcinoma. The lesion stabilizes during the stationary phase, which usually is of similar duration as the growth phase. Most lesions regress spontaneously within 6–12 months of onset, frequently leaving behind a depressed scar. The regression of keratoacanthomas is a curious phenomenon, which some investigators have theorized is related to a cytotoxic immune response to the tumor or inactivation of the Wnt signaling pathway. Some authors also have described a subset of lesions (termed *abortive keratoacanthoma*) that involute after only 4–6 weeks.

Several other variants exist, including *giant keratoacanthoma* (greater than 2–3 cm in diameter), *keratoacanthoma centrifugum marginatum* (characterized by continuous peripheral growth and central scarring), *subungual keratoacanthoma* (involving the nail bed), and *mucosal keratoacanthoma* (involving the oral, nasal, genital, ocular, or other regions). These variants often do not regress.

In addition, early onset of multiple keratoacanthomas has been described in association with two rare, heritable conditions: **Ferguson-Smith syndrome (multiple self-healing squamous epitheliomas)** and **Witten-Zak syndrome**. The former is characterized by nodular lesions and primarily affects patients of Scottish descent; the latter typically exhibits a mixture of variably sized lesions. In contrast, the nonhereditary **Grzybowski syndrome (generalized eruptive keratoacanthomas)** manifests later in life as hundreds or thousands of small, pruritic papules of the skin and upper digestive tract and may be associated with internal malignancy.



• **Fig. 10.96 Keratoacanthoma.** A nontender, well-demarcated nodule of the skin of the nose in an older woman. The nodule demonstrates a central keratin plug.

• **Fig. 10.97 Keratoacanthoma.** This lesion, which is located at the outer edge of the vermilion border of the lip, demonstrates a prominent core or plug of keratin.

Note small, central keratin-filled invagination. **B,** Same lesion 1 week later showing slight enlargement. **C,** Same lesion showing further growth 3 weeks after initial presentation. All three photographs were taken at the same magnification. (Courtesy of Dr. John Lovas.)

Histopathologic Features

Because the overall architectural pattern is crucial for the diagnosis of keratoacanthoma, excisional or large incisional biopsy with inclusion of adjacent, clinically normal skin is recommended for proper histopathologic interpretation. Microscopic examination with low-power magnification shows a generally symmetrical pattern. The surface epithelium at the edge of the tumor appears normal; at the lip of the central crater, however, a characteristic acute angle (or "buttress") is formed between the overlying epithelium and the lesion. The crater is filled with keratin, and the epithelium at the base of the crater proliferates downward (Fig. 10.99), often with a pronounced chronic inflammatory cell response. Downward proliferation typically does not extend below the sweat glands in skin lesions or into underlying muscle in vermilion lesions. The tumor cells appear mature, although marked dyskeratosis (abnormal keratin production) typically is seen. Late-stage lesions show considerably more keratinization in the deeper aspects of the tumor than do early lesions; the deep tumor islands often contain enlarged cells with pale pink, "glassy" cytoplasm. Perineural and vascular invasion have been reported rarely; although worrisome, such features do not necessarily indicate a worse prognosis. Migration of eosinophils or neutrophils into the epithelium with resultant microabscess formation is a frequent finding. Regressing lesions tend to flatten, hollow out, and exhibit an underlying band of fibrosis.

• **Fig. 10.99 Keratoacanthoma.** Low-power microscopic view showing extensive epidermal proliferation with a central keratin plug.

Numerous immunohistochemical studies comparing keratoacanthoma and squamous cell carcinoma have been reported, but no reliable marker for discernment between these two lesions has been identified.

Treatment and Prognosis

Because of the difficulty in clinically and histopathologically distinguishing between keratoacanthoma and squamous cell carcinoma, many authorities advocate excision without waiting for spontaneous regression. Also, early treatment may prevent significant scarring. Approximately 4%–8% of lesions recur after excision. Although conventional surgical excision is preferred, alternative therapies include cryosurgery (reserved for small early lesions); electrodesiccation and curettage; Mohs micrographic surgery (especially for lesions that are large or involve cosmetic areas); laser therapy; photodynamic therapy; intralesional injection of various agents (e.g., 5-fluorouracil, bleomycin, methotrexate, interferon alpha); and topical agents (e.g., imiquimod, 5-fluorouracil). In addition, systemic retinoids may be used alone or in combination with local treatment for patients with multiple or especially large lesions.

dentlearn.ir

Aggressive behavior and transformation into carcinoma have been reported in a small proportion of keratoacanthomas—particularly those occurring in the setting of immunosuppression. However, the close histopathologic similarities between this lesion and squamous cell carcinoma sometimes make it difficult to rule out the possibility of microscopic misinterpretation.

◆ SQUAMOUS CELL CARCINOMA

In the United States, approximately one of every two men and one of every three women will develop a malignancy (other than nonmelanoma skin cancer) at some point. It is estimated that for the year 2022, more than 1.9 million new cancer cases will be diagnosed in the United States, in addition to around 5.4 million nonmelanoma skin cancers. Although the relative 5-year cancer survival rate is approximately 68%, cancer still causes more than 609,000 deaths each year in the United States and represents the second leading cause of death after heart disease. From 1930 to 1991, the annual cancer death rate (excluding nonmelanoma skin cancer) increased and reached a peak of 215 per 100,000 population. This trend reflected an increase in the incidence of lung cancer as well as a decrease in mortality at an early age from other common disorders, such as cardiovascular disease and infection. Since 1991, however, the annual cancer death rate has declined to about 144 per 100,000 population. In part, this decline is related to a decrease in tobacco use and lung cancer deaths; in addition, improvements in detection and treatment have resulted in declines in breast, colorectal, and prostate cancer deaths.

Significant epidemiologic shifts also have occurred in head and neck cancer over the past several decades. In the United States and other developed nations, declining tobacco use has resulted in decreased annual incidence of laryngeal and floor of mouth cancers. In contrast, there has been a significant increase in the prevalence of oropharyngeal cancer associated with HPV infection.

Squamous cell carcinoma accounts for more than 90% of oral malignancies. Statistics for oral cancer can be difficult to review because of variations in terminology and reporting practices. In this section, we will use the term "oral" to refer to the oral cavity (including the intraoral mucosa and lip vermilion) as well as the oropharynx. However, some authors prefer to use the term "oral" when referring to the oral cavity only. Squamous cell carcinomas involving the intraoral mucosa, lip vermilion, and oropharynx exhibit different risk factors, clinical features, molecular profiles, and biologic behavior, although a clear distinction between these sites is not always made. Furthermore, cancer registries and investigators often report oral cavity and pharyngeal cancers in aggregate. (Among pharyngeal cancers, oropharyngeal lesions typically outnumber those arising from the nasopharynx and hypopharynx.) With that said, in the United States oral cavity and pharyngeal cancers combined account for less than 3% of all newly diagnosed cancers (excluding nonmelanoma skin cancers and *in situ* carcinomas for all sites but urinary bladder) and represent the eighth most common cancer in males. Around 54,000 new oral cavity and pharyngeal cancer cases are diagnosed annually, and these cancers account for approximately 11,200 deaths per year.

In the United States, males overall have a much higher annual incidence of oral cavity and pharyngeal cancer than females, with a male-to-female ratio of approximately 2.7:1. According to Surveillance, Epidemiology, and End Results (SEER) Program data for 2000–2019, the age-adjusted annual incidence has been growing at a faster pace for males than females (0.7% vs 0.4% annual change, respectively). However, among young adults and pediatric patients, recent annual incidence rates are similar for both genders.

The risk for oral cavity and pharyngeal cancer increases with age, especially among males. According to SEER Program data, the 5-year age-adjusted incidence rate for oral cavity and pharyngeal cancer from 2014 to 2018 was 3 per 100,000 for males younger than 50 years, 43 per 100,000 for males 50–64 years, and 67 per 100,000 for males aged 65 years and older. Among individuals 50 years and older, the incidence was higher for white males than black males, whereas similar incidence rates were seen for black and white males younger than 50 years.

In the United States from 2000 to 2019, the age-adjusted incidence of oral cavity and pharyngeal cancer increased by 1% per year. Subsite analysis reveals that during this period there was a notable 3.1% annual increase in the number newly diagnosed oropharyngeal cancers. This growth in oropharyngeal cancer cases has been driven by HPV-related tumors (see discussion of etiology below), which exhibit a predilection for the palatine tonsils and base of tongue. In the early 2000s, HPV-related oropharyngeal cancer was characterized as an epidemic mainly affecting middle-aged white men. However, with aging of this original cohort, oropharyngeal cancer incidence has been increasing significantly among elderly as well as middle-aged men over the past two decades.

In the United States from 2009 to 2018, increased incidence also was observed for carcinomas arising from the oral tongue (anterior two-thirds of the tongue). Interestingly, in many developed nations, increased incidence of oral tongue cancer has been noted among individuals younger than 45 years; also, in some regions this patient subset has exhibited an unusual female predilection. The underlying cause for this trend is uncertain. Such cases often are not associated with the traditional risk factors of tobacco and alcohol use, and the oral tongue—unlike the base of tongue—is an infrequent site for HPV-positive carcinomas.

Carcinoma of the lip vermilion is somewhat different from intraoral carcinoma. It has a pathophysiology more akin to squamous cell carcinoma of sun-exposed skin. According to SEER data for 2015–2019, the overall 5-year age-adjusted incidence rate for lip cancer (including labial mucosa and lip vermilion lesions) in the United States is 0.5 per 100,000 population. The incidence increases with age, with rates among those 75 years and older of approximately 5.6 per 100,000 for males and 1.9 per 100,000 for

dentlearn.ir

females. White males are affected most commonly, although there has been a considerable decrease in the incidence of lip cancer in this group over the last several decades; this trend may be related to a decline in the number of white males engaged in outdoor occupations. Among women and nonwhite men, lip carcinoma is infrequent. The low incidence among women may be related to little outdoor occupational activity and prevalent use of lip protective agents. In nonwhites, racial pigmentation may provide protection against sun exposure.

The worldwide incidence of oral cavity cancer is approximately 378,000 cases per year, with especially high rates reported in Melanesia, South-Central Asia, Australia/New Zealand, and Central/Eastern Europe. Much of the worldwide burden of oral cavity cancer is carried by low- and middle-income nations. Notably, Asia accounts for approximately two-thirds of newly diagnosed oral cavity cancer cases each year. For oropharyngeal cancer, the worldwide incidence is 98,000 cases per year, with the highest rates reported in Western Europe, Northern Europe, North America, Central/Eastern Europe, and Australia/New Zealand. Exceptionally wide variations in oral cancer incidence and mortality across regions likely results from differences in population habits, life expectancies, preventive education, and accuracy of disease reporting. Despite the difficulties involved in interpreting such data, these findings have been helpful in identifying potential causative factors.

Etiology of Oral Cancer

The cause of oral squamous cell carcinoma is multifactorial. Both extrinsic and intrinsic factors may be involved, and more than a single factor may be needed to produce such a malignancy. *Extrinsic* factors include tobacco smoke, alcohol, human papillomavirus (especially for oropharyngeal cancers), and sunlight (for vermilion cancers only). *Intrinsic* factors include systemic or generalized states, such as malnutrition or iron-deficiency anemia. Heredity does not appear to play a major causative role, although a few rare, heritable conditions (e.g., dyskeratosis congenita [see page 752], Fanconi anemia) have been associated with an increased risk for oral squamous cell carcinoma. Interestingly, a recent genome-wide association study reported that oral cavity and pharyngeal cancers were associated with certain HLA and other susceptibility loci.

Tobacco Smoking

More than 1 billion individuals currently smoke tobacco worldwide. Over the past 3 decades, smoking prevalence has decreased, although population growth has resulted in an increase in the total number of smokers. According to the 2019 Global Burden of Disease Study, tobacco smoking accounted for approximately 7.7 million deaths and was the leading risk factor for death among males. In the United States, tobacco smoking reached its greatest popularity during the 1940s, when at least 65% of white men smoked and other population subgroups were beginning to smoke in large numbers. Today less than 20% of US adults use tobacco products and less than 13% smoke cigarettes. Although an overall decrease in smoking prevalence has been observed, intensive efforts will be required to meet the US Department of Health and Human Services' Healthy People objective to reduce cigarette smoking prevalence by the year 2030 to 5% or less.

Tobacco smoke contains more than 70 carcinogens, including polycyclic aromatic hydrocarbons (such as benzo[*a*]pyrene), *N*-nitrosamines, aromatic amines, formaldehyde, acetaldehyde, and benzene. In addition, smoking produces free radicals and oxidants that promote the destruction and counteract the protective effects of endogenous antioxidants (such as, glutathione-S-transferase, glutathione reductase, and superoxide dismutase).

Much indirect clinical evidence implicates tobacco smoking in the development of oral squamous cell carcinoma. The proportion of smokers (80%) among patients with oral carcinoma is about four times greater than that among the general population. For patients who quit smoking, the risk for developing oral cancer declines over time; approximately 10 years after cessation, the incidence of oral cancer approaches that of individuals who have never smoked. The risk for a second primary carcinoma of the upper aerodigestive tract is two to six times greater for treated patients with oral cancer who continue to smoke than for those who quit after diagnosis.

According to a meta-analysis of observational studies on tobacco smoking and cancer in various regions of the world, the pooled risk for oral cancer is approximately three times greater among smokers than nonsmokers. Moreover, the relative risk (smoker's risk for oral cancer compared with that of a nonsmoker) is dose-dependent. It is at least five for persons who smoke 40 cigarettes daily, but increases to as much as 17 for persons who smoke 80 or more cigarettes daily. The risk also increases the longer a person smokes. Furthermore, studies suggest that cigar or pipe smoking is associated with a similar or greater risk for oral cancer compared to cigarette smoking.

In India it is common to smoke bidi (small, hand-rolled cigarettes consisting of flaked tobacco rolled in a temburni or tendu leaf), and bidi smoking is associated with an approximately threefold greater risk of oral cancer compared to cigarette smoking. The highest risk of all probably is found in certain Indian and South American cultures in which the practice of reverse smoking is popular, especially among women. In reverse smoking, the burning end of a handmade cigar or cigarette is held inside the mouth. Where reverse smoking is practiced, as many as 50% of all oral malignancies are found on the hard palate, a site usually spared by this disease.

Smokeless Tobacco

Smokeless tobacco is used in a wide variety of forms by more than 350 million individuals worldwide. More than 80% of these individuals reside in Asia, including countries where smokeless tobacco often is incorporated into a betel quid (see next section). Based on evaluation of published scientific studies, the International Agency for Research on Cancer has

dentlearn.ir

concluded that smokeless tobacco—whether used alone or with betel quid—is carcinogenic to humans. Among systematic reviews and meta-analyses of smokeless tobacco use in the world literature, most reported oral cancer odds ratios vary from approximately 4 to 8 in Southeast Asia and less than 1 to 5 in the Americas and Europe. In addition, a recent pooled analysis of data from National Health Interview Surveys in the United States reported an association between current smokeless tobacco use and oral cavity cancer (with an approximate hazard ratio of 9) among individuals who had never used other forms of tobacco. Variation in reported risk may be influenced by study methodology as well as the types of smokeless tobacco used. A recent meta-analysis of studies from various world regions found that oral cancer risk among betel quid product users may be more than double that for users of oral snuff. In the United States, studies suggest a lower risk associated with moist snuff and chewing tobacco and a higher risk associated with dry snuff. This apparent increased risk associated with dry snuff is supported by clinicopathologic investigations that have found an abnormal male-to-female ratio for oral carcinoma (>1.0:1.5) in geographic areas, such as the southeastern United States, where the habit is more popular among women than among men. In addition, approximately 50% of all oral cancers in smokeless tobacco users occur at the site where the tobacco is habitually placed.

Betel Quid (Paan)

Betel quid (or *paan*) is a combination of natural substances (i.e., areca palm nuts, betel leaf, slaked lime, and perhaps tobacco leaf) chewed for their psychostimulating effects. The carcinogenicity of betel quid traditionally has been attributed to tobacco, although areca nut alone also appears to be carcinogenic. In addition, commercially freeze-dried betel quid substitutes (e.g., *pan masala* and *gutkha*) packaged in convenient sachets have become increasingly popular. Oral cancer risk estimates by various systematic reviews and meta-analyses range from about six- to ninefold for users of paan and gutkha. Among betel quid users in Asia, the lifetime risk of developing oral cancer is a remarkable 8%. Notably, as many as 80% of oral squamous cell carcinomas in the Indian subcontinent and Taiwan are associated with betel quid use. This habit also is associated with development of precancers, such as leukoplakia. As many as 600 million persons worldwide chew these quids on a regular basis.

Alcohol

Since 1998, the International Agency for Research on Cancer has classified alcohol as a carcinogen for the upper aerodigestive tract, including the oral cavity, oropharynx, hypopharynx, larynx, and esophagus. In particular, alcohol in combination with tobacco is a significant risk factor for oral cancer development, with a reported relative risk of 15 or more among heavy users of both substances. Furthermore, even after controlling for tobacco use, epidemiologic studies have reported a 2- to 14-fold increased risk for oral cancer among heavy drinkers (often defined as individuals who consume more than four alcoholic beverages or approximately 50 g of alcohol per day). The risk generally appears to be dose-dependent and time-dependent.

Indirect evidence for alcohol's role in oral cancer development includes the fact that approximately one-third of male patients with oral cancer are heavy alcohol users, whereas less than 10% of the general population can be classified as such. Likewise, cirrhosis of the liver is found in at least 20% of male patients with oral cancer.

The exact role of alcohol in oral carcinogenesis is not well understood, although several mechanisms have been proposed. Ethanol in alcoholic beverages is metabolized into acetaldehyde, which is a known carcinogen. In addition, carcinogenic impurities—such as, polycyclic aromatic hydrocarbons and nitrosamines—may be present in some alcoholic beverages. Moreover, alcohol may help solubilize other carcinogenic compounds and may increase the permeability of the oral epithelium to these compounds. Nutritional deficiencies and immunosuppression associated with heavy alcohol consumption may be contributory factors as well.

There is much debate in the literature regarding the potential for alcohol-containing mouthwashes to increase the risk for oral cancer. High-quality epidemiologic studies are limited, and inconsistent findings across studies have failed to establish a definite link.

Occupational Exposures and Environmental Pollutants

Some studies have reported an increased oral cancer risk for workers in the wood products industry chronically exposed to certain chemicals, such as phenoxyacetic acids. Such workers also are at increased risk for nasal and nasopharyngeal carcinoma. In addition, there is limited and inconsistent evidence for elevated oral cancer risk among metal workers, electrical workers, plumbers, machinists, painters, and other individuals with occupational exposure to solvents or metal dust.

In regions of Taiwan with a particularly high incidence of oral cancer, investigators have reported elevated levels of heavy metal pollutants (e.g., nickel, chromium, and arsenic) in farm soil and increased blood concentrations of some of these metals in affected patients.

Radiation

The effects of UV radiation on the lips are discussed elsewhere (actinic cheilosis, see page 395). Interestingly, several epidemiologic and other large-scale studies have reported an association between lip cancer and certain antihypertensive medications (e.g., hydrochlorothiazide, hydrochlorothiazide-triamterene, nifedipine). A similar association also has been noted for nonmelanoma skin cancers. Although further studies are needed to establish direct causality, it has been hypothesized that such medications may act as photosensitizers and may potentiate the development of UV-induced lip or skin cancer.

In addition, it is well known that **x-irradiation** decreases immune reactivity and produces chromosomal abnormalities. Indeed, radiotherapy to the head and neck area increases the risk for later development of a new primary oral

dentlearn.ir

malignancy, either a carcinoma or sarcoma. This effect is dose-dependent, but even low-dose radiotherapy for benign entities may increase the local risk somewhat. Although there has been controversy regarding whether dental radiography may pose an increased risk for developing various tumors, dental imaging has not been associated with oral carcinoma.

Vitamin/Mineral Deficiencies and Dietary Factors

Iron deficiency, especially the severe, chronic form known as the **Plummer-Vinson** or **Paterson-Kelly syndrome** (see page 830), is associated with an elevated risk for squamous cell carcinoma of the esophagus, oropharynx, and posterior mouth. Malignancies develop at an earlier age than in patients without iron deficiency anemia. Iron deficiency may cause impaired cell-mediated immunity. In addition, because the epithelium of the upper digestive tract has a relatively high turnover rate, rapid loss of iron-dependent enzymes may lead to degenerative changes, including mucosal atrophy and **esophageal webs** (intertwining fibrous bands of scar tissue), with heightened susceptibility to malignant transformation.

Vitamin-A deficiency produces excessive keratinization of the skin and mucous membranes, and researchers have suggested that this vitamin may help to prevent oral precancer and cancer. Some believe that blood levels of retinol and the amount of dietary betacarotene ingested are inversely proportional to the risk of oral squamous cell carcinoma and leukoplakia. Long-term therapy with retinoic acids and betacarotene also has been associated with regression of at least some leukoplakic lesions and a concomitant reduction in the severity of dysplasia within such lesions.

Several epidemiologic studies suggest that high intake of fruits and vegetables decreases the risk for numerous cancer types, including oral cancer. This finding may be related to the protective effects of not only vitamin A but also various other substances (e.g., vitamins C and E, folate, flavonoids, fiber, lycopene, and phytosterols) present within plant foods. However, tobacco and alcohol may represent confounding factors, because heavy tobacco and alcohol users often consume small amounts of fruits and vegetables. Also, some studies suggest that animal fats and processed or salted meat may increase the risk for oral cancer.

A few studies have reported an increased risk for oral cancer in association with drinking hot maté (an herbal tea mainly consumed in parts of South and Central America). Furthermore, there has been interest in the potential protective effects of green tea, coffee, and their associated polyphenols. However, further studies are needed to confirm and explain the carcinogenic or protective properties of such beverages.

Bacteria

The potential for microflora of the oral cavity to contribute to carcinogenesis represents a growing area of scientific investigation. Proposed mechanisms by which oral bacteria may contribute to oral cancer development include the following: (1) production of an inflammatory microenvironment that enhances cell proliferation and inhibits apoptosis, (2) disruption of immunosurveillance, and (3) metabolism of tobacco- and alcohol-related carcinogens (e.g., conversion of ethanol into the carcinogen acetaldehyde). Studies using traditional culture methods and molecular techniques have suggested potential associations between oral cancer and *Prevotella* species, *Fusobacterium* species, *P. gingivalis*, *Capnocytophaga gingivalis*, and certain streptococci. In addition, epidemiological studies have suggested associations with poor oral hygiene, poor dental status, and periodontal disease. More recently, there has been a surge in studies examining the microbiome of patients with oral cancer or oral potentially malignant disorders. Investigators hypothesize that shifts in the composition of complex microbial communities may be more important than individual bacterial pathogens in promoting cancer development. Although most such studies have found significant changes in bacterial flora among patients with disease as compared to controls, there is considerable heterogeneity in reported microbial profiles across studies. Further research with methodological standardization is needed.

Although rarely seen today, tertiary syphilis has been associated with a fourfold increased risk for development of dorsal tongue carcinoma. This risk may be due to the carcinogenic properties of the arsenical agents and other heavy metals that were used to treat syphilis before the advent of modern antibiotic therapy.

Candida

Hyperplastic candidiasis (see page 206) frequently is cited as an oral precancerous condition. Because this lesion appears as a white plaque that cannot be rubbed off, it also has been called *candidal leukoplakia.* Unfortunately, it is difficult both clinically and histopathologically to distinguish between a true hyperplastic candidiasis and a preexisting leukoplakia with superimposed candidiasis. Experimentally, some strains of *C. albicans* have produced hyperkeratotic lesions of the dorsal rat tongue without any other contributing factors. Other studies have demonstrated that certain strains may produce nitrosamines (carcinogens that can activate certain proto-oncogenes) or may convert ethanol into the carcinogen acetaldehyde. In addition, upregulation of proinflammatory cytokines may promote cell proliferation and inhibit apoptosis. Recent studies of the oral microbiome suggest that interactions between complex bacterial and fungal communities may promote cancer development as well. Decreased fungal diversity and increased abundance of certain fungi (such as *Candida, Hannaella*, and *Gibberella*) may be seen in oral cancer patients compared to healthy individuals. However, the evidence for the promotion of oral carcinogenesis by fungi is largely circumstantial.

Oncogenic Viruses

Oncogenic (tumor producing) viruses may play a major role in a wide variety of cancers. Viral integration into the host's genetic material may result in abnormal cell growth and proliferation. The oncogenic viruses may immortalize the host cell, thereby facilitating malignant transformation. In the

dentlearn.ir

past, adenoviruses, Epstein-Barr virus (EBV), herpes simplex virus (HSV), human papillomavirus (HPV), and retroviruses (e.g., human immunodeficiency virus [HIV]) all have been suggested to play a role in the development of oral carcinoma. However, HPV and HIV are the only ones still implicated. HPV is discussed here; oral squamous cell carcinoma in the setting of HIV infection is discussed in the following section on immunosuppression and also on page 263.

HPV traditionally has been known for its role in the development of cancers of the anogenital region (especially the uterine cervix but also the anus, vulva, vagina, and penis). In addition, within the past few decades, a strong link between HPV and oropharyngeal carcinoma has been established, and the oropharynx has supplanted the uterine cervix as the most common site for HPV-attributable cancer in the United States. This epidemiologic shift has been hypothesized to result from an increase in oral sexual behavior and a decline in tobacco use. Significant increases in HPV-positive oropharyngeal cancer incidence also have been reported in other high-income nations. The proportion of oropharyngeal cancers attributable to HPV infection is estimated to be approximately 70% in the United States and 40% globally. In contrast, only a small subset of oral cavity carcinomas has been attributed to HPV infection.

The high-risk HPV types (see page 354) are most closely associated with dysplasia and squamous cell carcinoma. In particular, detection of HPV 16 in exfoliated oral epithelial cells or mouth rinse samples is associated with a nearly fourfold increased risk for oral cavity cancer and a 22-fold increased risk for oropharyngeal cancer. Investigators have proposed that persistent oral infection with HPV 16 and other high-risk HPV types increases the risk for eventual development of oropharyngeal cancer. HPV 16 has been identified in more than 90% of HPV-positive oropharyngeal squamous cell carcinomas. Similarly, in HPV-positive oral cavity squamous cell carcinomas, HPV 16 appears to be the most common type, although there may be a greater diversity of high-risk HPV types in oral cavity tumors compared to oropharyngeal ones. Most studies of HPV-positive oropharyngeal and oral cavity squamous cell carcinomas have focused on detection of HPV 16 and other high-risk types belonging to the genus *Alphapapillomavirus*; however, recent investigations using next-generation sequencing have suggested a possible role for certain *Betapapillomavirus* and *Gammapapillomavirus* types as well.

Meta-analyses of more recently published literature have estimated the prevalence of HPV DNA in oral squamous cell carcinomas to range from 13% to 58%; nonetheless, the presence of HPV DNA is not indicative of transcriptionally active HPV infection and cannot discriminate between biologically relevant vs bystander infection. Instead, detection of high-risk HPV E6/E7 mRNA is considered better evidence of HPV infection as a likely cause of tumor development. The primary mechanisms by which HPV is believed to contribute to carcinogenesis are linked to products of the *E6* and *E7* viral oncogenes: (1) E6 protein promotes degradation of the tumor suppressor protein p53 and (2) E7 increases degradation of the tumor suppressor protein pRb, which leads to upregulation of p16 and downregulation of cyclin D1. Using assays for both high-risk HPV DNA and E6/E7 mRNA, a multicenter retrospective study in North America reported that only 6% of oral cavity squamous cell carcinomas analyzed could be attributed to HPV infection. Similarly, a large-scale study of archived samples from 29 countries using assays for high-risk HPV DNA and either E6 mRNA or p16 reported the HPV-attributable fraction for oral cavity cancers to be approximately 4%. In addition, according to a meta-analysis of studies from 44 countries using such assays, approximately 16% of oral cavity squamous cell carcinomas may be attributed to HPV infection. Overall, in contrast to oropharyngeal cancers, only a small subset of oral cavity cancers appears to be HPV-related.

The characteristic risk profiles for patients in the United States with HPV-positive vs HPV-negative oropharyngeal squamous cell carcinoma exhibit some similarities but also significant differences. In both patient groups, there is a male predilection. However, compared to HPV-negative cases, HPV-positive cases exhibit a greater predilection for white individuals and individuals of higher socioeconomic status. During the early 2000s, HPV-positive oropharyngeal squamous cell carcinoma was characterized as a disease mainly arising in middle-aged individuals, with a younger average age at diagnosis compared to the HPV-negative group. However, since that time, the average age at diagnosis for oropharyngeal cancer has been increasing; this aging trend has been thought to be driven preferentially by the HPV-positive group, although some investigators have proposed that both groups may be aging. Also, a continued shift toward an older HPV-positive oropharyngeal cancer patient population has been forecasted over the next couple of decades based on low HPV vaccine coverage in older cohorts. Compared to HPV-negative tumors, HPV-positive tumors are more strongly associated with certain parameters of sexual behavior (e.g., increased number of lifetime sexual or oral sexual partners, early age at sexual debut, increased intensity of oral sexual exposure [as measured by sex-years, or the number of oral sexual partners per 10 years since sexual debut]). In addition, among individuals who do not use tobacco or alcohol, HPV-positive disease is more prevalent than HPV-negative disease. Nevertheless, patients with HPV-positive oropharyngeal squamous cell carcinoma often have some history of tobacco and alcohol use, and recent population-based studies in the United States have demonstrated a significantly greater burden of HPV-positive oropharyngeal cancers among ever-smokers than never-smokers.

The reasons underlying the marked predilection of HPV-positive oropharyngeal squamous cell carcinomas for the palatine and lingual tonsils are uncertain. However, proposed explanations include the following: (1) the specialized reticular epithelium lining the tonsillar crypts represents a zone of weakness, with a discontinuous basement membrane permissive to viral infection and tumor invasion; (2) the deep invaginations of the tonsillar crypts act as a reservoir for pathogens (including HPV); and (3) decreased T-cell response

dentlearn.ir

(due to binding of PD-L1 on epithelial cells to the PD-1 receptor on T-cells) protects the tonsils from chronic antigen stimulation but also favors viral persistence and cancer development.

Immunosuppression

Immunosuppression may play a role in the development of at least some malignancies of the upper aerodigestive tract. Without effective immunologic surveillance and attack, it is thought that malignant cells cannot be recognized and destroyed at an early stage. Persons with HIV infection and those who are undergoing immunosuppressive therapy for malignancy or organ transplantation are at increased risk for oral squamous cell carcinoma and other head and neck malignancies, especially when tobacco smoking and alcohol abuse are present.

Oncogenes and Tumor Suppressor Genes

The molecular basis of carcinogenesis involves mutations or epigenetic changes in two broad classes of genes: proto-oncogenes and tumor suppressor genes. Proto-oncogenes may be transformed into activated oncogenes by environmental agents (e.g., viruses, irradiation, and chemical carcinogens) or inherited changes. Activated oncogenes promote uncontrolled cell division and are involved in the initiation and progression of a wide variety of malignancies. Tumor suppressor genes, on the other hand, inhibit cell division and indirectly allow tumor production when they become inactivated or mutated.

Traditionally, most authorities have proposed that sequential accumulation of several genetic aberrations is necessary before a cell expresses a malignant phenotype. On the other hand, based on recent analyses of transcriptomic functional pathways, copy number, and/or ultra-deep sequencing, some investigators have detected rather random molecular changes in oral precursor lesions. Further studies are needed to reconcile such findings.

Genetic aberrations commonly identified in head and neck squamous cell carcinomas include abnormalities of the *RAS*, *MYC*, *EGFR*, and *PIK3CA* oncogenes, and the *TP53*, *RB1*, *CDKN2A*, and E-cadherin-related tumor suppressor genes. Mutations also may be observed in genes that function as both oncogenes and tumor suppressor genes (e.g., *FAT1*, *NOTCH1*). Genetic alterations may result in dysregulation of various pathways (e.g., those involving Wnt/beta-catenin, PI3K/Akt/mTOR, JAK/STAT, RAS/RAF/MAPK, and TGF-beta) important for key cellular functions (e.g., cell cycle control, cell proliferation, and survival). Head and neck squamous cell carcinomas associated with tobacco and alcohol use often exhibit mutated *TP53*, overexpression of pRb (encoded by *RB1*), decreased expression of p16 (encoded by *CDKN2A*), and amplification of 3q26/28 and 11q13/22. In contrast, HPV-associated cases typically express exhibit wild-type *TP53*, low levels of pRb, and increased levels of p16. Additional alterations that tend to be found in HPV-positive tumors include those involving *PIK3CA*, *TRAF3*, *E2F1*, immune-related genes (e.g., *HLA-A/B*), and genes encoding FGF and JAK/STAT signaling proteins.

Chronic Trauma or Irritation

The potential role of chronic trauma or irritation in promoting oral cancer is controversial. Frictional keratoses (see page 383), broken or sharp teeth, and overall denture use are not associated with a significantly increased risk for cancer. However, some studies have reported a markedly increased risk for oral cavity cancer among individuals with ill-fitting dentures (estimated odds ratio of 3.9)—even after controlling for confounding factors, such as tobacco, alcohol, and betel quid use. It is unclear whether this increased risk might reflect the direct effects of an inflammatory environment (with associated oxidative stress) or, possibly, altered microbiota in promoting carcinogenesis. Alternatively, this apparent risk may result from decreased opportunities for clinical detection of oral premalignancy due to infrequent professional dental care.

Clinical and Radiographic Features

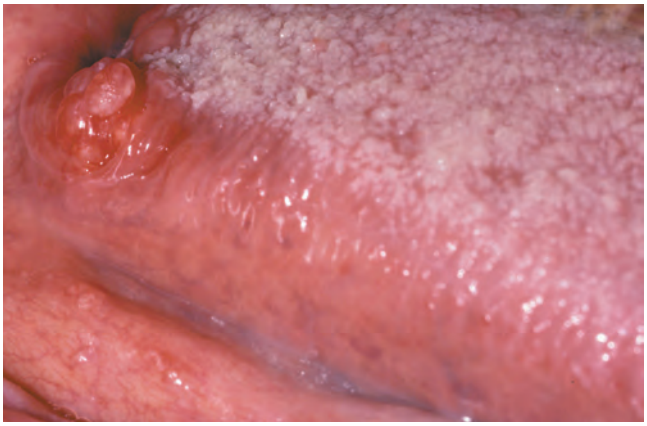
Oral Cavity Carcinoma

Persons with oral cavity squamous cell carcinoma are most often older men who have been aware of an alteration for 4–8 months before seeking professional help (8–24 months among lower socioeconomic groups). There is minimal pain during the early growth phase, which may explain the delay in seeking professional care. If the health care professional does not have a high index of suspicion, then additional weeks or months may elapse before a biopsy is performed.

Oral cavity squamous cell carcinoma has a varied clinical presentation, including the following:

- Exophytic (mass-forming; fungating, papillary, and verruciform)
- Endophytic (invasive, burrowing, and ulcerated)
- Leukoplakic (white patch) (Fig. 10.100)
- Erythroplakic (red patch)
- Erythroleukoplakic (combined red-and-white patch) (Fig. 10.101)

• **Fig. 10.100 Squamous Cell Carcinoma.** Leukoplakic lesion with a granular surface on the left ventrolateral tongue. (Courtesy of Dr. Larry Cunningham.)

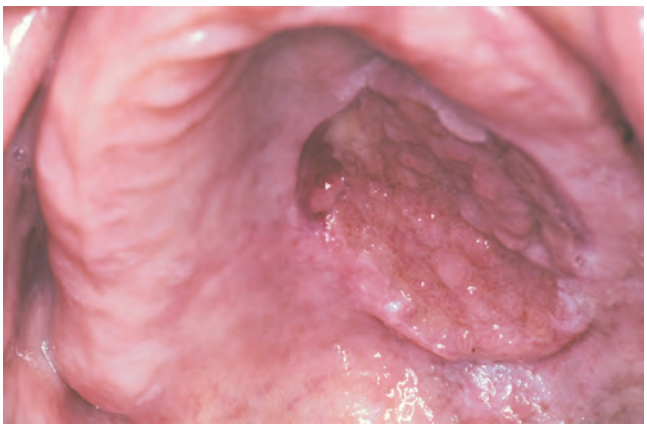


dentlearn.ir

• **Fig. 10.101 Squamous Cell Carcinoma.** Speckled erythroplakia of the left posterior buccal mucosa. Brush sampling had been reported to be negative for epithelial abnormality, but incisional biopsy revealed invasive squamous cell carcinoma. (From Chi AC, Ravenel MC: AAOMP case challenge: a "speckled" lesion, *J Contemp Dent Pract* 6:168–172, 2005.)

• **Fig. 10.103 Squamous Cell Carcinoma.** An exophytic buccal lesion shows a roughened and irregular surface with areas of erythema admixed with small areas of white keratosis. Surface ulceration is evident.

• **Fig. 10.102 Squamous Cell Carcinoma.** An exophytic lesion of the posterior lateral tongue demonstrates surface nodularity and minimal surface keratin production. It is painless and indurated.



• **Fig. 10.104 Squamous Cell Carcinoma.** Chronic ulcerated lesion on the right ventral surface of the tongue. The rolled anterior margin felt indurated on palpation.

The *leukoplakic* and *erythroplakic* examples are probably early cases that have not yet produced a mass or ulceration, and the clinical features are identical to those described for leukoplakia and erythroplakia (see pages 381 and 390).

An *exophytic* lesion typically has a surface that is irregular, fungating, papillary, or verruciform, and its color may vary from normal to white or red, depending on the amount of keratin and vascularity (Figs. 10.102 and 10.103). The surface is often ulcerated, and the tumor feels hard **(indurated)** on palpation (Fig. 10.104).

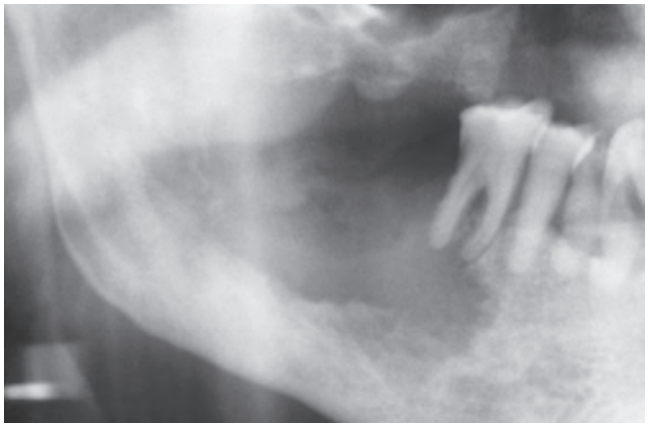
The *endophytic* growth pattern has a central, depressed, irregularly shaped ulcer with a surrounding "rolled" border of pink, red, or white mucosa (Fig. 10.105). The rolled border results from invasion of the tumor downward and laterally under adjacent epithelium. Traumatic granulomas, deep fungal infections, tuberculosis, tertiary syphilis, and oral lesions of granulomatosis with polyangiitis (Wegener granulomatosis) or Crohn disease may exhibit a similar clinical appearance.

• **Fig. 10.105 Squamous Cell Carcinoma.** An ulcerated or endophytic lesion of the hard palate demonstrates rolled borders and a necrotic ulcer bed. This cancer was painless, although it had partially destroyed underlying palatal bone.

dentlearn.ir

Destruction of underlying bone, when present, may be painful or completely painless; it appears on radiographs as a "moth-eaten" radiolucency with ill-defined or ragged margins (an appearance similar to osteomyelitis) (Fig. 10.106). Perineural invasion may cause paresthesia.

Lip Vermilion Carcinoma



Carcinoma of the lip vermilion typically is found in light-skinned persons with chronic exposure to UV radiation from sunlight. Seventy percent of affected individuals have outdoor occupations. It usually is associated with **actinic cheilosis** (see page 395) and may arise at the site where the patient holds a cigarette, cigar, or pipe. Almost 90% of lesions are located on the lower lip.

The typical vermilion carcinoma is a crusted, oozing, nontender, indurated ulceration that is usually less than 1 cm in greatest diameter when discovered (Figs. 10.107 and 10.108). The tumor usually grows slowly, and most patients are aware of a "problem" in the area for 12–16 months before diagnosis. Metastasis is a late event; at diagnosis, fewer than 10% of patients have lymph node metastasis, usually in the submental region. Perineural invasion may result in extension of the tumor into the mandible through the mental foramen. Although this tumor typically is diagnosed and treated at an early stage, patient neglect can result in considerable destruction of normal tissue (Fig. 10.109).

Intraoral Carcinoma

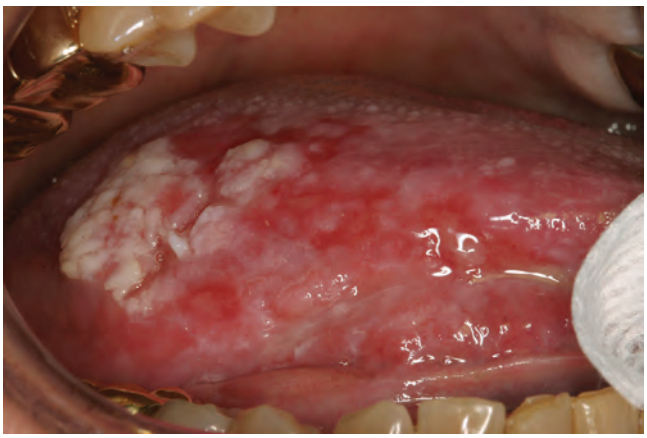
In the United States, the most common sites for intraoral carcinoma are the tongue (usually the posterior lateral and ventral surfaces) and floor of mouth. Other sites of involvement (in descending order of frequency) are the gingiva/alveolar mucosa, buccal mucosa, labial mucosa, and hard palate.

Carcinoma of the tongue accounts for more than 50% of intraoral cancers in the United States (Fig. 10.110). Two-thirds of lingual carcinomas appear as painless, indurated masses or ulcers of the posterior lateral border; 20% occur on anterior lateral or ventral surfaces, and only 4% occur on the dorsum. For unknown reasons, the oral tongue represents an increasingly common site of involvement in young patients.

• **Fig. 10.106 Squamous Cell Carcinoma.** Bone involvement is characterized by an irregular, "moth-eaten" radiolucency with ragged margins—an appearance similar to that of osteomyelitis.

• **Fig. 10.108 Squamous Cell Carcinoma.** Ulcerated mass of the lower lip vermilion.

• **Fig. 10.107 Squamous Cell Carcinoma.** Crusted, ulcerated nodule of the lower lip vermilion. Risk factors in this patient included chronic sun exposure as well as immunosuppression due to bone marrow transplantation.



• **Fig. 10.109 Squamous Cell Carcinoma.** Patient neglect can result in extensive involvement, even in a readily visible site such as the lip vermilion. This ulcerating lesion of the lower lip had been present for more than 1 year before diagnosis.

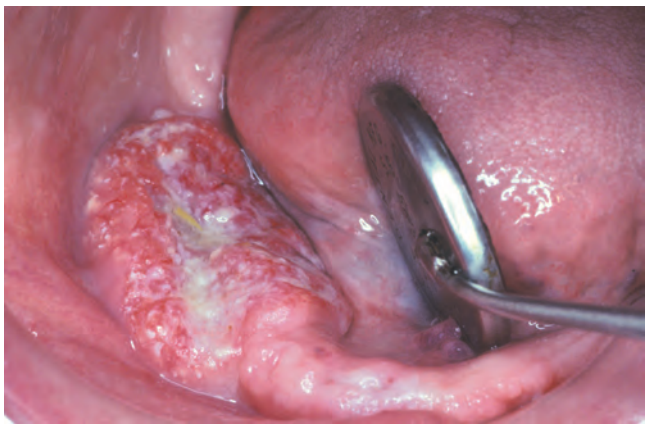
dentlearn.ir

Of all intraoral carcinomas, floor of mouth lesions are the most likely to arise from a preexisting leukoplakia or erythroplakia (Fig. 10.111). The floor of mouth also represents the oral cancer site most often associated with the development of a second primary malignancy, either elsewhere in the aerodigestive tract or in a distant organ. Floor of mouth carcinomas most often arise in the midline region near the frenum.

Gingival and alveolar carcinomas are usually painless and most frequently arise from keratinized, posterior mandibular mucosa (Fig. 10.112). Interestingly, among intraoral carcinomas, gingival lesions are least associated with tobacco smoking and have the greatest predilection for females. Gingival and alveolar carcinomas have a special propensity to mimic common, benign inflammatory and reactive lesions, such as the pyogenic granuloma, gingivitis (Fig. 10.113), periodontal disease, and peri-implantitis. Gingival tumors often destroy the underlying bone and cause tooth mobility. The lesion may go unrecognized until after tooth extraction, when it proliferates out of the socket to mimic the hyperplastic granulation tissue of an epulis granulomatosa (see page 526). Cancers that develop in an edentulous area may "wrap around" a denture flange and superficially resemble inflammatory fibrous hyperplasia (epulis fissuratum) (Fig. 10.114).

• **Fig. 10.110 Squamous Cell Carcinoma.** Diffuse, red and white lesion of the posterior lateral border of the tongue.

• **Fig. 10.111 Squamous Cell Carcinoma.** Granular red and white lesion in the anterior floor of mouth.



Tumors of the maxillary alveolar ridge may extend onto the hard palate. Some studies suggest that carcinomas involving the maxillary mucosa may be more aggressive than previously thought, with approximately 30% of cases harboring occult cervical lymph node metastasis.

• **Fig. 10.112 Squamous Cell Carcinoma.** Red and white granular lesion of the posterior lingual mandibular gingiva.

• **Fig. 10.113 Squamous Cell Carcinoma.** An innocuous, pebbled surface change of the gingiva was interpreted as inflammatory until multifocal white keratoses developed.

• **Fig. 10.114 Squamous Cell Carcinoma.** An exophytic lesion with an irregular and pebbled surface. There is a linear indentation along the facial aspect resulting from pressure from the patient's lower denture. The underlying alveolar bone was destroyed.

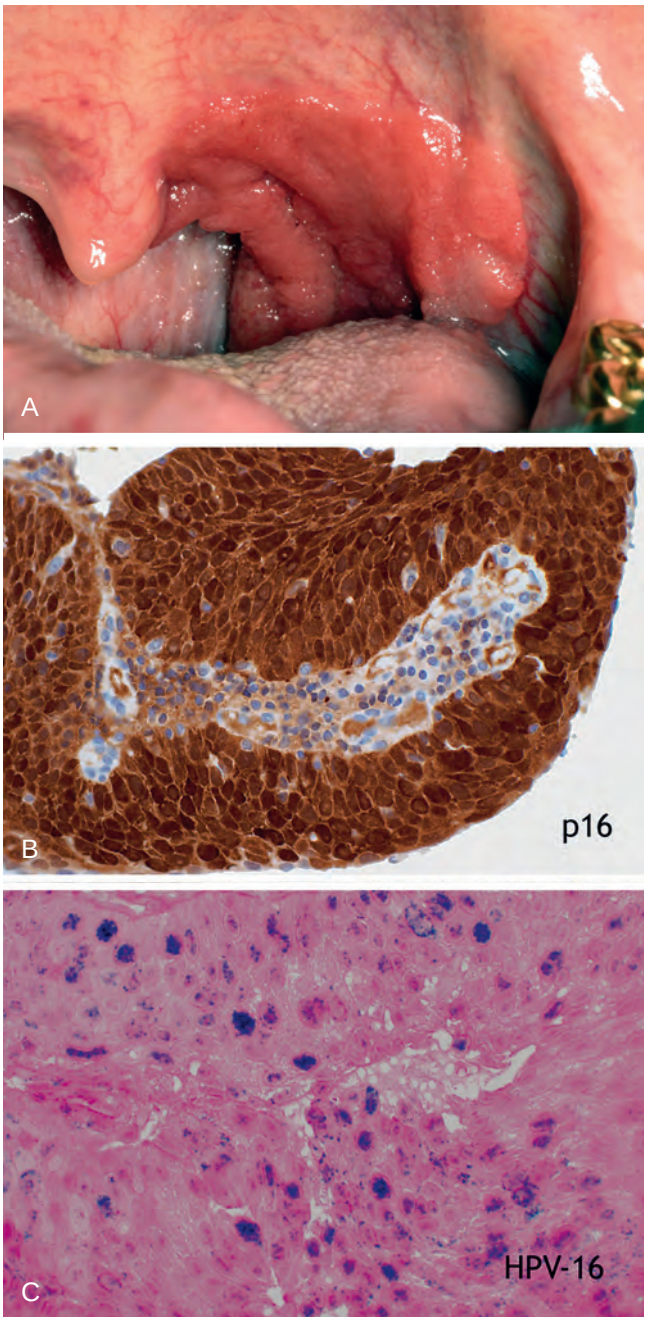
dentlearn.ir

Similarly, some investigators suggest that carcinomas of the buccal mucosa may be more aggressive than previously suspected, with reported locoregional recurrence rates ranging from 30% to 80%. The buccal mucosa is an especially common site for intraoral carcinoma in regions of the world where betel quid use is prevalent.

Carcinomas of the retromolar trigone may spread to numerous adjacent structures, including the oropharynx, buccal mucosa, alveolar ridge, and pterygomandibular raphe (Fig. 10.115). Invasion of the pterygomandibular raphe may lead to involvement of the skull base, masticator space, and floor of mouth.

Oropharyngeal Carcinoma

Subsites for oropharyngeal carcinoma include the soft palate, posterior wall, palatine tonsil region (i.e., palatine tonsils, tonsillar fossa, and pillars), and base of tongue (including the lingual tonsils). In particular, the palatine tonsils and base of tongue are favored sites for HPV-positive tumors, and the majority of oropharyngeal carcinomas in the United States currently are attributed to HPV infection (Fig. 10.116A).

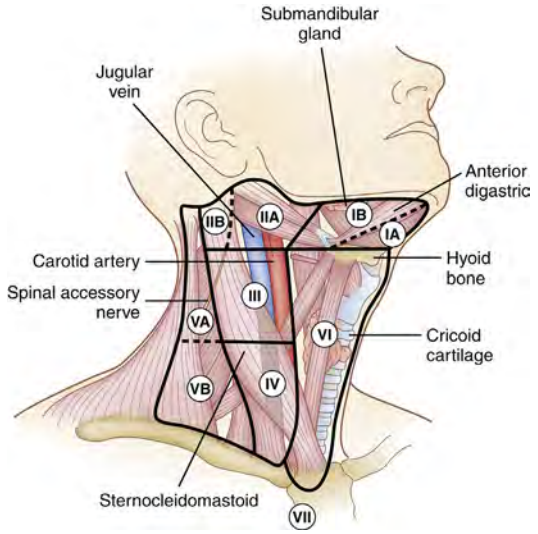


Oropharyngeal carcinomas may appear as an erythematous plaque, an ulcerated mass, or mucosal fullness. Small lesions arising from the tonsillar crypts may not be clinically apparent. Many patients have minimal symptoms at the time of diagnosis. HPV-positive oropharyngeal carcinomas tend to metastasize relatively early, and it is not unusual for patients to have a small, clinically evident or occult primary tumor yet prominent cervical metastasis (Fig. 10.117). Among patients with HPV-positive disease, the most common chief complaints at initial presentation are a neck mass followed by sore throat and **dysphagia** (difficulty in swallowing). In contrast, among patients with HPV-negative disease, the most common presenting complaints are sore throat followed by dysphagia and a neck mass. Other possible findings in patients with oropharyngeal cancer may include **globus sensation** (feeling of a lump) and **odynophagia** (pain on swallowing). The pain may be dull or sharp and frequently is referred to the ear.

• **Fig. 10.115 Squamous Cell Carcinoma.** Carcinoma of the retromolar trigone with extension into the oropharynx (including the soft palate and anterior faucial pillar). Associated leukoplakia also extends anteriorly along the buccal mucosa.

Metastasis

Metastasis of oral squamous cell carcinoma occurs largely via the lymphatics to the cervical lymph nodes. Based on anatomic location, lymph nodes in the neck are divided into seven levels, as shown in Fig. 10.118. Regional metastasis is more often ipsilateral than contralateral or bilateral. Oral cavity carcinomas most frequently metastasize to the lymph nodes in levels I through III. Oropharyngeal carcinomas tend



• **Fig. 10.116 Squamous Cell Carcinoma, Oropharyngeal. A,** Large, erythroplakic lesion involving the left soft palate and tonsillar region. **B,** Immunohistochemistry showed the tumor to be positive for p16, which is a surrogate marker for transcriptionally active, high-risk human papillomavirus (HPV) infection among oropharyngeal squamous cell carcinomas. **C,** *In situ* hybridization (ISH) demonstrated the presence of intranuclear HPV 16 DNA.

dentlearn.ir

• **Fig. 10.117 Squamous Cell Carcinoma, Oropharyngeal with Regional Metastasis.** Computed tomography/positron emission tomography (CT/PET) fusion study of a patient with human papillomavirus-positive oropharyngeal squamous cell carcinoma. The scan highlights a relatively small (T1) primary tumor at the base of tongue/tonsillar region plus a prominent cervical lymph node metastasis in the lateral neck. (Courtesy of Dr. Terry Day).

• **Fig. 10.118 Squamous Cell Carcinoma, Potential Sites for Cervical Lymph Node Metastasis.** Diagram demonstrating lymph node levels in the neck where metastatic deposits may be found:

I. Submental/submandibular nodes
  IA. Submental nodes
  IB. Submandibular nodes
II. Upper jugular nodes
  IIA. Anterior (medial) to the vertical plane defined by the spinal accessory nerve
  IIB. Posterior (lateral) to the vertical plane defined by the spinal accessory nerve
III. Middle jugular nodes
IV. Lower jugular nodes
V. Posterior triangle nodes
  VA. Upper nodes extending from the skull base to bottom of the cricoid cartilage
  VB. Lower nodes extending from bottom of the cricoid cartilage to the clavicle
VI. Anterior (central) compartment nodes
VII. Superior mediastinal nodes

(From Thyroid. In Townsend CM, Daniel Beauchamp R, Mark Evers B, Mattox KL, Sabiston DC, editors: *Sabiston textbook of surgery: the biological basis of modern surgical practice*, 2022, Elsevier, pp 159–169.)

to metastasize to the lymph nodes in levels II and III. Involvement of other cervical lymph node groups is possible as well; in addition, oropharyngeal tumors may metastasize to the retropharyngeal nodes.

Upon clinical examination, a cervical lymph node that contains metastatic carcinoma is usually firm to stony hard, nontender, and enlarged (Fig. 10.119). If the malignant cells have perforated the capsule of the node and invaded into surrounding tissues, then the node will feel "fixed," or not easily movable. **Extranodal extension** (metastatic tumor present within the confines of the lymph node and extending through the capsule into the surrounding connective tissue, with or without an associated stromal reaction) is an adverse prognostic factor for intraoral and lip vermilion carcinomas. This feature is incorporated into the staging classification systems (see next section) for these tumors.

Distant metastasis also may occur—especially to the lungs, liver, and bones. Interestingly, recent studies have noted that post-treatment HPV-positive oropharyngeal carcinomas occasionally metastasize to atypical distant sites (e.g., kidneys, skin, skeletal muscle, axillary lymph nodes).

• **Fig. 10.119 Squamous Cell Carcinoma.** Metastatic deposits within cervical lymph nodes present as firm, painless enlargements as seen in this patient with metastasis to a superior jugular node from a posterior lateral tongue carcinoma.

dentlearn.ir

Metastasis is not an early event for oral cavity carcinomas. However, because of delay in diagnosis, approximately 20%–30% of patients have cervical metastases evident at diagnosis (60% in reports from tertiary care medical centers). In contrast, oropharyngeal tumors are prone to early metastasis, with more than 50% of affected persons exhibiting cervical lymph node metastasis and 10% exhibiting distant metastasis at diagnosis. Furthermore, approximately 10%–40% of oral and oropharyngeal carcinoma patients who present without apparent cervical metastasis subsequently are found to have *occult* (subclinical) nodal disease.

Staging

The *tumor-node-metastasis (TNM) system* is used for **staging**, or describing the extent of cancer in the body. Staging is essential for guiding patient treatment and determining prognosis. The TNM system includes three basic parameters:

1. T—Size of the primary tumor, in centimeters
2. N—Regional lymph node involvement
3. M—Distant metastasis

Clinical staging is based on information obtained from procedures (e.g., physical examination, imaging, incisional biopsy) performed before initial definitive treatment of a cancer, whereas *pathologic staging* can be determined after additional information is obtained from pathologic examination of a surgically resected primary tumor and regional lymph nodes. Tables 10.2–10.7 summarize the tumor-node-metastasis (TNM) staging classification systems and corresponding prognostic stage groups for carcinomas of the oral cavity (including the intraoral lip mucosa), head and neck

TABLE 10.2 Tumor-Node-Metastasis (TNM) Staging Classification for Oral Cavity Carcinoma (Including Lip Mucosa)

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
Tis	Carcinoma *in situ*
T1	Tumor 2 cm or less, with depth of invasion (DOI) no more than 5 mm
T2	Tumor 2 cm or less, with DOI more than 5 mm but no more than 10 mm *or* tumor more than 2 cm but no more than 4 cm, with DOI no more than 10 mm
T3	Tumor more than 2 cm but no more than 4 cm, with DOI more than 10 mm *or* Tumor more than 4 cm, with DOI no more than 10 mm
T4a	Moderately advanced local disease: Tumor more than 4 cm, with DOI more than 10 mm *or* tumor invades adjacent structures only (e.g., through cortical bone of the mandible or maxilla, or involves the maxillary sinus or skin of the face) *Note*: Superficial erosion of bone or tooth socket alone by a gingival primary is not sufficient to classify a tumor as T4.
T4b	Very advanced local disease: Tumor invades masticator space, pterygoid plates, or skull base and/or encases the internal carotid artery
Clinical Regional Lymph Node Involvement (cN)*	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral node 3 cm or less in greatest dimension, and negative extranodal extension (ENE)
N2	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, and negative ENE; *or* metastases in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, and negative ENE; *or* metastases in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension, and negative ENE
N2a	Metastasis in a single ipsilateral node, more than 3 cm but not more than 6 cm in greatest dimension, and negative ENE
N2b	Metastases in multiple ipsilateral nodes, none more than 6 cm in greatest dimension, and negative ENE
N2c	Metastases in bilateral or contralateral nodes, none more than 6 cm in greatest dimension, and negative ENE
N3	Metastasis in a node more than 6 cm in greatest dimension and negative ENE; *or* metastasis in any node(s) and clinically overt ENE
N3a	Metastasis in a node more than 6 cm in greatest dimension and negative ENE
N3b	Metastasis in any node(s) and clinically overt ENE
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

DOI, depth of invasion; ENE, extranodal extension.
**Note:* A designation or "U" or "L" may be used for any N category to indicate metastasis above the lower border cricoid (U) or below the lower border of the cricoid (L).

TABLE 10.3 Tumor-Node-Metastasis (TNM) Staging Classification for Cutaneous Carcinoma of the Head and Neck (Including Lip Vermilion Carcinoma)

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
Tis	Carcinoma *in situ*
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but no more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension *or* Minor bone invasion *or* Perineural invasion* *or* Deep invasion†
T4	Tumor with gross cortical bone/marrow invasion, skull base invasion, and/or skull base foramen invasion
T4a	Tumor with gross cortical bone/marrow invasion
T4b	Tumor with skull base invasion and/or skull base foramen invasion
Clinical Regional Lymph Node Involvement (cN)‡	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral node, 3 cm or less in greatest dimension, and negative ENE
N2	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, and negative ENE; *or* metastases in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, and negative ENE; *or* metastases in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension, and negative ENE
N2a	Metastasis in a single ipsilateral node, more than 3 cm but not more than 6 cm in greatest dimension, and negative ENE
N2b	Metastases in multiple ipsilateral nodes, none more than 6 cm in greatest dimension, and negative ENE
N2c	Metastases in bilateral or contralateral nodes, none more than 6 cm in greatest dimension, and negative ENE
N3	Metastasis in a node more than 6 cm in greatest dimension and negative ENE; *or* metastasis in any node(s) and clinically overt ENE
N3a	Metastasis in a node more than 6 cm in greatest dimension and negative ENE
N3b	Metastasis in any node(s) and clinically overt ENE
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

ENE, extranodal extension.
*Perineural invasion for T3 classification is defined as tumor cells within the nerve sheath of a nerve lying deeper than the dermis or measuring 0.1 mm or larger in caliber, or presenting with clinical or radiographic involvement of named nerves without skull base invasion or transgression.
†Deep invasion is defined as invasion beyond the subcutaneous fat or more than 6 mm as measured from the granular layer of adjacent normal epidermis to the base of the tumor).
‡*Note:* A designation or "U" or "L" may be used for any N category to indicate metastasis above the lower border cricoid (U) or below the lower border of the cricoid (L).
(From Califano JA, Lydiatt WM, Nehal KS, et al: Cutaneous carcinoma of the head and neck. In Amin MB, Edge SB, Greene FL, et al, editors, *AJCC cancer staging manual,* ed 8, Chicago, 2018, American College of Surgeons, pp. 171–181.)

skin (including the lip vermilion), and oropharynx. In general, the higher the stage, the worse the prognosis. In other words, a stage IV lesion is associated with a much worse prognosis than a stage I lesion. Note that different TNM staging classification systems are used for HPV-mediated oropharyngeal carcinoma and non-HPV-mediated oropharyngeal carcinoma (see the "Histopathologic Features" section for a discussion of p16 immunohistochemistry in the determination HPV status, and see the treatment and prognosis section for a discussion of HPV status as a key prognostic factor for oropharyngeal carcinoma). For oral cavity carcinomas, T category is based on primary tumor size as well as *depth of invasion* (as determined microscopically by measuring the distance from the level of the basement membrane of the adjacent normal surface epithelium to the deepest point of tumor invasion).

Summary (or *SEER*) *staging* represents a simplified system frequently used by tumor registries. This staging system uses basic categories (including localized, regional, and distant) to describe tumor spread. Table 10.8 provides survival rates by SEER stage for patients with oral cavity and pharyngeal cancer in the United States.

Histopathologic Features

Squamous cell carcinoma typically arises from dysplastic surface epithelium and is characterized histopathologically by invasive islands and cords of malignant squamous epithelial cells. At the earliest moment of invasion, the adjectives *superficially invasive* or *microinvasive* often are used. The features of epithelial dysplasia are discussed in more detail in the section on leukoplakia (see page 381).

Invasion is represented by irregular extension of lesional epithelium through the basement membrane and into subepithelial connective tissue. Individual squamous cells and sheets or islands of cells proliferate within the connective tissue, without attachment to the surface epithelium. The invading tumor destroys normal tissue and may extend deeply into underlying adipose tissue, muscle, or bone. Lesional cells may breach the perineurium that encases nerve bundles **(perineural invasion)** or may invade the lumina of veins or

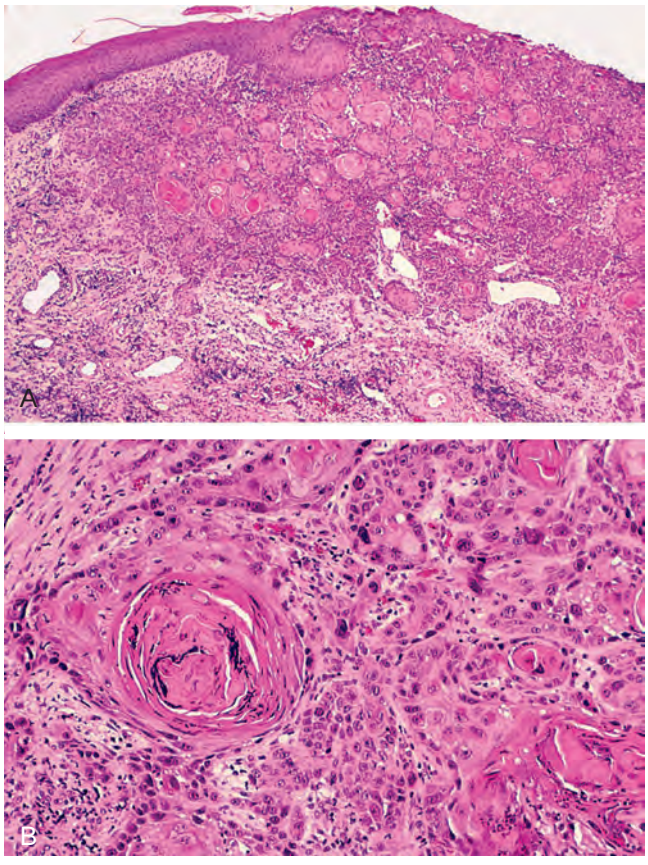
†Survival of oropharyngeal carcinoma is related to HPV status of the tumor. Some centers have reported overall 5-year survival rates of 54%–89% for HPV(+) oropharyngeal carcinomas and 33%–65% for HPV(−) tumors.

dentlearn.ir



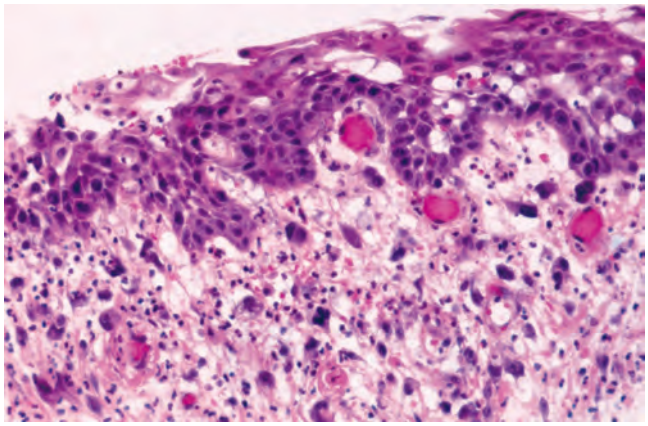
• **Fig. 10.120 Squamous Cell Carcinoma. A,** Perineural invasion. Tumor has breached the perineurium encasing this nerve fiber. **B,** Angioinvasion. Tumor is present within the lumen of this vessel.

lymphatics **(vascular invasion)** (Fig. 10.120). There is often a strong inflammatory or immune cell response to invading epithelium, and necrosis may be present. The tumor may induce dense fibrosis **(desmoplasia** or **scirrhous change)** and the formation of new blood vessels **(angiogenesis).**

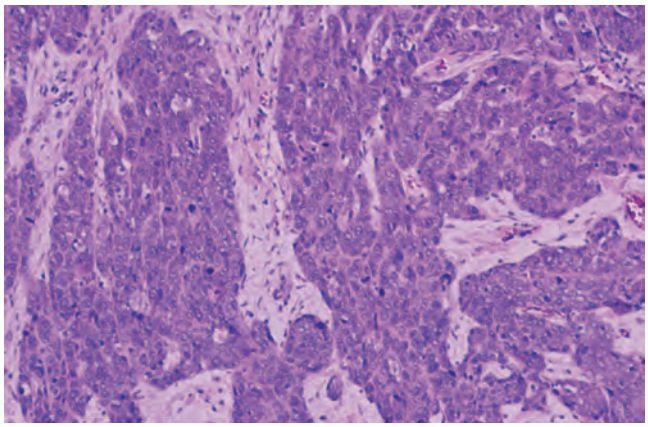
The lesional cells generally show abundant eosinophilic cytoplasm with large, often darkly staining **(hyperchromatic)** nuclei and an increased nuclear-to-cytoplasmic ratio. Varying degrees of cellular and nuclear pleomorphism are seen. The normal product of squamous epithelium is keratin, and **keratin pearls** (a round focus of concentrically layered, keratinized cells) may be produced within lesional epithelium. Individual cells also may undergo keratinization.

HPV-positive squamous cell carcinomas of the oropharynx are rather distinctive in that they tend to arise from a specialized type of epithelium ("reticulated epithelium") lining the tonsillar crypts. Such tumors are not associated with dysplasia or keratosis of the surface epithelium, and there is often an abrupt transition between the adjacent surface epithelium and the endophytic tumor arising from the crypts. Features indicative of premalignancy in the reticulated epithelium are not well-defined. Reminiscent of the reticulated epithelium from which they usually arise, HPV-positive oropharyngeal squamous cell carcinomas tend to be nonkeratinizing with basaloid cytologic features. Koilocytes generally are not evident. The invasive tumor islands and nests often are surrounded by lymphoid cells, and infiltration of tumor by lymphocytes is a variable finding. Prominent stromal desmoplasia tends to be lacking. Cystic degeneration may be evident in the primary tumor and is a common feature in cervical lymph node metastases. Similar features may be seen in HPV-positive tumors involving non-oropharyngeal head and neck sites (such as the oral cavity, larynx, and hypopharynx). Infrequent microscopic variants among this HPV-positive non-oropharyngeal subset include exophytic warty and conventional keratinizing types.

Histopathologic **grading** of squamous cell carcinoma is based upon the degree of resemblance to normal squamous epithelium and the amount of keratin production. Lesions typically are graded on a three-point (grades I–III) scale. The less differentiated tumors receive the higher numerals. The histopathologic grade of a tumor is related somewhat to its biologic behavior. In other words, a tumor that is mature enough to closely resemble its tissue of origin often grows at a slightly slower pace and metastasizes later in its course. Such a tumor is called *low-grade, grade I,* or *well-differentiated* (Fig. 10.121). In contrast, a tumor with marked pleomorphism and little or no keratin production may be so immature that it becomes difficult to identify



• **Fig. 10.121 Well-differentiated Squamous Cell Carcinoma. A,** Low-power photomicrograph showing islands of malignant squamous epithelium invading into the lamina propria. **B,** High-power view showing dysplastic epithelial cells with keratin pearl formation.



dentlearn.ir

the tissue of origin. In such cases, immunohistochemical studies (e.g., for cytokeratins, p63, p40) may be needed to support an epithelial origin. Such tumors often enlarge rapidly, metastasize early, and are termed *high-grade, grade III/IV, poorly differentiated,* or *anaplastic* (Fig. 10.122). A tumor with a microscopic appearance somewhere between these two extremes is called *moderately differentiated* (Fig. 10.123). Histopathologic grading is performed for conventional oral cavity squamous cell carcinomas and for HPV-negative oropharyngeal squamous cell carcinomas but not for tumor variants that have an intrinsic biologic potential (e.g., HPV-positive oropharyngeal squamous cell carcinoma, verrucous carcinoma, spindle cell carcinoma, adenosquamous carcinoma, basaloid squamous carcinoma).

Grading is a somewhat subjective process, depending on the area of the tumor sampled and the individual pathologist's criteria for evaluation. Moreover, clinical staging correlates much better with the prognosis than microscopic grading. In the past, investigators have proposed various multi-parameter histopathologic assessment systems in an attempt to provide more objective criteria that correlate with prognosis. Variables such as pattern of invasion, tumor thickness, degree of keratinization, nuclear pleomorphism, lymphocytic response, and mitotic rate have been included in such grading systems. However, widespread agreement regarding the use of such methods is lacking.

• **Fig. 10.122 Poorly Differentiated Squamous Cell Carcinoma.** The numerous pleomorphic cells within the lamina propria represent anaplastic carcinoma.

• **Fig. 10.123 Moderately Differentiated Squamous Cell Carcinoma.** Although no keratinization is seen in this medium-power view, these malignant cells are still easily recognizable as being of squamous epithelial origin.

For oropharyngeal squamous cell carcinoma, HPV status is especially important in determining prognosis, and distinct staging systems have been developed for HPV-positive vs HPV-negative disease. HPV-positive oropharyngeal squamous cell carcinomas tend to metastasize to cervical lymph nodes relatively early during the course of disease. Nevertheless, HPV-positive cases tend to have better treatment outcomes compared to HPV-negative cases.

For newly diagnosed oropharyngeal squamous cell carcinomas, HPV status typically is assessed by using immunohistochemical expression of p16 as a surrogate marker for transcriptionally active, high-risk HPV infection (see Fig. 10.116B). (The molecular basis for this finding is that overexpression of p16 results from destabilization of the tumor suppressor pRB [retinoblastoma protein] by the HPV oncoprotein E7.) A positive result is defined as at least 70% nuclear and cytoplasmic expression of p16 with moderate to strong intensity. Also, in the case of a cervical lymph node with metastatic squamous cell carcinoma of unknown origin, p16 immunoreactivity may be useful in directing the search for the primary tumor to the oropharynx. The advantages of p16 immunohistochemistry include its cost effectiveness, wide availability, and ease of use on formalin-fixed paraffin-embedded tissue. Other types of HPV testing (e.g., DNA or RNA *in situ* hybridization [ISH] [see Fig. 10.116C], E6/E7 mRNA reverse transcriptase polymerase chain reaction [RT-PCR]) are generally more costly and not so widely available but may be performed in certain cases. For example, some authorities recommend second-line ISH for confirmation of HPV status in p16-positive cases. This recommendation is based on recent studies in which 8%–33% of oropharyngeal squamous cell carcinomas examined were found to be p16-positive yet HPV DNA-negative. Patients within this subset exhibit a worse prognosis than those with p16-positive/HPV DNA-positive disease.

In contrast to oropharyngeal squamous cell carcinomas, p16 immunohistochemistry performed on oral cavity squamous cell carcinomas exhibits low positive predictive value for transcriptionally active HPV infection and is not useful for prognostication. Furthermore, there is only limited data regarding high-risk HPV E6 and E7 expression in oral cavity squamous cell carcinoma, with no significant correlation with prognosis demonstrated thus far. Overall, routine p16 immunohistochemistry or HPV-specific testing is not recommended for non-oropharyngeal head and neck squamous cell carcinomas because of a lack of current evidence to support the prognostic significance of such findings.

Treatment and Prognosis

Clinical staging guides the treatment of squamous cell carcinoma. Most lip vermilion carcinomas are detected at an early stage and treated by surgical excision with excellent results. Surgery may be performed by conventional excision or Mohs

dentlearn.ir

micrographic surgery. More advanced cases may be treated by definitive radiation therapy or surgery combined with radiation or chemoradiation therapy. At diagnosis, less than 10% of all lip vermilion carcinomas have metastasized; therefore, neck dissection seldom is indicated. However, a notable exception is squamous cell carcinoma of the upper lip vermilion, which exhibits a high risk for regional lymph node metastasis (apparently related to the extensive lymphatic network in this location). Fortunately, squamous cell carcinoma only rarely occurs in the upper lip vermilion. Interestingly, recent studies also suggest that squamous cell carcinomas involving the lip vermilion exhibit a greater risk for metastasis compared to those limited to the skin adjacent to the lip vermilion.

For intraoral squamous cell carcinoma, early-stage lesions usually are treated with surgery; definitive radiation therapy may be an alternative for patients unable to tolerate surgery. Treatment options for patients with moderately advanced disease include surgery and clinical trials; after surgery, *adjuvant* treatment with radiation or combined radiation and systemic therapy may be considered. Adverse features that may indicate the need for adjuvant therapy include close or positive resection margins, extranodal extension, pathologic T3 or T4 primary, pathologic N2 or N3 nodal disease, nodal disease in levels IV or V of the neck, perineural invasion, and lymphovascular invasion. For individuals with very advanced disease, treatment options include clinical trials, radiation therapy, systemic therapy, *induction* (initial) systemic therapy followed by radiation or combined radiation and additional systemic therapy, supportive care, and palliative treatment.

In patients with intraoral carcinoma, cervical lymph node involvement is evident at presentation in approximately 30% of cases. In addition, approximately 10%–40% of patients initially presenting without apparent cervical metastasis subsequently are found to have occult nodal disease. However, the risk for regional metastasis varies considerably by subsite. In the past, **radical neck dissection** (*en bloc* removal of the lymphatics of the lateral triangle of the neck along with associated nonlymphatic structures, including the internal jugular vein, submandibular gland, sternocleidomastoid muscle, and spinal accessory nerve) was standard treatment for clinically evident or suspected cervical lymph node metastasis. However, over the past several decades, **modified radical neck dissection** (similar to radical neck dissection but with preservation of nonlymphatic structures) and **selective neck dissection** (removal of only select cervical lymph node groups) have gained favor; these techniques are associated with decreased morbidity and, depending upon the extent of disease, often allow for disease control comparable to that of classical radical neck dissection. Histopathologic findings (e.g., number and size of positive nodes, extranodal extension) in a selective neck dissection may aid in determining the need for postoperative radiation with or without systemic therapy. A current preference among some authorities is to classify cervical lymph node dissections as either *comprehensive* (including all lymph node groups of a classical radical neck dissection regardless of whether or not nonlymphatic structures are preserved) or *selective*. Another technique, **sentinel-node biopsy** (biopsy of the first lymph node in the lymphatic basin to receive drainage from the tumor), may be useful for identifying patients with occult neck metastasis. Also, microscopic measurement of primary tumor *depth of invasion* is predictive of occult cervical lymph node metastasis and may be considered when determining the need for *elective* selective neck dissection.

With regard to radiotherapy, *intensity-modulated radiation therapy (IMRT)* represents a technique used to target the treatment area while minimizing damage to neighboring tissue. Also, *brachytherapy* (placement of tiny, radioactive seeds) may be performed at experienced treatment centers for select applications (e.g., large superficial intraoral or lip tumors for which surgical removal would cause significant functional or cosmetic morbidity).

Systemic agents for the management of intraoral, oropharyngeal, and other head and neck squamous cell carcinomas include the following: (1) chemotherapy drugs, including platinum-containing compounds (e.g., cisplatin and carboplatin), 5-fluorouracil, and taxanes (e.g., paclitaxel and docetaxel); (2) targeted agents, including cetuximab (monoclonal antibody directed against epidermal growth factor receptor [EGFR]) and tipifarnib (farnesyltransferase inhibitor recently granted breakthrough therapy designation by the United States Food and Drug Administration for patients with recurrent or metastatic, *HRAS*-mutant tumors); and (3) immune checkpoint inhibitors (e.g., pembrolizumab, nivolumab) (at times considered for patients with recurrent, unresectable, or metastatic disease). In particular, cisplatin is the first-line agent for patients receiving adjuvant (postoperative) chemoradiation therapy for the management of head and neck mucosal squamous cell carcinomas (other than those involving the nasopharynx).

Induction or *neoadjuvant* chemotherapy may be administered initially to shrink a tumor prior to additional therapy. For locoregionally advanced head and neck cancers, some investigators have advocated this approach for enhanced organ preservation, reduced need for adjuvant radiation therapy, and decreased risk for distant metastasis. However, studies suggest that this approach may not result in a significant improvement in overall patient survival or disease control.

For oropharyngeal squamous cell carcinoma, treatment options generally include surgery or definitive radiation therapy for early-stage disease, combined-modality therapy for more advanced disease, and clinical trials. Notably, advances in minimally invasive surgical techniques—such as transoral robotic surgery (TORS) and transoral laser microsurgery (TLMS)—have allowed for reduced morbidity compared to conventional open surgery while still producing favorable outcomes in patients with early-stage disease. TORS or TLMS may be followed by adjuvant radiation therapy or combined radiation and systemic therapy. For patients with HPV-positive oropharyngeal squamous cell carcinoma, areas of interest among clinical trials include deintensified radiation or chemoradiation therapy protocols (aiming to reduce treatment-associated morbidity while maintaining acceptable survival rates) and therapeutic HPV vaccines (such as those targeting HPV 16 E6 and/or E7).

After head and neck cancer treatment, patients should be placed under surveillance to monitor for tumor recurrence or

dentlearn.ir

additional primary tumor development. As many as two-thirds of patients with head and neck squamous cell carcinoma develop recurrence, with most instances presenting within the first 2 years after completion of initial treatment. In addition to clinical examination and imaging, follow-up visits may include nutritional counseling, tobacco and alcohol counseling, speech/swallowing rehabilitation, and dental health assessment. Reevaluation typically is performed every few months (or sooner if needed) during the first 5 years, and at least yearly thereafter.

Based on SEER data in the United States for 2011–2017, the estimated 5-year relative survival rate for oral cavity and pharyngeal cancers combined is approximately 67%. Notably, there is a disparity in the 5-year survival rate for white compared to black patients (69% vs 51%, respectively); in part this finding may reflect a white male predilection for HPV-positive oropharyngeal carcinoma, which tends to exhibit more favorable outcomes compared to HPV-negative disease.

The prognosis varies considerably by tumor stage and subsite (Table 10.8). Because most lip vermilion carcinomas are diagnosed at an early stage, the overall 5-year relative survival rate is excellent (approximately 91%). In contrast, intraoral and oropharyngeal carcinomas often are diagnosed at later stages, with significantly lower 5-year relative survival rates (e.g., 52% for floor of mouth lesions and 71% for oropharyngeal lesions).

For oropharyngeal carcinoma, HPV-positive tumor status is a key favorable prognostic factor. Compared to patients with HPV-negative tumors, those with HPV-positive tumors typically exhibit a better response to chemotherapy and/or radiation therapy, with an approximately 60% reduction in risk of death and 30% greater 5-year absolute survival rate. (However, as the average age of HPV-positive group has been increasing, there has been a gradual uptick in mortality within the past decade.) The favorable survival rate for patients with HPV-positive oropharyngeal squamous cell carcinoma may reflect a unique underlying tumor biology, including an intact p53-mediated apoptotic response to radiation, upregulation of DNA repair proteins, a tendency for fewer genomic alterations, a distinctive immune microenvironment, and a lack of field cancerization (see next section). Unlike oropharyngeal squamous cell carcinoma, oral cavity squamous cell carcinoma does not exhibit a clear correlation between HPV tumor status and prognosis.

Current investigations aim to stratify head and neck cancer patients into subgroups based on HPV status, anatomic subsite, gene expression profiling, and cluster analysis for tailored treatment determination and improved prognostication. Studies evaluating the prognostic utility of individual molecular markers (e.g., p53, survivin) abound but lack sufficient evidence for routine clinical application.

Based on SEER data in the United States for 2015–2019, the 5-year age-adjusted mortality rate for oral cavity and pharyngeal cancers combined was 2.5 per 100,000 population. This finding represents a marked improvement over the age-adjusted mortality rate of 4.3 per 100,000 population in 1975. However, mortality increased by 0.4% per year from 2010 to 2019 apparently because of an uptick in deaths from HPV-related tumors. Notably, there was a 2.1% annual increase in incidence-based oropharyngeal cancer mortality among males compared to a 1.2% annual decrease among females from 2006 to 2017 according to data from the National Center for Health Statistics and the SEER Program. This growing trend in male mortality appears to reflect increased numbers of men diagnosed with oropharyngeal cancer in advanced stages of disease and in older age groups. Presumably, elderly individuals may have significant co-morbidities complicating treatment.

Current areas of investigational interest for addressing oral and pharyngeal cancer mortality include improvements in prevention, early diagnosis, and treatment. In particular, recent oropharyngeal cancer prevention efforts have focused on HPV vaccination. In the United States in 2020, the Food and Drug Administration granted accelerated approval for adding prevention of oropharyngeal and other head and neck cancers as an indication for the recombinant 9-valent HPV vaccine. Postapproval confirmatory studies are in process as of this writing. Unfortunately, immunization rates have been relatively low, with only 59% of US adolescents 13–17 years of age receiving the recommended doses of the vaccine in 2020. Notably, more than half of oropharyngeal cancer cases diagnosed in the US from 2001 to 2017 occurred in the Southeast and Midwest, where many states have some of the lowest HPV vaccination rates in the country. Nevertheless, some US studies have reported encouraging observations, including recent declines in absolute oropharyngeal cancer incidence among young white males and recent reductions in the number of vaccine-type oral HPV infections.

Secondary prevention of HPV-mediated oropharyngeal cancer through screening is complicated by the lack of a well-defined premalignant lesion in the tonsillar region. Investigational oropharyngeal cancer screening methods designed for certain patient groups include oral rinse/gargle testing for high-risk HPV DNA and blood-based assays for HPV-16 DNA or antibodies. Nothwithstanding, further research is needed to demonstrate the clinical utility of such screening tests, and FDA approval has not been granted. In addition, some researchers have proposed risk prediction models for oropharyngeal or other head and neck cancers based on various parameters, such as age, sex, race, smoking, alcohol use, education, number of lifetime sexual partners, and high-risk HPV status. However, further studies are needed.

Multiple Carcinomas

Patients with one carcinoma of the oral cavity, oropharynx, or other head and neck mucosa are at increased risk for developing additional concurrent (synchronous) or, more commonly, later (metachronous) primary carcinomas of the head and neck mucosa, lungs, and esophagus. Indeed, about a third of head and neck squamous cell carcinoma patient deaths are attributed to second primary malignancies. According to a pooled analysis of data from 13 cancer registries, approximately 3%–7% of head and neck squamous cell carcinoma patients per year develop an additional primary malignancy, with a 20-year cumulative risk of 36%. Other

dentlearn.ir

studies have estimated the annual risk to be in the range of 2%–3%. In addition, analyses of SEER data for head and neck squamous cell carcinoma patients in the United States have shown that the risk for a second primary malignancy is greater for those with index tumors arising in non-oropharyngeal sites (which are mostly non-HPV-mediated) compared to those arising in the oropharynx (which are predominantly HPV-mediated).

This tendency for the development of multiple mucosal cancers is hypothesized to result from *field cancerization*—a process whereby exposure to carcinogens, such as tobacco and alcohol, creates a diffuse field of altered epithelial cells with increased potential for malignant transformation. Molecular analyses of various markers, including loss of heterozygosity (LOH), microsatellite alterations, *TP53* tumor suppressor gene mutations, and X-chromosome inactivation, have identified genetic alterations shared between tumor tissue and adjacent clinically normal-appearing tissue in one-third to one-half of cases examined. In addition, investigators have shown that a significant proportion of second primary tumors develop from the same preneoplastic precursor lesion or "field," with the remaining cases representing tumors that develop independently. Furthermore, researchers have proposed that patches of clonal cells can progress to develop additional mutations and give rise to subclones in a process known as *clonal divergence,* which would account for the genetic heterogeneity typically seen among these tumors. Interactions between mutant clones and the microenvironment appear to play an important role in field cancerization and carcinogenesis as well.

Interestingly, malignancies attributed to HPV infection do not appear to be associated with field cancerization. Nevertheless, there are emerging reports of patients with HPV-mediated head and neck squamous cell carcinoma who have developed additional primary tumors. A recent analysis combining a systematic review of the literature, SEER data, and institutional reports found that multiple tumors were present in approximately 0.5%–2.5% of individuals with HPV-mediated head and neck squamous cell carcinoma. In particular, this subset of individuals often exhibited small, synchronous, bilateral tonsillar tumors. The mechanism underlying this phenomenon is unknown, although proposed theories include the following: (1) intra-host spread of HPV infection via a lymphatic, hematogenous, or salivary route, (2) infection of different anatomic locations by different HPV strains, (3) infection of different anatomic locations by the same HPV strain upon initial or subsequent exposure, and (4) lymphatic intraoropharyngeal metastasis of tumor cells.

◆ VERRUCOUS CARCINOMA (SNUFF DIPPER'S CANCER; ACKERMAN'S TUMOR)

Verrucous carcinoma is a low-grade variant of oral squamous cell carcinoma. In 1948, Ackerman described this lesion in detail, although the term *verrucous carcinoma* had been used in 1944 in a series of cases reported by Burford, Ackerman, and Robinson. Ackerman postulated that some of these lesions might be associated with smokeless tobacco use, because 11 of his 31 patients were "tobacco chewers." However, there was no mention of the type of smokeless tobacco used and no mention of whether any of these patients also had smoked tobacco. In addition to the oral mucosa, verrucous carcinoma has been identified at several extraoral sites, including laryngeal, vulvovaginal, penile, anorectal, sinonasal, and esophageal mucosa, as well as the skin of the breast, axilla, ear canal, and soles of the feet. Extraoral cases are unrelated to tobacco use. Several investigators have identified DNA from HPV types 6, 11, 16, and 18 in a minority of oral verrucous carcinomas, although the possibility that these cases represent coincidental HPV infection cannot be excluded.

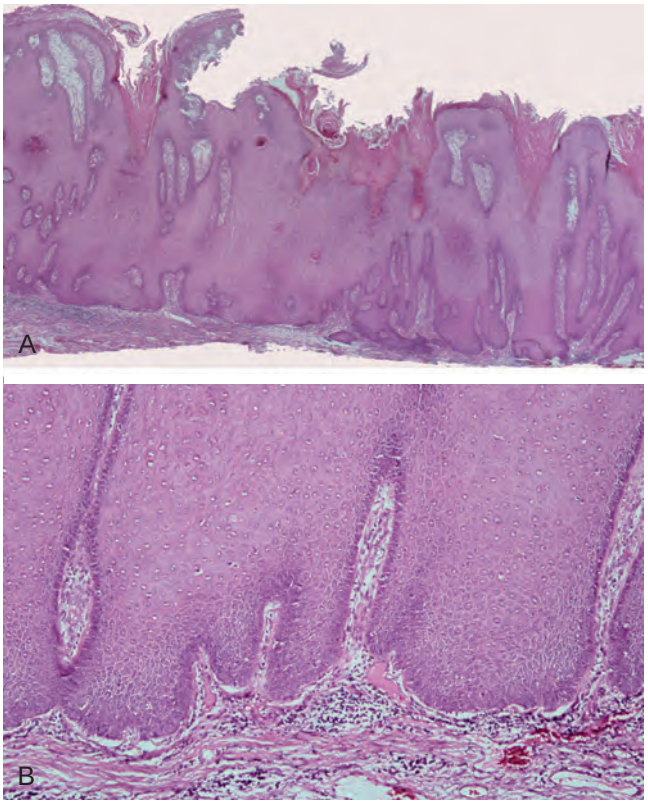
Verrucous carcinoma represents less than 1%–16% of all oral squamous cell carcinomas, depending on the local popularity of smokeless tobacco use. The only epidemiologic assessment of this tumor in a Western culture reported an average annual incidence rate of one to three oral lesions per 1 million population each year. Among head and neck malignancies recorded in the SEER database from 1973 to 2015, only 0.5% of cases were diagnosed as verrucous carcinoma.

Some oral verrucous carcinomas arise in people who chronically use chewing tobacco, snuff, or betel quid. Cases also occur in those who combine habits (i.e., smokeless tobacco, smoking, and alcohol), exclusively smoke tobacco, or have no identifiable risk factors. However, exact figures are difficult to assess because patients often deny their habits. Nevertheless, among smokeless tobacco users, conventional squamous cell carcinoma is much more likely to develop than this low-grade variant.

Clinical Features

Verrucous carcinoma is found predominantly in older individuals (approximate average age: 65–70 years). Most studies report a male predilection or a nearly even gender distribution; however, in areas where women frequently use dry snuff, females may predominate. The most common sites of oral mucosal involvement include the mandibular vestibule, buccal mucosa, gingiva, tongue, and hard palate. The involved area often corresponds to the site of chronic tobacco placement. In cultural groups who keep the tobacco in the maxillary vestibule or under the tongue, these locations are involved most commonly.

Oral verrucous carcinoma is usually extensive by the time of diagnosis, and it is not unusual for a tumor to be present for 2–3 years before definitive diagnosis. The lesion appears as a diffuse, well-demarcated, painless, thick plaque with papillary or verruciform surface projections (Figs. 10.124 and 10.125). Lesions are typically white but also may appear erythematous or pink. The color depends on the amount of keratin produced and the degree of host inflammatory response to the tumor. When left untreated, the lesions may destroy underlying structures, such as bone, cartilage, muscle, and salivary glands. Enlarged cervical lymph nodes in patients with verrucous carcinoma usually represent inflammatory reactive changes rather than nodal metastasis.



dentlearn.ir

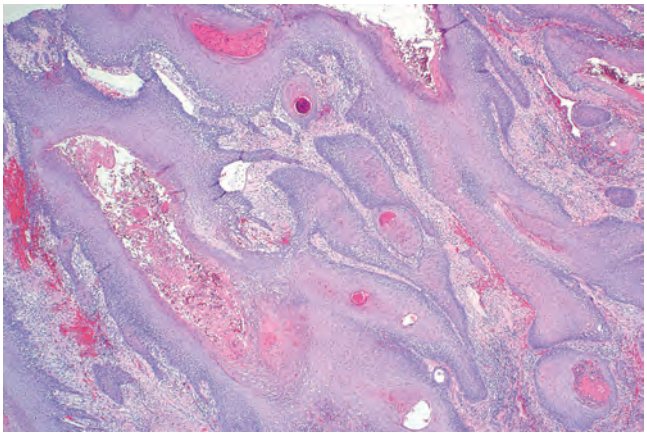
• **Fig. 10.125 Verrucous Carcinoma.** Large, exophytic, papillary mass of the maxillary alveolar ridge.

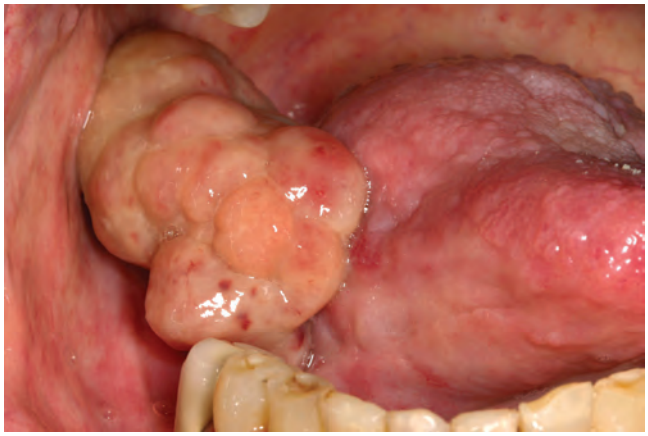
• **Fig. 10.126 Verrucous Carcinoma. A,** Low-power photomicrograph showing marked epithelial hyperplasia with a rough, papillary surface, and keratin plugging. **B,** High-power view showing bulbous rete ridges without significant dysplasia.

Leukoplakia or **tobacco pouch keratosis** may be seen on adjacent mucosal surfaces, and verrucous carcinoma is a lesion that may develop from the high-risk precancer, proliferative verrucous leukoplakia (PVL) (see page 384). PVL and verrucous carcinoma may have been reported in the past by the name **oral florid papillomatosis.**



Histopathologic Features

Verrucous carcinoma has a deceptively benign microscopic appearance; it is characterized by wide and elongated rete ridges that appear to "push" into the underlying connective tissue (Fig. 10.126). Lesions usually show abundant keratin (usually parakeratin) production and a papillary or verruciform surface. Parakeratin typically fills the depressions **(parakeratin clefts)** between the surface projections. These projections may be long and pointed or short and blunted. The lesional epithelial cells generally show no significant cytologic atypia. There is frequently an intense inflammatory cell infiltrate in the subjacent connective tissue. Sometimes this infiltrate exhibits "lichenoid" features (i.e., a superficial bandlike chronic inflammatory cell infiltrate).



The histopathologic diagnosis of verrucous carcinoma requires an adequate incisional biopsy. Because the individual cells are not very dysplastic, the pathologist must evaluate the overall histomorphologic configuration of the lesion to make the diagnosis. Adequate sampling also is important because conventional squamous cell carcinoma develops concurrently within up to 20% of verrucous carcinomas.

The microscopic differential diagnosis may include *carcinoma cuniculatum*—another well-differentiated variant of squamous cell carcinoma lacking significant cytologic atypia. This variant is characterized by deeply infiltrative tumor islands with branching, keratin-filled crypts resembling "rabbit burrows" and an often brisk inflammatory infiltrate (Fig. 10.127). This complex, infiltrative growth pattern differs from the broad, "pushing" rete seen in verrucous carcinoma. In carcinoma cuniculatum, the endophytic component predominates, and the surface is mildly exophytic with a subtle, papillary, or cobblestone-like architecture. In contrast, verrucous carcinoma exhibits a more prominent and warty exophytic component. Furthermore, some examples of carcinoma cuniculatum exhibit frank infiltration of bone to produce a "moth-eaten" lytic lesion on radiographs, whereas verrucous carcinoma typically causes no bony destruction or, at most, pressure resorption of the underlying bone. Both variants generally exhibit a favorable prognosis.

dentlearn.ir

• **Fig. 10.128 Spindle Cell Carcinoma.** Large polypoid mass arising from the right lateral tongue.

Treatment and Prognosis

The treatment of choice is surgical excision. The surgery generally need not be as extensive as that required for conventional squamous cell carcinoma of a similar size. If cervical lymph node enlargement is clinically evident, then a selective neck dissection may be performed, although most such cases turn out to represent reactive lymphadenopathy rather than metastasis. Approximately 90% of patients are disease free 5 years after surgery, but some patients will require at least one additional surgical procedure during that time. The treatment failures usually occur in patients with the most extensive involvement or in those unable to tolerate extensive surgery because of unrelated systemic diseases. An additional cause of treatment failure is the initial inability to identify focal, concurrent conventional squamous cell carcinoma; such cases should be treated as conventional squamous cell carcinomas.

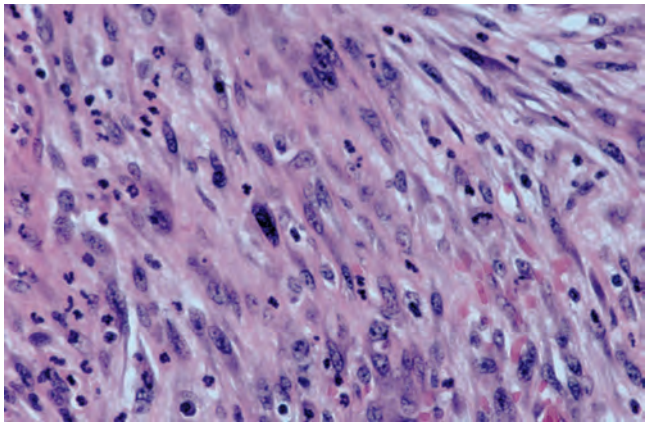
Radiotherapy is an alternative primary treatment modality but provides poorer local control and, thus, is considered less effective than surgery. In addition, radiotherapy has been unpopular because of published reports of poorly differentiated or anaplastic carcinoma developing within the lesion after treatment. However, more recent analysis suggests that this threat is overexaggerated. In a limited number of cases, tumor regression after chemotherapy, radiochemotherapy, or photodynamic therapy has been reported, although these treatment alternatives require further study.

◆ SPINDLE CELL CARCINOMA (SARCOMATOID SQUAMOUS CELL CARCINOMA; POLYPOID SQUAMOUS CELL CARCINOMA; CARCINOSARCOMA; PSEUDOSARCOMA)

Spindle cell carcinoma is a rare variant of squamous cell carcinoma characterized by dysplastic surface epithelium in conjunction with an invasive spindle cell element. With routine light microscopy, it may be indistinguishable from connective tissue sarcomas or other spindle cell malignancies. Spindle cell carcinoma of the upper aerodigestive tract is closely associated with tobacco and alcohol use. Some cases develop after radiotherapy for a more differentiated squamous cell carcinoma, a phenomenon known as **dedifferentiation.** Transcriptionally active HPV has been detected infrequently in this variant.

In the past, this biphasic lesion was thought to be a "collision" tumor between a carcinoma and sarcoma; however, current evidence supports a monoclonal origin for both tumor components. Electron microscopy, immunohistochemical analysis, and molecular genetic studies suggest that the lesional cells undergo a shift from a squamous epithelial to a mesenchymal-like phenotype (*epithelial-mesenchymal transition*), with decreased intercellular adhesion and increased infiltrative behavior.

Clinical Features



Spindle cell carcinoma tends to arise in older individuals and affects males more often than females. The lesion may develop anywhere within the upper aerodigestive tract, with a predilection for the larynx and oral cavity. In the mouth, the tongue, alveolar mucosa, oral floor, and lower lip are common sites, but other areas may be involved.

In contrast to other oral cancers, spindle cell carcinoma typically appears as a pedunculated, polypoid mass, but occasionally it may appear as a sessile, nodular, or fungating mass (Fig. 10.128). The surface often is ulcerated. Pain and paresthesia are prominent features. Lower lip lesions seem to have a special propensity to travel along nerves through the mental foramen and into the mandibular canal.

Histopathologic Features

Spindle cell carcinoma is composed predominantly of fascicles of anaplastic, spindle-shaped cells (Fig. 10.129). Some spindle cells may appear as obvious epithelial elements, but others strongly resemble atypical mesenchymal cells.

dentlearn.ir

• **Fig. 10.129 Spindle Cell Carcinoma.** Streaming fascicles of pleomorphic spindle cells that represent anaplastic epithelial cells.

On rare occasions, bone, cartilage, or muscle differentiation may be seen. Numerous mitotic figures often are present. The overall picture is similar to that of an anaplastic fibrosarcoma (see page 559), except for the often-inconspicuous squamous element.

The squamous component usually consists of dysplasia or carcinoma *in situ* of the overlying surface epithelium but may appear as islands of atypical squamous epithelium among the spindle cells. Direct transition between the two cell types may be seen. Because of frequent surface ulceration, a neoplastic surface component may be difficult to discern. Tumors with a prominent inflammatory background may mimic granulation tissue. Metastatic lesions may show only spindle cells, only squamous cells, or a combination of spindle and squamous cells.

Serial sections may be needed to find areas of unequivocal squamous cell carcinoma, and immunohistochemical techniques can be particularly useful in distinguishing this tumor from mesenchymal spindle cell malignancies. Most mesenchymal tumors express vimentin but not epithelial markers. In contrast, most spindle cell carcinomas react with antibodies directed against at least one epithelial marker (such as cytokeratins, p63 with or without p40, and/or epithelial membrane antigen [EMA]). Nearly all cases express vimentin; immunoreactivity for other mesenchymal markers is possible but highly variable.

Treatment and Prognosis

The mainstay of treatment for oral spindle cell carcinoma is radical surgery, with neck dissection when clinically positive nodes are present. The benefit of radiotherapy and/or chemotherapy is unclear. However, adjuvant radiation therapy may be administered for patients with nodal metastasis or surgical margins positive for tumor. According to SEER data in the United States for 2004 through 2009, the 3-year disease-specific survival rate is approximately 50% for oral lesions; however, other studies have reported survival rates as low as 24%. Negative prognostic factors include endophytic (rather than polypoid) growth and an origin from a previously irradiated carcinoma. Compared to conventional squamous cell carcinoma, spindle cell carcinoma appears to have a worse prognosis among oral cavity tumors but a more favorable prognosis among laryngeal tumors. The more favorable prognosis for laryngeal cases may reflect early detection due to symptoms from polypoid glottic lesions.

◆ ADENOSQUAMOUS CARCINOMA

Adenosquamous carcinoma is a rare squamous cell carcinoma variant that is characterized histopathologically by a combination of adenocarcinoma and squamous cell carcinoma. In the head and neck, this variant most often occurs in the larynx. The oral cavity, sinonasal tract, oropharynx, hypopharynx, and other subsites may be affected as well. This lesion generally is considered to represent a distinct clinicopathologic entity, although in the past some authorities considered it to be merely a high-grade **mucoepidermoid carcinoma** (see page 493). The histogenesis is not entirely certain. An origin from excretory ducts of minor glands, surface squamous epithelium, or both has been proposed. Tobacco and alcohol use have been implicated as causative factors. In addition, transcriptionally active HPV has been identified in a few cases involving the oropharynx and nasal cavity.

Clinical Features

Adenosquamous carcinoma exhibits a male predilection and usually occurs in older adults. In the oral cavity, the tumor may involve the tongue, floor of mouth, and other mucosal surfaces. The tumor typically presents as a nodular, broad-based, variably painful mass with or without ulceration. The majority of patients have cervical lymph node metastasis at diagnosis.

Histopathologic Features

Adenosquamous carcinoma appears as an admixture of a surface squamous cell carcinoma and an underlying adenocarcinoma. The glandular component tends to be most prominent in deeper portions of the tumor. Mucicarmine or Alcian blue staining demonstrates intracytoplasmic mucin in most cases, making differentiation from mucoepidermoid carcinoma difficult. However, features that may aid in distinction from mucoepidermoid carcinoma include the following: presence of dysplasia or carcinoma *in situ* in the surface epithelium, frank squamous differentiation (such as keratin pearl formation and intercellular bridges), and discrete adenocarcinomatous foci mainly found in deeper portions of the tumor. In addition, *MAML2* translocations may be detected in mucoepidermoid carcinoma but have not been noted in adenosquamous carcinoma. Squamous cell carcinoma with acantholysis or pseudoglandular degeneration also may be considered in the differential diagnosis but lacks intracytoplasmic mucin production and usually

dentlearn.ir

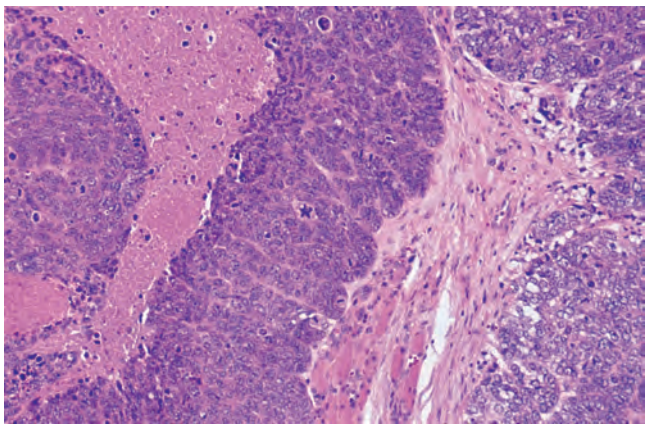
forms gland-like structures with irregular, rather than smooth and rounded, contours.

Both squamous and glandular components immunoreact with antibodies directed against high molecular–weight cytokeratins. In addition, the squamous component may express p63, whereas the glandular component may express CK7, CAM 5.2, and CEA. There is typically no immunoreactivity for CK20.

Treatment and Prognosis

Adenosquamous carcinoma typically is treated with radical surgical excision, at times supplemented with radiation or chemoradiation therapy. One review of previously reported head and neck cases noted local recurrence in 36%, regional metastasis in 47%, and distant metastasis in 25%; among cases for which outcomes were reported, 44% of patients died of disease. According to SEER data in the United States from 1973 through 2012, 5-year overall and disease-specific survival rates are 30% and 50%, respectively. Adenosquamous carcinoma generally has been considered to represent an aggressive variant of squamous cell carcinoma. However, after controlling for variables such as anatomic subsite, patient demographics, stage, treatment, and/or HPV status, a few studies suggest that outcomes for patients with adenosquamous carcinoma may not be substantially different from those for patients with conventional squamous cell carcinoma.

◆ BASALOID SQUAMOUS CARCINOMA (BASALOID SQUAMOUS CELL CARCINOMA)



Basaloid squamous carcinoma is a rare squamous cell carcinoma variant that arises primarily in the upper aerodigestive tract. Heavy tobacco and alcohol use appear to represent major risk factors. In addition, HPV may play an important role in the etiopathogenesis of a subset of basaloid squamous carcinomas—particularly those arising in the oropharynx.

Clinical Features

Basaloid squamous carcinoma tends to occur in older individuals (average age approximately 60 years) and arises more commonly in males than females. The most frequently involved sites within the head and neck include the oropharynx, larynx, oral cavity, and hypopharynx. Oral cavity tumors often arise in the floor of mouth, although other subsites may be affected as well. The lesion clinically appears as a fungating mass or ulcer and may be painful or interfere with swallowing **(dysphagia).** Most cases are diagnosed at an advanced clinical stage.

Histopathologic Features

As its name connotes, basaloid squamous carcinoma has two microscopic components. The first is a superficial, well-differentiated or moderately differentiated squamous cell carcinoma, often with surface ulceration, multifocal origin, and areas of carcinoma *in situ*. The second, deeper component is an invasive basaloid epithelium arranged in islands, cords, and glandlike lobules. This deeper tumor often shows palisading of peripheral cells, central necrosis, and occasional squamous differentiation (Fig. 10.130). This component appears similar to basal cell carcinoma, adenoid cystic carcinoma, basal cell adenocarcinoma, or neuroendocrine carcinoma. The interface between the two components is typically sharp and distinct, but gradual transition from squamous to basaloid cells may be seen occasionally. The tumor islands may be surrounded by hyalinized stroma and arranged in a "jigsaw puzzle" pattern. Microcystic spaces filled with PAS-positive basal lamina material may be interspersed among the tumor islands as well.

• **Fig. 10.130 Basaloid Squamous Carcinoma.** Sheets of basaloid squamous epithelium exhibiting a high mitotic index and tumor necrosis.

Treatment and Prognosis

Treatment typically consists of surgery, often followed by radiation or chemoradiation therapy. Studies based on cancer registry data in the United States for head and neck cases have reported 5- and 10-year survival rates of approximately 64% and 52%, respectively. This tumor generally has been considered an aggressive malignancy. However, several more recent investigations have noted that basaloid squamous carcinoma may have a similar outcome compared with conventional squamous cell carcinoma when controlling for variables such as clinical stage, anatomic location, and HPV status. Therefore, reports of poor outcomes for basaloid squamous carcinoma in part might reflect a tendency for these patients to be diagnosed with late-stage disease. In addition, studies suggest that oropharyngeal basaloid squamous carcinomas often harbor HPV, with significantly improved survival among HPV-positive cases compared to HPV-negative cases. Thus, conflicting reports in the literature regarding prognosis may reflect differences in subsite distribution and HPV tumor status among study cohorts.

dentlearn.ir

◆ CARCINOMA OF THE MAXILLARY SINUS

Carcinoma of the maxillary sinus or antrum is an uncommon malignancy of largely unknown cause. It does not appear to be related to sinusitis or nasal polyps. Unlike squamous cell carcinomas in other head and neck sites, squamous cell carcinomas of the paranasal sinuses have been associated only weakly with tobacco use. A strong causal relationship to occupational wood and leather dust exposure has been established for the rarely occurring sinonasal intestinal type of adenocarcinoma. In addition, HPV may be an etiologic factor in some cases, with transcriptionally active high-risk HPV detected in approximately 25% of sinonasal squamous cell carcinomas examined.

Maxillary sinus carcinomas comprise only about 3% of all head and neck carcinomas; however, among paranasal sinus carcinomas, the maxillary sinus is the most common site (accounting for 80% of lesions). Most lesions remain asymptomatic or mimic sinusitis for long periods while the tumor grows to fill the sinus. Therefore, the diagnosis may not be made until the lesion has perforated through the surrounding bone.

The majority of maxillary sinus carcinomas represent squamous cell carcinomas. However, additional carcinomas that may arise in this location include sinonasal adenocarcinoma, **sinonasal undifferentiated carcinoma (SNUC)** (see next section), neuroendocrine (small cell undifferentiated) carcinoma, salivary gland-type adenocarcinoma, and sinonasal lymphoepithelial carcinoma. Rare examples of newly described carcinoma types (e.g., NUT carcinoma, SWI/SNF complex-deficient sinonasal carcinoma, HPV-related multiphenotypic carcinoma) may involve this location as well.

Clinical and Radiographic Features

Carcinoma of the maxillary sinus mainly affects older adults, with a slight male predilection. More than 80% of cases are advanced (stage III or IV) at the time of diagnosis. Patients generally complain of chronic unilateral nasal stuffiness or notice an ulceration or mass of the hard palate or alveolar bone (Fig. 10.131). When the second division of the trigeminal nerve is involved, intense pain or paresthesia of the midface or maxilla may occur, perhaps simulating a toothache. Adjacent teeth may become loose, and dental radiographs often reveal a "moth-eaten" destruction of the lamina dura and surrounding bone. A panoramic radiograph shows a cloudy sinus with destruction of its bony wall; however, the extent of the tumor is best visualized by CT or MRI.

If the tumor perforates the lateral wall of the sinus, unilateral facial swelling and pain are usually present. With medial extension, nasal obstruction and hemorrhage are common. Superior extension results in displacement or protrusion of the eyeball. Approximately 9%–14% of patients have regional lymph node metastasis at the time of diagnosis. Distant metastasis is uncommon until late in the progression of disease.

• **Fig. 10.131 Carcinoma of the Maxillary Sinus.** The tumor has produced a bulge of the posterior maxillary alveolar ridge and is beginning to ulcerate through the surface mucosa.

Histopathologic Features

Although the antrum is lined by respiratory epithelium, the great majority of maxillary sinus carcinomas are **squamous cell carcinomas,** usually moderately or poorly differentiated. Squamous cell carcinomas in the sinonasal tract may be subclassified as keratinizing, nonkeratinizing, or less frequent variants (such as, basaloid, papillary, adenosquamous, spindle cell, and verrucous).

Treatment and Prognosis

Treatment depends upon tumor type and stage. Most patients are treated by surgical resection, which may be combined with radiotherapy and/or chemotherapy. Neck dissection may be performed for patients with regional metastasis. Individuals with unresectable disease should consider clinical trial participation; treatment options for these patients typically include radiation therapy and/or chemotherapy. According to SEER data in the United States for 2010 through 2016, 5-year relative survival rates for cancer of the nasal cavity and paranasal sinuses are 82% for patients with localized disease, 52% for patients with regional metastasis, 43% for patients with distant metastasis, and 58% for all tumor stages combined. According to the National Cancer Database for 2004 through 2012, median survival for individuals with cancer of the maxillary sinus is 29 months. Death among patients with carcinoma of the maxillary sinus usually occurs from local destruction and the inability to control the primary disease. Some investigators have suggested that HPV-positive sinonasal carcinomas may exhibit improved clinical outcomes compared to HPV-negative cases; however, further studies are needed.

◆ SINONASAL UNDIFFERENTIATED CARCINOMA

Sinonasal undifferentiated carcinoma (SNUC) is a rare, highly aggressive neoplasm of the nasal cavity and paranasal sinuses. It comprises less than 3% of sinonasal malignancies.

dentlearn.ir

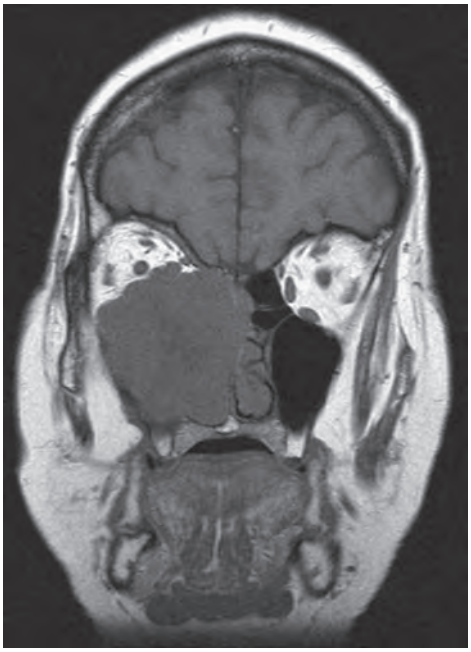
The tumor initially was described in 1986, and fewer than 400 cases have been reported.

There has been some disagreement regarding whether SNUC constitutes a distinct clinicopathologic entity vs a diagnosis of exclusion. The recent identification of *IDH2* mutations in a significant proportion of cases combined with earlier descriptions of SNUC based on histomorphology and immunophenotyping would support classification as a distinct entity. Tumors within this category generally should lack the following features: (1) squamous, glandular, or other specific lines of cellular differentiation; (2) Epstein-Barr virus or human papillomavirus; (3) definite neuroendocrine differentiation; and (4) specific genotypes other than oncogenic *IDH* mutations.

In the earlier literature, these tumors probably were classified as anaplastic carcinomas or high-grade olfactory neuroblastomas. In more recent years, the definition of SNUC has been further refined as advanced molecular profiling techniques have led to the identification of novel tumor types excluded from this category. Such newly described entities, which have been distinguished from SNUC, include the following aggressive malignancies: *NUT carcinoma* (defined by balanced translocations involving the *NUTM1* gene on chromosome 15q14), *HPV-related multiphenotypic carcinoma* (associated with HPV33 and other high-risk HPV types), and *SWI/SNF complex-deficient sinonasal carcinoma* (i.e., *SMARCB1 [INI-1]-deficient sinonasal carcinoma* characterized *SMARCB1* inactivation and resultant loss of nuclear INI-1 protein expression, *SMARCA4-deficient sinonasal carcinoma* characterized by *SMARCA4* inactivation and resultant loss of SMARCA4 expression). SMARCB1 and SMARCA4 represent components of the SWI/SNF complex, which is involved in chromatin remodeling.

The histogenesis and etiopathogenesis of SNUC are poorly understood. Some investigators have theorized that the cell of origin may be related to the Schneiderian membrane or olfactory epithelium. In addition to characteristic *IDH2* mutations, many cases harbor concurrent alterations in *SOX9*, *SOX2*, PI3K pathway genes, *KIT*, *TP53*, *MYC*, and various other genes. There is only a weak association with tobacco smoking. In some instances, patients have developed SNUC secondary to radiation therapy for nasopharyngeal carcinoma or retinoblastoma.

Clinical and Radiographic Features



SNUC occurs over a broad age range (third through ninth decades), with a median age at presentation in the sixth decade. The male-to-female ratio is approximately 2:1 to 3:1.

The tumor is well known for rapid development of locally extensive disease. It typically appears as a large mass that can involve multiple regions of the sinonasal tract, including the nasal cavity, maxillary sinus, and ethmoid sinuses. In addition, extension into contiguous sites—such as, the nasopharynx, orbit, and cranial cavity—is common. Inferior penetration into the oral cavity is possible as well. There is often rapid development of multiple sinonasal symptoms, including nasal obstruction or discharge, epistaxis, swelling, and pain. Orbital involvement may lead to proptosis, periorbital swelling, diplopia, and vision loss. Cranial nerve palsies are common as well.

Tumor extent is best assessed by CT or MRI, which typically reveals a large, expansile sinonasal mass with bony destruction and invasion of adjacent structures (Fig. 10.132).

Histopathologic Features

SNUC is characterized by trabeculae, nests, islands, ribbons, and sheets of polygonal cells with minimal cytoplasm and pleomorphic, hyperchromatic to vesicular nuclei. No squamous or glandular differentiation should be observed. Mitotic figures are numerous. Tumor necrosis, apoptosis, and lymphovascular invasion usually are prominent. Lymphovascular invasion and perineural invasion often are noted. The surface epithelium overlying the tumor may exhibit dysplasia or carcinoma *in situ*. Immunohistochemistry for cytokeratins (such as AE1/AE3 and low molecular weight cytokeratins) or epithelial membrane antigen (EMA) typically is positive. Careful histopathologic examination, a broad immunohistochemical panel, and, at times, molecular studies are needed to rule out other entities, such as poorly differentiated squamous cell carcinoma, olfactory neuroblastoma, nasopharyngeal undifferentiated nonkeratinizing squamous cell carcinoma, neuroendocrine carcinoma, NUT carcinoma, SMARCB1-deficient sinonasal carcinoma, SMARCA4-deficient sinonasal carcinoma,

dentlearn.ir

melanoma, lymphoma, synovial sarcoma, Ewing sarcoma, and alveolar rhabdomyosarcoma.

Treatment and Prognosis

Most patients present with locally advanced disease. In such cases, the standard approach is aggressive multimodal therapy, including surgical resection, radiation therapy, and/or chemotherapy. Unresectable disease is treated by definitive chemoradiation therapy. When resectability is questionable, some authorities advocate induction chemotherapy in order to shrink the tumor prior to additional treatment. Clinical studies are needed to assess whether patients with *IDH*-mutant tumors may benefit from targeted IDH inhibitors.

The prognosis is generally poor, although several centers have reported improved outcomes with modern treatment approaches. An analysis of SEER data in the United States from 1973 to 2010 reported overall 5- and 10-year relative survival rates of about 35% and 31%, respectively; the overall median survival was 22 months. However, a recent multicenter collaborative study in France noted 62% overall survival among their patient cohort, with a majority exhibiting advanced disease at presentation. Local recurrence is common and is the major cause of morbidity and mortality. Metastasis is possible, usually to cervical lymph nodes, bone, liver, or brain. Some reports suggest that cases exhibiting *IDH2* mutations may have more favorable outcomes compared to those without such mutations.

◆ NASOPHARYNGEAL CARCINOMA

Nasopharyngeal carcinoma represents a group of malignancies that arise from the lining epithelium of the lymphoid tissue–rich nasopharynx; similar tumors are found in the palatine tonsil and base of tongue. These three anatomic sites are collectively called **Waldeyer tonsillar tissue** or **Waldeyer ring.**

Nasopharyngeal carcinoma is relatively uncommon. According to global data collected by the International Agency for Research on Cancer, there were approximately 133,000 new cases of nasopharyngeal cancer in the year 2020, which accounted for only about 0.7% of all cancers diagnosed during this period. Age-standardized annual incidence rates varied from less than 1 per 100,000 persons in the Americas and Europe to 5 per 100,000 persons in Southeast Asia. In southern Chinese men, however, the rate is a startling 25 per 100,000. Among southern Chinese men who migrate to the United States, the rate is intermediate, which suggests possible interactions between an environmental causative agent and host genetics. Intermediate rates also are observed among many indigenous people of Southeast Asia (including Thais, Vietnamese, Malays, and Filipinos), Inuits of Alaska and Canada, and Arabs of North Africa.

Both genetic and environmental factors have been implicated in the etiopathogenesis of nasopharyngeal carcinoma. Linkage and genome-wide association studies have identified several susceptibility genes, particularly HLA genes residing at the MHC region on chromosome 6p21. Chief among environmental risk factors is Epstein-Barr virus (EBV) infection. Some studies also have implicated diets deficient in vitamin C, consumption of salted fish containing carcinogenic N-nitrosamines, and tobacco smoking. However, the risk for carcinoma development for a given level of tobacco exposure is lower in the nasopharynx than in other parts of the upper aerodigestive tract. Furthermore, investigators have detected high-risk HPV in a small subset of nasopharyngeal carcinomas with a predilection for white individuals.

Clinical Features

Nasopharyngeal carcinoma occurs in all age groups, with a peak between the ages of 40–59 years in high-incidence regions. In low-incidence regions, there is a modest peak during adolescence/young adulthood and a higher peak after 65 years of age. The disease occurs about two to three times more commonly in men than in women.

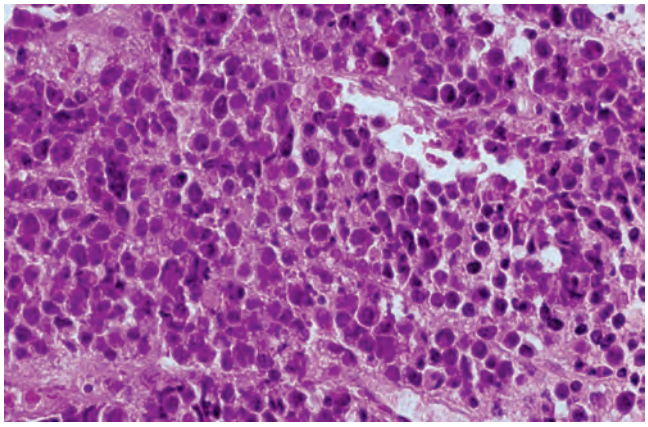
The primary tumor tends to arise in the fossa of Rosenmuller (a deep recess in the posterolateral nasopharyngeal wall). The lesion often is small and difficult to detect, even by endoscopy. In regions where nasopharyngeal carcinoma is endemic, plasma EBV DNA measurement may be combined with endocoscopic examination and MRI for detection of early-stage disease in asymptomatic patients. Serologic testing also may aid in diagnosis. The first sign of disease for 50%–60% of patients is an enlarged, firm to hard, cervical lymph node, which represents metastatic tumor (Fig. 10.133). Symptoms related to the ear are described by slightly less than half of patients. If the tumor obstructs the eustachian tube, then unilateral serous otitis media, otalgia, or hearing loss may be the presenting complaint. Epistaxis, nasal obstruction, and pharyngeal pain may be present as well. The tumor may invade through the foramen lacerum into the brain, producing CNS symptoms, or it may involve cranial nerves in the area, causing specific symptoms related to those nerves. Involvement of the pterygoid muscles can produce facial pain with limited jaw movement, thereby mimicking a temporomandibular joint disorder. Significantly, 5%–10% of patients also have distant metastasis at the time of diagnosis.

Histopathologic Features

The surgeon often has difficulty finding the primary lesion, and multiple systematic biopsy samples of the nasopharyngeal mucosa may be necessary for tumor identification and diagnosis. Nasopharyngeal carcinoma includes the following histopathologic types:

1. Keratinizing squamous cell carcinoma
2. Nonkeratinizing squamous cell carcinoma (including differentiated and undifferentiated variants)
3. Basaloid squamous cell carcinoma

dentlearn.ir



• **Fig. 10.133 Nasopharyngeal Carcinoma.** This patient initially appeared with metastatic carcinoma in the left lateral neck. Further evaluation revealed a primary tumor of the nasopharynx. (Courtesy of Dr. D. E. Kenady.)

When more than one histopathologic type is present, the tumor is classified according to the predominant type.

The histopathologic features of **keratinizing squamous cell carcinoma** are identical to those of squamous cell carcinoma of other head and neck regions (see page 416). Keratinization must be evident at the light microscopic level.

Nonkeratinizing squamous cell carcinoma represents the most common type of nasopharyngeal carcinoma. This group can be further categorized as *differentiated* and *undifferentiated,* although these subtypes are of no clinical or prognostic significance. The lesional cells of **differentiated nonkeratinizing squamous cell carcinoma** are relatively mature and somewhat squamous in nature, but they produce no keratin. Broad interconnecting bands of oval or round cells are organized in plexiform and papillary patterns. **Undifferentiated nonkeratinizing squamous cell carcinoma** consists of sheets of undifferentiated cells with indistinct margins, very little cytoplasm, and large, vesicular nuclei (Fig. 10.134). These tumor cells are often intermixed with the lymphoid cells normally found at this anatomic site. The term **lymphoepithelioma** (or **lymphoepithelial carcinoma**) has been used to describe this variant because it was once thought to be a malignancy that originated from both epithelial and lymphoid tissues. This terminology should be discouraged, however, because the lymphoid tissue is not part of the neoplastic process. Such undifferentiated tumors may be difficult to distinguish from lymphoma by routine light microscopic examination, and immunohistochemical studies often are used to demonstrate cytokeratins within the carcinoma cells. Occasional cases show neuroendocrine differentiation.

• **Fig. 10.134 Nasopharyngeal Carcinoma.** Poorly differentiated tumor exhibiting sheets of rounded tumor cells.

Basaloid squamous cell carcinoma is very rare in the nasopharynx. This tumor type is discussed in a separate section (see page 425).

The keratinizing type comprises less than 20% of nasopharyngeal carcinoma cases worldwide and is found more frequently in nonendemic than endemic areas. In contrast, the nonkeratinizing type comprises the vast majority (greater than 95%) of cases in endemic regions. In addition, the nonkeratinizing type is very closely associated with EBV infection (as best demonstrated by *in situ* hybridization for EBV-encoded early RNA [EBER]), whereas EBV status is variable in the keratinizing and basaloid squamous types. Among the small subset of HPV-positive cases, the keratinizing type is found more often than the nonkeratinizing type. Interestingly, according to an analysis of SEER data in the United States from 1973 through 2015, the annual incidence of nasopharyngeal cancer overall has been declining, but there has been a marked increase in the annual incidence of the nonkeratinizing type.

Treatment and Prognosis

Because of the inaccessibility of the nasopharynx and the keen radiosensitivity of nasopharyngeal carcinoma, radiotherapy is the mainstay of treatment. Early-stage disease typically is managed by radiotherapy alone. However, most patients present with locoregionally advanced disease, for which current evidence supports concurrent platinum-based systemic therapy and radiation therapy plus either induction or adjuvant chemotherapy. Clinical trial participation is encouraged for patients with locoregionally advanced or distant metastatic disease. Targeted therapies and immunotherapy (e.g., immune checkpoint inhibitors, EBV-directed vaccination, adoptive T-cell therapy) are currently under investigation.

dentlearn.ir

In the United States, the relative 5-year survival rates for patients with localized, regional, and distant disease are 85%, 71%, and 49%, respectively. For all stages combined, the relative 5-year survival rate is 61%. A large-scale retrospective study performed in Asia for validation of the current TNM staging system reported 5-year overall survival rates of 98% for stage I disease, 92% for stage II disease, 83% for stage III disease, and 71% for stage IV disease. When treated with radiation therapy, the nonkeratinizing type exhibits a higher local control rate but a greater risk for distant metastasis compared with the keratinizing type. In the United States, higher survival rates have been observed among Asian-American patients compared with other ethnic groups. Additional favorable prognostic factors include age under 40 years, female gender, and low titers of circulating EBV DNA (determined pre-treatment and post-treatment by real-time PCR). The prognostic significance of HPV-positivity currently is unclear. Persons treated for nasopharyngeal carcinoma are also at increased risk for developing a second primary malignancy of the head and neck mucosa.

◆ BASAL CELL CARCINOMA (BASAL CELL EPITHELIOMA; RODENT ULCER)

Basal cell carcinoma represents the most common skin cancer, as well as the most common of all cancers. It is a locally invasive, slowly spreading, epithelial malignancy that arises from the basal cell layer of the skin and its appendages. About 80% are found on the skin of the head and neck.

The annual incidence is difficult to determine because basal cell carcinoma typically is not reported to cancer registries. However, researchers estimate that 5.4 million nonmelanoma skin cancers (basal and squamous cell carcinomas; "keratinocyte cancers") were treated in more than 3.3 million people in the United States in 2012. The worldwide incidence of basal cell carcinoma varies considerably by region, ranging from <1 per 100,000 person-years in Africa to >1000 per 100,000 person-years in Australia. The risk generally increases with age, proximity to the equator, and lighter skin pigmentation. Furthermore, the incidence has been increasing in many countries around the world; in part, this trend may be due to aging populations, although some investigators have reported a disproportionate increase among young adults (particularly women) as well.

This cancer mainly results from exposure to UV radiation—especially intense intermittent exposure but also cumulative exposure. Frequent sunburns and tendency for freckling in childhood are associated with an increased risk. Additional risk factors include outdoor occupational activity, psoralen and ultraviolet A (PUVA) treatment (often used for psoriasis), tanning device use, inability to tan, presence of nevi on the extremities, ionizing radiation exposure, immunosuppression, and arsenic ingestion. Allelic variations in genes related to DNA repair, pigmentation, tumor suppression, or other functions (e.g., the *melanocortin 1 receptor [MC1R]* gene, *TP53*) also may confer increased susceptibility. Furthermore, several genodermatoses are associated with basal cell carcinoma, including the nevoid basal cell carcinoma syndrome (see page 694), xeroderma pigmentosum (see page 753), albinism, Rombo syndrome, Bazex Dupré-Christol syndrome, Bloom syndrome, Werner syndrome, Rothmund-Thomson syndrome, Muir-Torre syndrome, Cowden syndrome (see page 765), Brooke-Spiegler syndrome, and the Dowling-Meara subtype of epidermolysis bullosa simplex (see page 766).

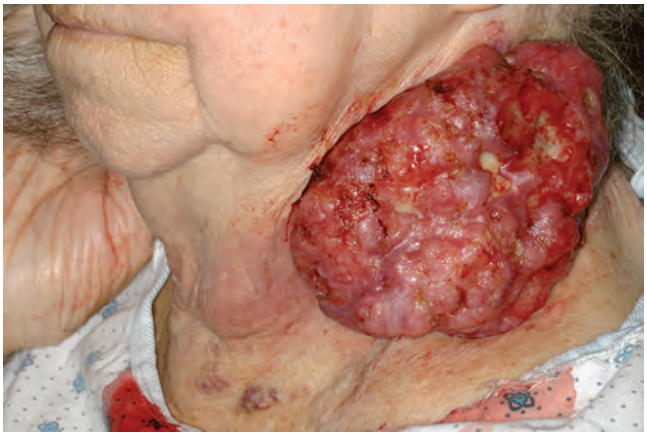
Molecular genetic studies have shown that dysregulation of the hedgehog signaling pathway is a critical early event in the development of basal cell carcinoma. Inactivating mutations in the *patched 1 (PTCH1)* gene on chromosome 9q22 have been identified in both sporadic cases and patients with the nevoid basal cell carcinoma syndrome. Mutations in other genes participating in this pathway (e.g., *smoothened [SMO]*, *suppressor of fused [SUFU]*, *PTCH2*) may be found in sporadic cases as well. These mutations result in constitutive activation of hedgehog signaling and enhanced cellular proliferation. In addition, *TP53* mutations are found in about 60% of sporadic basal cell carcinomas and may represent a later event in tumor development.

Well-documented reports of oral basal cell carcinoma are rare. Many of the cases described in the literature actually represent misdiagnosed salivary or odontogenic neoplasms.

Clinical Features

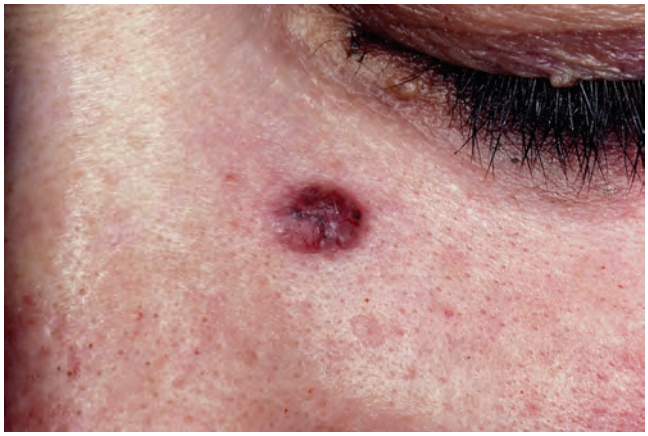
Basal cell carcinoma most often affects white adults, especially those with fair complexions. Although most patients are older than 40 years at diagnosis, some lesions are detected as early as the second decade of life, particularly in patients with red or blonde hair and blue or green eyes. Males are affected about twice as often as females; however, among young patients, there is a female predilection (possibly due to tanning bed use). Approximately 80% of lesions occur on the head and neck, with the remainder involving the trunk and limbs. Lesions arising in the lip area most often involve the skin adjacent to the upper lip vermilion; upper lip vermilion tumors are more frequent than lower lip vermilion tumors.

The most common clinicopathologic variant, **nodular (noduloulcerative) basal cell carcinoma,** begins as a firm, painless papule that slowly enlarges and develops a central depression or umbilication. Telangiectatic blood vessels usually are evident within the rolled border surrounding the central depression (Figs. 10.135 and 10.136). When the lesion is pressed, a characteristic pearly opalescent quality is discerned. Expanding ulceration often develops in the central depression, and the patient may report intermittent bleeding followed by healing. Untreated lesions continue to enlarge slowly, with ulceration and destruction of underlying structures—hence the term **rodent ulcer** (Fig. 10.137). Destruction of underlying bone or cartilage may occur, but metastasis is extremely rare.



dentlearn.ir

• **Fig. 10.135 Basal Cell Carcinoma.** Early noduloulcerative basal cell carcinoma of the forehead showing raised, rolled borders and focal ulceration. Fine, telangiectatic blood vessels can be seen on the surface.



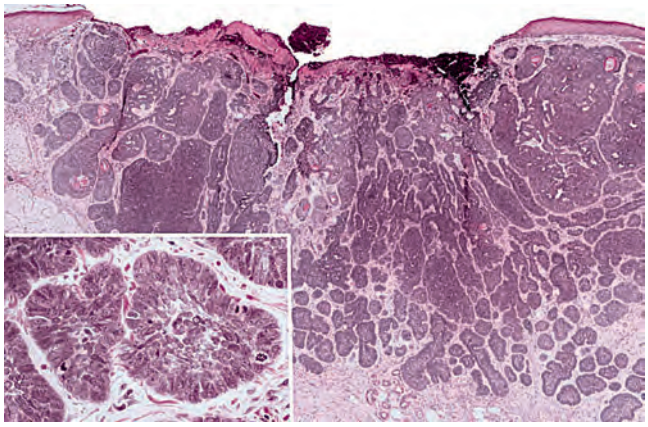
• **Fig. 10.136 Basal Cell Carcinoma.** Noduloulcerative lesion of the upper lip demonstrating telangiectasia and small ulceration.

• **Fig. 10.137 Basal Cell Carcinoma.** This tumor was neglected for many years and became exceptionally large. (Courtesy of Dr. Terry Day.)

Several other variants have been described. **Pigmented basal cell carcinoma** represents a noduloulcerative tumor colonized by benign melanocytes (Fig. 10.138). The melanin production imparts a tan, brown, black, or even bluish color, and usually the pigment is not distributed uniformly, as it would be in a melanocytic nevus (see page 374).

• **Fig. 10.138 Basal Cell Carcinoma.** Pigmented basal cell carcinoma of the cheek.

Sclerosing (morpheaform) basal cell carcinoma is an insidious lesion that often mimics scar tissue. The overlying skin appears pale and atrophic, and the lesion is firm to palpation with poorly demarcated borders. A slight elevation may be noted at the tumor edges. Often a great deal of invasion has occurred before the patient becomes aware of a problem.



Superficial basal cell carcinoma occurs primarily on the skin of the trunk and extremities. Often, lesions are multiple and appear as well-demarcated, erythematous, scaly patches that may be mistaken clinically for psoriasis or eczema. A fine, elevated, "threadlike" border is seen at the margins.

Some investigators believe that basal cell carcinomas associated with the **nevoid basal cell carcinoma syndrome** (see page 694) should be placed in a separate category. These lesions develop in both sun-exposed and protected areas of the skin and may number in the hundreds for a single patient. The tumors associated with this syndrome usually do not produce significant tissue destruction.

Histopathologic Features

Basal cell carcinoma displays considerable histopathologic diversity and includes the following microscopic patterns: noduloulcerative (nodulocystic), pigmented, keratotic, adenoid, superficial, infiltrative, sclerosing (morpheaform), and micronodular. The noduloulcerative, pigmented, and syndrome-related basal cell carcinomas are comprised of uniform, ovoid, dark-staining basaloid cells with medium-sized nuclei and little cytoplasm (Fig. 10.139). The cells are arranged in well-demarcated islands and strands, which appear to arise from the basal cell layer of the overlying epidermis and invade the underlying connective tissue. Epithelial islands typically demonstrate palisading of the peripheral cells; frequently, artifactual retraction is seen between the epithelial islands and the connective tissue. Although most of these neoplasms show no differentiation, some exhibit areas of keratin production, sebaceous differentiation, or interlacing strands of lesional cells that resemble duct

dentlearn.ir

• **Fig. 10.139 Basal Cell Carcinoma.** Low-power photomicrograph showing ulceration of the epidermal surface associated with an invading tumor of hyperchromatic epithelial cells. *Inset* demonstrates islands of basophilic epithelium with peripheral palisading.

formation ("adenoid"). Necrosis of epithelial islands may produce a cystic appearance. Actinic damage in the form of **solar elastosis** almost always is seen in adjacent stroma.

Pigmented basal cell carcinoma demonstrates dendritic melanocytes within tumor islands, and melanophages may be seen in the surrounding stroma. Both the infiltrative and sclerosing types exhibit infiltrating thin strands of basaloid tumor cells; the latter type also shows a densely collagenous background. Superficial basal cell carcinoma includes lobules of tumor cells that drop from the epidermis in a multifocal pattern. Micronodular basal cell carcinoma exhibits small, round tumor nests less than 0.15 mm in diameter (or about the size of a hair follicle bulb). Occasionally, basal cell carcinoma is admixed with an independent primary squamous cell carcinoma of the skin. The resulting "collision" tumor is called **basosquamous carcinoma.** Some authorities consider basosquamous carcinoma to be a simple basal cell carcinoma with abundant squamous metaplasia.

Some studies suggest that immunohistochemical expression of Ber-EP4 (a cell surface glycoprotein preferentially expressed in cutaneous basal cell carcinoma) may help to distinguish extremely rare cases of intraoral basal cell carcinoma from peripheral ameloblastoma.

Treatment and Prognosis

The following features are associated with increased risk for recurrence among cutaneous basal cell carcinomas of the head and neck:

- Lesions of any size involving the cheeks, forehead, scalp, and neck
- For lesions involving subsites other than those above: (1) 6 mm or greater in size, or (2) less than 6 mm in size but unable to achieve clinically tumor-free margins of at least 4 mm
- Ill-defined clinical borders
- Micronodular, infiltrative, and sclerosing types
- Perineural invasion
- Recurrent lesions
- Lesions arising in immunosuppressed individuals or in a prior site of radiotherapy

Lesions with low risk for recurrence typically are treated by routine surgical excision or electrodesiccation and curettage, with 4-mm margins of clinically normal-appearing skin beyond the visible lesion. These methods result in a cure rate of 95%–98%. Head and neck lesions with a high risk for recurrence often are treated by **Mohs micrographic surgery.** This technique uses intraoperative, frozen-section evaluation of specially mapped and marked surgical specimens to ensure complete tumor removal. Radiotherapy may be an option for patients unable to tolerate surgery.

Alternative treatments—such as topical 5-fluorouracil, topical imiquimod, photodynamic therapy, or vigorous cryotherapy—may be effective for low-risk, superficial basal cell carcinomas. Such alternatives are associated with suboptimal but acceptable cure rates, and topical medical therapies may yield superior cosmetic outcomes. Patients with high-risk basal cell carcinomas for which curative surgery and radiation are not feasible may be treated with recently developed hedgehog pathway inhibitors (such as, vismodegib or sonidegib). Several other targeted agents are under development.

Recurrence of a properly managed basal cell carcinoma is uncommon, and metastasis is exceptionally rare. Unusual cases of metastatic disease may be treated with hedgehog pathway inhibitors or off-label use of PD-1 inhibitors. In patients with uncontrollable disease, death usually results from local invasion into vital structures. However, with early detection and the advent of Mohs surgery, such an outcome is unusual today.

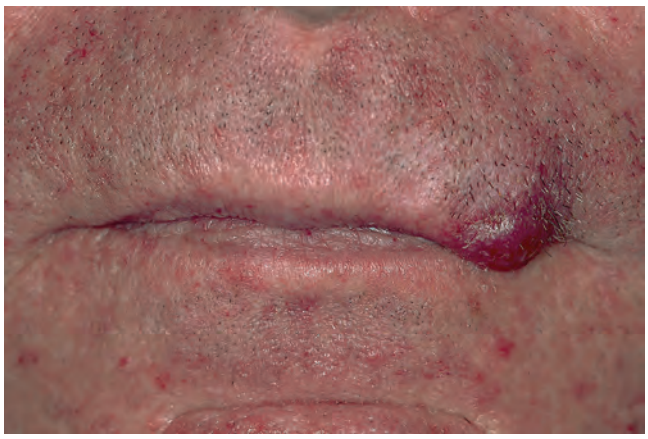
Patients with a history of basal cell carcinoma must be evaluated periodically. There is an estimated 44% chance of a second basal cell carcinoma and 6% chance of a cutaneous squamous cell carcinoma developing within 3 years of treatment of the initial tumor. Some studies suggest that oral nicotinamide may be an effective chemopreventive agent for patients at high risk of developing additional nonmelanoma skin cancers.

◆ MERKEL CELL CARCINOMA (MERKEL CELL TUMOR; PRIMARY NEUROENDOCRINE CARCINOMA OF SKIN; SMALL CELL CARCINOMA OF SKIN; TRABECULAR CARCINOMA OF SKIN; TOKER TUMOR)

Merkel cell carcinoma is a rare, aggressive malignancy with neuroendocrine features. It most often occurs on the skin of the head and neck region in elderly individuals. The etiopathogenesis is driven by Merkel cell polyomavirus (MCPyV) infection and/or chronic UV light exposure. MCPyV is found in up to 80% of cases in North America and Europe, whereas most cases in regions of the southern hemisphere with high exposure to UV light (such as Australia)

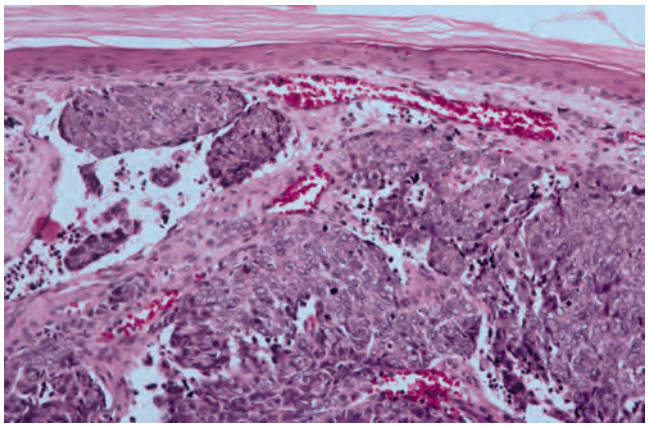
dentlearn.ir

are negative for the virus. MCPyV-negative tumors tend to demonstrate a molecular UV signature (i.e., preponderance of C-to-T or CC-to-TT transitions in dipyrimidine sites), recurrent mutations in *TP53* and *RB1*, and an overall higher mutational burden than MCPyV-positive tumors. In addition, immunosuppression is a risk factor, with increased frequency of Merkel cell carcinoma noted among transplant recipients, patients receiving immunosuppressive therapy for autoimmune diseases, patients with other underlying malignancies (especially chronic lymphocytic leukemia), and patients with HIV infection.



In the United States, only about 2000 cases of Merkel cell carcinoma are diagnosed annually. However, the incidence has been increasing over the past few decades in this and other countries—a trend that may be caused by population aging, prolonged lifespan of individuals with conditions causing immunosuppression, and improved diagnosis and cancer registry tracking.

The exact cell of origin is uncertain. This neoplasm traditionally was thought to arise from Merkel cells (mechanoreceptor cells found primarily in skin, but also in other sites, including oral mucosa). However, this theory seems unlikely given that Merkel cells are terminally differentiated and mainly reside in the basal layer of the epidermis, whereas most Merkel cell carcinomas are dermal-based tumors without an intraepithelial component. A possible origin from dermal mesenchymal stem cells, epidermal stem cells, fibroblasts, or primitive B-cells also has been proposed.



Intraoral and lip vermilion cases have been reported rarely. However, some oral neuroendocrine malignancies previously reported as Merkel cell carcinomas actually may be more akin to high-grade small cell neuroendocrine carcinomas of the upper aerodigestive tract mucosa. The latter tumor type is closely associated with tobacco and alcohol abuse, is not associated with UV light exposure or MCPyV, exhibits microscopic features similar to small cell carcinoma of the lung, and may behave even more aggressively than Merkel cell carcinoma.

Clinical Features

Approximately 82% of cases are diagnosed in patients in their 7th through 9th decades of life. The tumor mainly affects whites (96% of cases) and exhibits a male predominance. It occurs primarily on sun-exposed areas of fair-skinned individuals, with a predilection for the skin of the face, upper limbs, and shoulders. The lip vermilion is also susceptible (Fig. 10.140). Extracutaneous lesions are rare and may involve the oral, nasal, pharyngeal, laryngeal, esophageal, and genital mucosa. The tumor usually appears as an asymptomatic, rapidly enlarging, smooth, dome-shaped nodule with prominent surface vessels **(telangiectasias).** Some authors have used the acronym **AEIOU** (**A**symptomatic, **E**xpanding rapidly, **I**mmunosuppression, **O**ld age, **U**ltraviolet-exposed fair skin) to summarize the salient clinical findings. The lesion typically is red, violaceous, or pink and ranges in size from 0.5 to 5.0 cm. An often innocuous clinical appearance may cause delay in diagnosis. Approximately 27% of cases demonstrate regional lymph node metastasis at diagnosis. In about 14% of cases, there is metastasis of unknown primary origin, presumably due to regression of the primary tumor. In addition, so-called high-grade neuroendocrine carcinoma of the salivary glands (especially the parotids) may represent metastasis from an occult or regressed cutaneous Merkel cell carcinoma.

• **Fig. 10.140 Merkel Cell Carcinoma.** Red nodule on the vermilion border of the upper lip. (From Chang JYF, Stewart JM, Cheng YSL, et al: Upper lip nodule, *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 105:549–553, 2008.)

• **Fig. 10.141 Merkel Cell Carcinoma.** A sheet of undifferentiated basophilic cells is seen beneath the epidermal surface.

Histopathologic Features

Merkel cell carcinoma consists of sheets, nodules, nests, and trabeculae of small to moderately sized, round, basophilic cells, which infiltrate the dermis and subcutis (Fig. 10.141). Epidermal involvement is infrequent. The tumor cells typically exhibit overlapping nuclei, finely granular ("salt and pepper") chromatin, scant cytoplasm, indistinct cell borders, brisk mitotic activity, and frequent apoptosis. MCPyV-positive lesions tend to have small to medium cells with uniformly round nuclei, whereas MCPyV-negative cases often exhibit irregular, elongated

dentlearn.ir

nuclei or large cells with clear cytoplasm. Intracytoplasmic argyrophilic granules may be demonstrated by the Grimelius stain, and immunohistochemical staining for cytokeratin 20 (CK20) usually shows a "perinuclear dot" pattern. Immunopositivity for neuroendocrine markers (e.g., chromogranin A, synaptophysin, neuron-specific enolase, and CD56), neurofilament, and SATB2 also may be helpful in establishing the diagnosis. In approximately 60%–80% of cases, MCPyV can be detected by polymerase chain reaction (PCR) for viral DNA or immunohistochemistry (using the CMB24 clone) for MCPyV large T-antigen. Lack of immunoreactivity for thyroid transcription factor 1 (TTF-1) may help to exclude metastatic small cell carcinoma of the lung, which may have similar histomorphologic features. The microscopic differential diagnosis also may include amelanotic melanoma, metastatic olfactory neuroblastoma, and other "round-cell" malignancies. Immunohistochemical studies and thorough physical examination may aid in excluding these other entities. Furthermore, Merkel cell carcinomas may occur in combination with other neoplasms, especially actinic keratosis and invasive or *in situ* squamous cell carcinoma.

Treatment and Prognosis

Treatment and prognosis are guided by staging. Surgery (i.e., wide local excision or Mohs micrographic surgery) is the mainstay of treatment and often is combined with adjuvant radiotherapy. Lymph node dissection is performed when clinically palpable nodes are found. Sentinel lymph node biopsy typically is used to determine whether regional lymph node dissection and/or radiation are indicated in patients with clinically negative nodes. Clinical trial participation is recommended for patients with regional or distant metastasis. Checkpoint immunotherapy using PD-1 or PD-L1 inhibitors recently has replaced chemotherapy as first-line treatment for advanced disease.

Recurrence develops in 55% of cases, most commonly within the draining lymph nodes. Monitoring titers of antibodies to MCPyV oncoproteins may aid in early detection of recurrent disease. Furthermore, approximately 25% of patients with Merkel cell carcinoma develop additional malignancies (e.g., squamous cell carcinomas of the skin, hematologic malignancies, or adenocarcinomas of the breast or ovary). Therefore, patients should be followed closely.

In the United States, a recent analysis of data from the National Cancer Database reported 5-year overall survival rates of 51% for patients with localized disease, 35% for patients with regional metastasis, and 14% for patients with distant metastasis. Female sex, upper limb involvement, and age under 70 years are positive predictors of survival. Primary mucosal lesions exhibit a worse prognosis than the more common, primary cutaneous lesions. Similarly, lip lesions may have a worse prognosis than those arising in more frequently involved head and neck sites. Additional adverse prognostic factors include immunosuppression and negative MCPyV tumor status.

◆ MELANOMA (MALIGNANT MELANOMA; MELANOCARCINOMA)

Melanoma is a malignant neoplasm of melanocytic origin; it may arise *de novo* or from a preexisting benign melanocytic lesion. Most cases occur on the skin, although mucosal lesions also are possible. UV radiation exposure from sunlight is a major etiologic factor, with increased incidence of melanoma among white populations as they approach the equator. Acute intermittent sun damage may be of greater causative importance than chronic exposure. Oral mucosal lesions, of course, are not related to sun exposure.

Risk factors for cutaneous melanoma include a fair complexion, light-colored hair and eyes, a tendency to sunburn or freckle easily, a history of severe sunburns in childhood, an indoor occupation with outdoor recreational habits, a personal or family history of melanoma, a personal history of dysplastic nevus or giant congenital nevus, a personal history of excessive (>100) conventional nevi, and presence of conventional nevi on the extremities. Associations with tanning device use, various childhood malignancies, and immunosuppressive therapy for organ transplantation also have been proposed.

Melanoma represents the third most common skin cancer. Invasive melanoma accounts for less than 5% of total skin cancer cases but the majority of skin cancer deaths. In the United States for the year 2022, the American Cancer Society estimates that over 99,000 new cases of cutaneous invasive melanoma will be diagnosed and more than 7000 people will die of the disease. However, within the past few years mortality rates have decreased in the United States by about 4% annually on average due to advances in treatment. According to the most recent estimate by the SEER Program, 1 in 50 persons in the United States will be diagnosed with cutaneous melanoma during his or her lifetime. Based on SEER data from 2015 through 2019, the age-adjusted annual incidence rates for skin melanoma are approximately 28 per 100,000 men and 17 per 100,000 women. The highest incidence rates are seen among elderly white men; however, women are affected more frequently than men among the younger patient subset. Over the past several decades, dramatic increases in the incidence of melanoma have been reported worldwide. Some investigators contend that this trend reflects increased numbers of skin biopsies and improved diagnosis of early-stage disease. However, others have demonstrated increased frequency of both early- and late-stage disease and, thus, propose that there is a true increase in disease rate.

According to the *National Cancer Database Report on Cutaneous and Noncutaneous Melanoma,* 91.2% of all melanomas arise on the skin, whereas ocular, mucosal, and unknown primaries account for 5.2%, 1.3%, and 2.2% of cases, respectively. Almost 25% of cutaneous melanomas arise in the head and neck area, 40% on the extremities, and the rest on the trunk. More than half of mucosal melanomas occur in the head and neck (including the oral and sinonasal regions).

dentlearn.ir

Oral mucosal melanoma is very rare, accounting for only about 0.26%–0.5% of all oral cavity cancers. Several reports suggest that mucosal melanoma is more frequent in certain countries, such as Japan and Uganda; however, other investigators have suggested that the true annual incidence of mucosal melanoma is not greater in these countries but only appears so because of the comparatively low incidence of cutaneous melanoma in these racial groups. Potential associations with tobacco use, chronic trauma, and other environmental factors have been suggested by some authors but remain unsubstantiated.

There have been many discoveries regarding recurrent genetic alterations in melanomas, including those involving the MAPK and PI3K/Akt signaling pathways. In particular, researchers have identified the following four major types of somatic genetic abnormalities: (1) activating mutations in *BRAF* (identified in about half of cutaneous melanomas, especially *BRAF* V600E in tumors arising on the trunk and lower extremities of younger patients), (2) activating mutations in *NRAS* (identified in approximately 20% of cutaneous melanomas, especially those in the head and neck region of older patients), (3) *NF1* loss (identified in about 10% of cutaneous melanomas and strongly associated with severe sun exposure, older age, and desmoplastic tumors), and (4) "triple wild-type" (lacking the three aforementioned mutations but exhibiting alterations in *KIT, GNAQ, GNA11,* or other genes) (such as melanomas involving mucosa and acral skin). In addition to these major types of driver mutations, subsequent alterations typically develop in various other genes, such as *CDKN2A*, *PTEN*, *TERT*, *ARID2*, and *TP53*. Interestingly, mucosal melanomas tend to have a lower overall burden of somatic mutations compared to cutaneous lesions.

Molecular genetic studies focusing specifically on oral mucosal melanomas are limited. In several small-scale investigations, frequent *KIT* mutations have been noted. There are a few reports of infrequent mutations in other genes (e.g., *NRAS*, *FMNL2*, *BAP1*) as well. Unlike cutaneous melanoma, oral mucosal melanoma only rarely harbors *BRAF* mutations.Among some melanoma-prone kindreds, investigators have identified various germline mutations that confer a high risk for melanoma development. In particular, hereditary melanomas frequently are associated with *CDKN2A* mutations, and researchers have identified numerous other susceptibility loci.

Clinical Features

Cutaneous melanomas most commonly develop in white adults. Although the lesion occurs over a broad age range, most cases arise in individuals 45 through 84 years old, with a median age at diagnosis of 61 years. There is a female predilection among patients younger than 40 years (possibly related to tanning bed use); in contrast, a male predilection is seen among older patients. The most frequent primary site in men is the back, whereas in women the lower extremities are affected most commonly. Because many clinical similarities exist between cutaneous melanoma and its benign counterpart, the melanocytic nevus, an "ABCDE" clinical evaluation system has been developed to help distinguish between these two entities (Box 10.5). Referral for clinical assessment and dermoscopy by a dermatologist should be considered for patients with lesions exhibiting such atypical features.

Based on clinicopathologic, epidemiologic, and genetic findings, the World Health Organization's melanoma classification system (Box 10.6) delineates 9 "pathways" (or subtypes) and three major categories: (1) melanomas typically arising in skin with cumulative solar damage (pathways I-III) (including superficial spreading melanoma and lentigo maligna melanoma), (2) melanomas not consistently associated with cumulative solar damage (pathways IV-IX) (including acral and mucosal melanoma), and (3) melanomas that may arise in any pathway (including nodular melanoma). In particular, the following subtypes of melanoma are described below:

1. Superficial spreading melanoma
2. Nodular melanoma

• BOX 10.5 The "ABCDE" Clinical Features of Melanoma

- **A**symmetry (because of its **uncontrolled** growth pattern)
- **B**order irregularity (often with notching)
- **C**olor variegation (which varies from shades of brown to black, white, red, and blue, depending on the amount and depth of melanin pigmentation)
- **D**iameter greater than 6 mm (which is the diameter of a pencil eraser)
- **E**volving (lesions that have changed with respect to size, shape, color, surface, or symptoms over time)

• BOX 10.6 Melanoma Classification (Modified From the 2018 World Health Organization Classification)*

A. Melanomas typically associated with CSD
   - Pathway I: superficial spreading melanoma/low-CSD melanoma
   - Pathway II: lentigo maligna melanoma/high-CSD melanoma
   - Pathway III: desmoplastic melanoma

B. Melanomas not consistently associated with CSD
   - Pathway IV: Spitz melanoma
   - Pathway V: acral melanoma
   - Pathway VI: mucosal melanoma
   - Pathway VII: melanoma arising in a congenital nevus
   - Pathway VIII: melanoma arising in a blue nevus
   - Pathway IX: uveal melanoma

C. Melanomas arising in any pathway
   - Nodular melanoma
   - Nevoid melanoma

CSD, cumulative sun damage (as assessed by degree of solar elastosis on biopsy).
*Modified from Elder DE, Barnhill RL, Bastian BC, et al: Melanocytic tumor classification and the pathway concept of melanoma pathogenesis. In Elder DE, Massi D, Scolyer RA, et al, editors: *WHO classification of skin tumours*, ed 4, Lyon, 2018, IARC, pp. 66–71.

dentlearn.ir

3. Lentigo maligna melanoma
4. Acral melanoma
5. Mucosal melanoma

Melanomas tend to exhibit two directional patterns of growth: (1) the **radial growth phase** and (2) the **vertical growth phase.** In the early stages, the radial growth phase tends to predominate in lentigo maligna melanoma, superficial spreading melanoma, and acral lentiginous melanoma. In these lesions, the malignant melanocytes have a propensity to spread horizontally through the basal layer of the epidermis. Eventually, however, the malignant cells begin to invade the underlying connective tissue, thus initiating the vertical growth phase. In nodular melanoma, the radial growth phase is very short or nonexistent, and the vertical growth phase predominates.

Superficial Spreading Melanoma

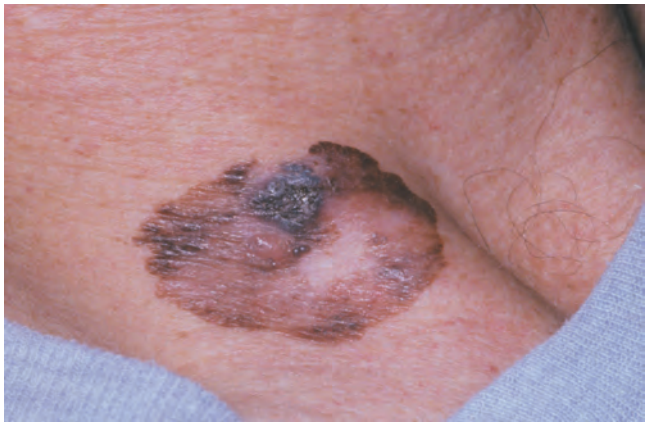
Superficial spreading melanoma is the most common subtype of melanoma, representing 70% of cutaneous lesions (Fig. 10.142). The most frequent sites of origin are the interscapular area of males and the back of the legs of females. The lesion appears as a macule or plaque with a variety of potential colors (i.e., tan, brown, gray, black, blue, white, and pink). Typically, the lesion is smaller than 3 cm in greatest diameter at diagnosis, but it may be several times that size. Clinically, invasion is indicated by the appearance of surface nodules or induration, and usually occurs within 1 year of discovery of the precursor macule. Satellites may develop around the primary lesion.

Nodular Melanoma

Nodular melanoma represents 15% of cutaneous melanomas, and one-third of such lesions develop in the head and neck. Nodular melanoma is thought to begin almost immediately in the vertical growth phase; therefore, it typically appears as a nodular elevation that rapidly invades the connective tissue. Nodular melanoma is usually deeply pigmented, although sometimes the melanoma cells are so poorly differentiated that they no longer can produce melanin, resulting in a nonpigmented **amelanotic melanoma.**

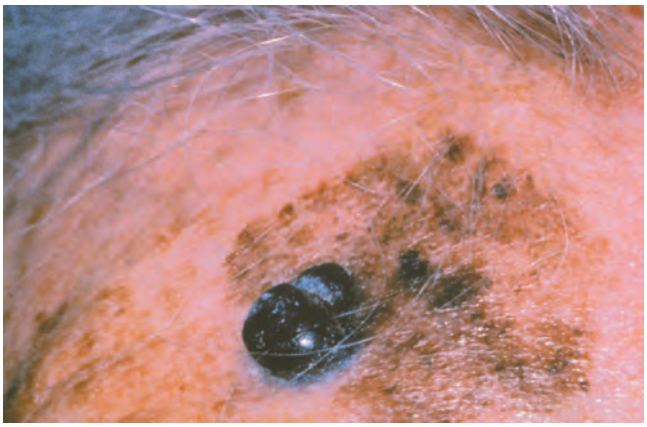
Lentigo Maligna Melanoma

Lentigo maligna melanoma, which accounts for 5%–10% of cutaneous melanomas, develops from a precursor lesion called **lentigo maligna (Hutchinson freckle).** Lentigo maligna occurs almost exclusively on heavily sun-exposed skin of fair-complexioned older adults, particularly in the midfacial region, and represents a **melanoma *in situ*** in a purely radial growth phase.



The lesion appears as a large, slowly expanding macule with irregular borders and a variety of colors, including tan, brown, black, and even white (Fig. 10.143). Patients usually indicate that the lesion has been present and has slowly expanded laterally for years. The average duration of the radial growth phase is 15 years. The appearance of nodularity within a lentigo maligna signals the onset of the invasive or vertical growth phase and the transition to lentigo maligna melanoma.

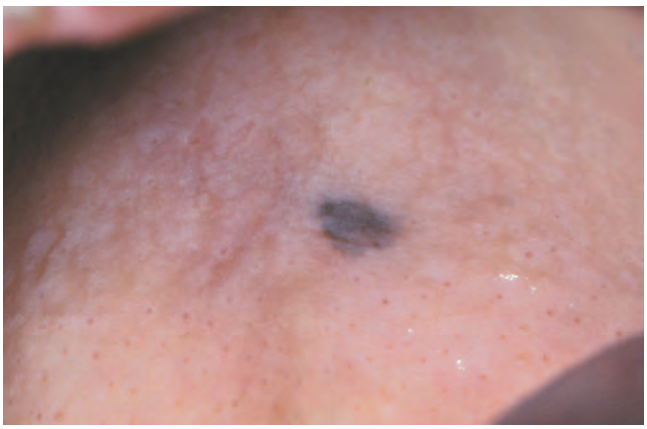
Acral Melanoma (Acral Lentiginous Melanoma)



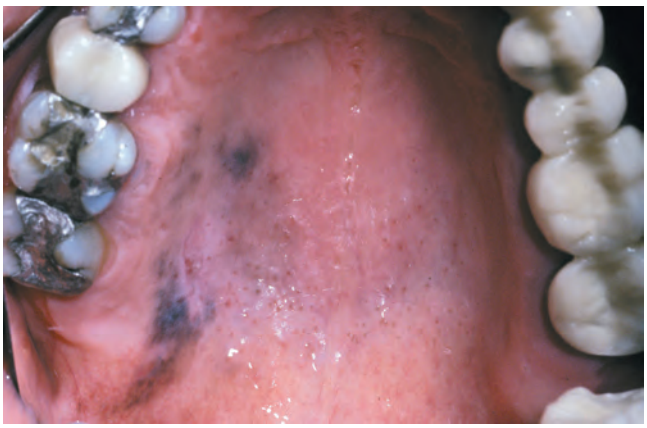
Acral melanoma develops on glabrous (or non-hair-bearing) skin, such as the palms of the hands, soles of the feet, volar aspects of the fingers and toes, and subungual area. It represents the most frequent subtype of melanoma in individuals of African or Asian descent. The lesion typically begins as a dark, irregularly marginated macule or patch (*acral lentiginous melanoma*); a nodular invasive growth phase may develop after several months to years.

Mucosal Melanoma

Mucosal melanoma tends to arise in the mucosa of the sinonasal passages, oral cavity, urogenital tract, anorectal region, and conjunctiva, although various other primary sites are possible. Early lesions in the radial growth phase (*mucosal lentiginous melanomas*) typically appear flat. However, many examples are not recognized until they become nodular. Importantly, mucosal melanoma is much more aggressive than its cutaneous counterpart.



• **Fig. 10.142 Superficial Spreading Melanoma.** This lesion on the neck demonstrates the ABCDE warning signs of melanoma: **A**symmetry, **B**order irregularity, **C**olor variegation, **D**iameter larger than a pencil eraser, and **E**volving larger size. (Courtesy of Dr. Mark Bowden.)



• **Fig. 10.143 Lentigo Maligna Melanoma.** A slowly evolving pigmented lesion of the facial skin in an older adult man.

dentlearn.ir

Oral mucosal melanoma most often develops during the fifth through seventh decades of life. Most studies have reported either a slight male predilection or no significant gender predilection. Approximately 70%–80% of oral melanomas are found on the hard palate or maxillary alveolus. At least one in three patients with oral melanoma has a history of a pigmented macule in the tumor region for some time before melanoma diagnosis. The lesion typically begins as a brown to black macule with irregular borders (Figs. 10.144 and 10.145). However, some lesions contain little pigment and exhibit either a normal mucosal tint or a vascular appearance. The macule extends laterally, and a lobulated, exophytic mass develops once vertical growth is initiated (Fig. 10.146). Ulceration may develop early, but many lesions are not ulcerated at the time of diagnosis. Pain is uncommon except in ulcerated lesions, and most lesions remain relatively soft to palpation. Adjacent bone may show radiographic evidence of irregular or "moth-eaten" destruction. At the time of diagnosis, cervical lymph node metastasis is evident in about a third of cases, and distant metastasis is noted in about a quarter of cases.

• **Fig. 10.144 Oral Melanoma.** This discrete area of pigmentation, measuring approximately 5 mm in diameter, was discovered on the posterior hard palate of a middle-aged woman during a routine oral examination. Biopsy revealed melanoma *in situ*.

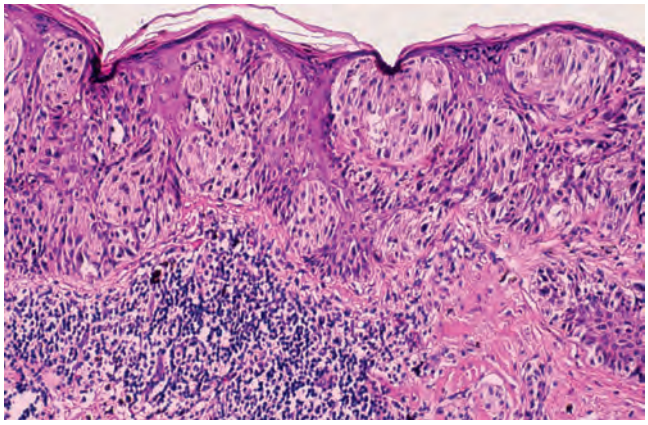
• **Fig. 10.145 Oral Melanoma.** Diffuse, splotchy area of pigmentation of the lateral hard palate. (Courtesy of Dr. Len Morrow.)

In addition, melanoma occasionally affects the parotid gland, usually as a metastatic deposit from a scalp, conjunctival, or paranasal tumor.

Histopathologic Features

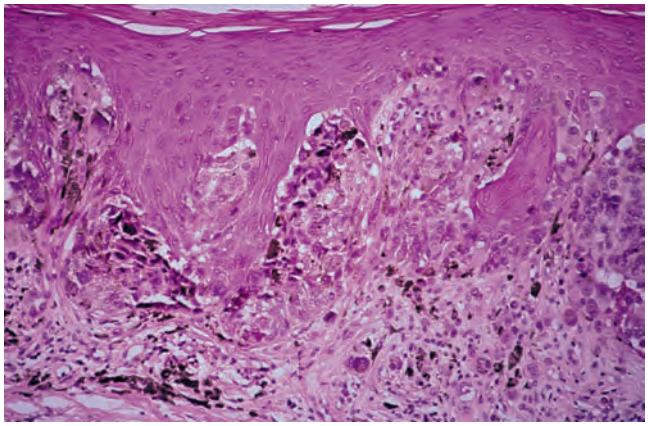
With cutaneous and oral melanomas, atypical melanocytes initially are seen at the epithelial and connective tissue junction. From here, they have the potential to proliferate throughout the epithelium, laterally along the basal cell layer, and downward into the connective tissue. In early stages, atypical melanocytes are seen either scattered singly among the basal epithelial cells or as nests within the basal cell layer. The atypical melanocytes are enlarged, with varying degrees of nuclear pleomorphism and hyperchromatism.

In superficial spreading melanoma, there is often *pagetoid spread* (i.e., single tumor cells infiltrating into the upper layers of the surface epithelium) (Fig. 10.147). This microscopic pattern resembles an intraepithelial adenocarcinoma known as *Paget's disease of skin*.



The spread of the lesional cells along the basal layer of the surface epithelium constitutes the radial growth phase. Appreciable lateral spread prior to invasion of the underlying connective tissue is characteristic of superficial spreading melanoma, lentigo maligna melanoma, acral lentiginous melanoma, and mucosal lentiginous melanoma. In acral and mucosal lentiginous melanomas, many of the melanocytes have prominent dendritic processes (Fig. 10.148).

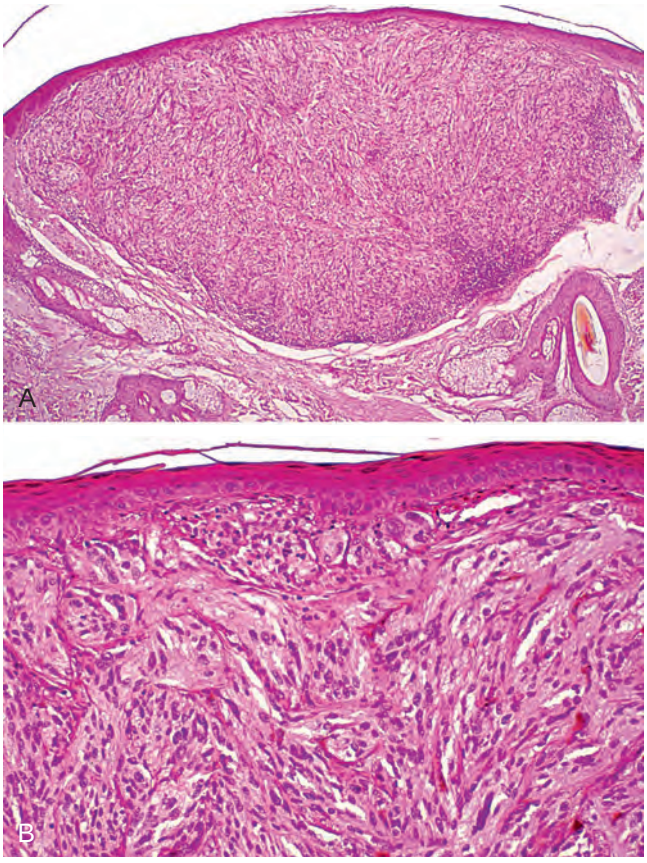
The vertical growth phase is characterized by malignant melanocytes invading the connective tissue. In nodular melanoma, this vertical growth phase occurs early in the disease course. No radial growth can be observed in the overlying epithelium beyond the edge of the invasive tumor (Fig. 10.149). The tumor usually appears as pleomorphic, spindle-shaped or epithelioid cells arranged in loosely aggregated cords or sheets. Oral lesions show invasion of lymphatic and blood vessels more often than skin lesions. Several mucosal melanomas have been reported to contain unequivocal bone and cartilage, a feature that may cause



• **Fig. 10.146 Oral Melanoma.** Extensive, pigmented mass of the palate and maxillary alveolar ridge. An exophytic component is evident.

dentlearn.ir

• **Fig. 10.147 Superficial Spreading Melanoma.** The radial growth phase is characterized by the spread of atypical melanocytes along the basilar portion of the epidermis. Also note the presence of individual melanocytes invading the higher levels of the epithelium.



• **Fig. 10.148 Mucosal Lentiginous Melanoma.** This palatal melanoma demonstrates numerous atypical melanocytes in the basilar portion of the epithelium with invasion into the superficial lamina propria. This represents the biopsy specimen from Fig. 10.145.

diagnostic confusion with pleomorphic adenoma, sarcomatoid carcinoma, osteosarcoma, and mesenchymal chondrosarcoma.

Approximately 10% of oral melanomas are amelanotic. A lack of melanin production may cause diagnostic confusion with various other undifferentiated tumors at the light microscopic level. Immunohistochemical studies showing reactivity for S-100 protein, HMB-45, SOX10, and MART-1 (Melan-A) may aid in diagnosis.

Treatment and Prognosis

Depth of invasion is an important prognostic factor for cutaneous melanoma. The Clark system assigns a "level" corresponding to the deepest region that has been invaded by tumor cells (Table 10.9). The more recent Breslow classification, however, correlates more accurately with prognosis and is based on measurement of the distance from the top of the granular cell layer to the deepest identifiable point of tumor invasion.

• **Fig. 10.149 Nodular Melanoma. A,** Low-power photomicrograph showing a nodular mass of malignant melanocytes invading into the dermis. Note the lack of radial growth in the adjacent overlying epidermis. **B,** Higher-power photomicrograph showing atypical spindle-shaped melanocytes.

TABLE 10.9 Clark Classification for Cutaneous Melanoma

Clark Definition of Level of Tumor Invasion	Clark Classification
Cells confined to epithelium	Level I
Cells penetrating papillary dermis	Level II
Cells filling papillary dermis	Level III
Cells extending into reticular dermis	Level IV
Cells invading subcutaneous fat	Level V

Clinical staging for cutaneous melanoma is performed using a TNM classification system that takes into account Breslow tumor thickness, ulceration, regional lymph node metastasis, regional non-nodal lymphatic metastasis, and distant metastasis (Table 10.10). In addition, the serum level of lactate dehydrogenase (LDH) is considered in subclassifying cases with distant metastasis.

Wide surgical excision is the mainstay of treatment for patients with resectable disease. Current evidence indicates that a 1-cm margin is adequate for cutaneous tumors with

Regional Lymph Node Involvement and/or Lymphatic Metastasis (N)		
N Category	**No. of Metastatic Regional Lymph Nodes**	**Presence of In-transit, Satellite, and/or Microsatellite Metastasis**
N3a	4 or more clinically occult nodes (i.e., detected by sentinel lymph node biopsy)	No
N3b	4 or more nodes, at least 1 of which was clinically detected; *or* any number of matted nodes	No
N3c	2 or more clinically occult or clinically detected nodes; *and/or* any number of matted nodes	Yes

Distant Metastasis (M)		
M Category	**Anatomic Site**	**Serum Lactate Dehydrogenase Level**
M0	No evidence of distant metastases	NA
M1	Evidence of distant metastasis	
M1a	Distant metastasis to skin, soft tissue including muscle, and/or nonregional lymph node	Not recorded or unspecified
M1a(0)		Not elevated
M1a(1)		Elevated
M1b	Distant metastasis to lung with or without M1a sites of disease	Not recorded or unspecified
M1b(0)		Not elevated
M1b(1)		Elevated
M1c	Distant metastasis to non-CNS visceral sites with or without M1a or M1b sites of disease	Not recorded or unspecified
M1c(0)		Not elevated
M1c(1)		Elevated
M1d	Distant metastasis to CNS with or without M1a, M1b, or M1c sites of disease	Not recorded or unspecified
M1d(0)		Not elevated
M1d(1)		Elevated

CNS, central nervous system.
NA, not applicable.
In-transit metastasis is defined as clinically evident dermal and/or subcutaneous metastases occurring beyond 2 cm from the primary melanoma in the region between the primary and the regional lymph node basin.
Satellite metastasis is defined as grossly visible cutaneous and/or subcutaneous metastases occurring within 2 cm of and discontinuous from the primary melanoma.
Microsatellite metastasis is defined as microscopic cutaneous and/or subcutaneous metastasis adjacent or deep to a primary melanoma; the metastatic tumor cells must be discontinuous from the primary tumor and not separated only by fibrosis or inflammation, which could represent regression of the intervening tumor.
(From Gershenwald JE, Scolyer RA, Hess KR, et al: Melanoma of the skin. In Amin MB, Edge SB, Greene FL, et al, editors, *AJCC cancer staging manual,* ed 8, New York, 2018, American College of Surgeons, pp. 565–585.)

dentlearn.ir

a thickness of 1 mm or less. For skin tumors with a thickness greater than 1 mm but not more than 2 mm, margins between 1 and 2 cm are recommended. Cutaneous tumors thicker than 2 mm typically require excision with 2-cm margins.

Lymph node dissection usually is performed on patients with clinically evident regional metastasis in the absence of distant metastasis. Because regional lymph node metastases are frequently occult, sentinel lymph node biopsy (biopsy of the first lymph node in the lymphatic basin to receive drainage from the tumor) often is performed to detect metastases that are not evident with clinical examination or imaging. If the sentinel lymph node biopsy is positive, completion lymphadenectomy may be performed. Additional treatment after surgery may include immunotherapy, targeted therapy, chemotherapy, or radiation therapy.

Recent discoveries regarding the role of the immune system in cancer and the molecular basis of melanoma and have led to novel approaches to therapy, particularly for patients with advanced disease. Newly developed immunotherapeutic agents include immune system checkpoint inhibitors against cytotoxic T-lymphocyte antigen-4 (CTLA-4), programmed death-1 (PD-1), or programmed death protein ligand-1 (PDL-1) (such as imiplimab, pembrolizumab, nivolumab, and atezolizumab). These agents represent significant improvements to the arsenal of immunotherapy, which also includes older agents such as interleukin-2 and interferon-alpha. For *BRAF*-mutant metastatic melanoma, recently approved targeted treatments include BRAF inhibitors (such as vemurafenib and dabrafenib), which may be used alone or in combination with MEK inhibitors. For patients with mucosal or acral melanomas exhibiting certain types of *KIT* mutations, targeted therapy with small molecule KIT inhibitors (such as imatinib, sunitinib, sorafenib, or nilotinib) may be of benefit. These recent developments in immunotherapy and genotype-directed therapy have led to significantly prolonged survival for patients with advanced cutaneous melanoma.

Primarily as a result of public education efforts, the clinical features of cutaneous melanoma are so widely known that the majority of lesions are discovered and treated at an early stage. Based on SEER data from 2011 through 2017, the 5-year relative survival rate for patients with localized cutaneous melanoma is approximately 99%, whereas patients with regional or distant metastasis exhibit survival rates of approximately 68% and 30%, respectively (see Table 10.11). However, in more recent years with major advances in treatment, many centers have reported 5-year survival rates greater than 50% for patients with distant metastasis.

Besides tumor stage, various other prognostic factors have been noted for cutaneous melanoma. Adverse microscopic findings include increased mitotic activity and minimal to absent tumor-infiltrating lymphocytes. For reasons that are unclear, cutaneous melanomas on the trunk, head, and neck carry a worse prognosis than those on the extremities. In particular, among head and neck lesions, those arising on the scalp and neck are associated with decreased survival rates. In contrast, favorable prognostic factors include age younger than 20 years and female gender. Follow-up after treatment is important not only to monitor for metastatic disease but also because, in 3%–5% of these patients, a second primary melanoma eventually will develop.

TABLE 10.11 Overall 5-Year Relative Survival Rates for Cutaneous Melanoma by SEER Stage*

SEER Stage at Diagnosis	Estimated 5-Year Relative Survival Rate
Localized	99%
Regional	68%
Distant	30%†
All Stages	93%

*Based upon Surveillance Epidemiology and End Results (SEER) 18 area data for patients diagnosed in 2011–2017. Source: Surveillance Research Program, National Cancer Institute. SEER*Explorer: an interactive website for SEER cancer statistics, http://seer.cancer.gov/explorer. Accessed November 23, 2021.
†In more recent years with the introduction of novel immunotherapeutic and targeted agents, many centers have reported 5-year survival rates of 50% or higher for patients with distant metastasis.

For mucosal melanomas of the head and neck, TNM classification takes into account the anatomic extent of the primary tumor (i.e., confined to mucosa or invading adjacent structures), regional lymph node metastasis, and distant metastasis (Table 10.12). Because head and neck mucosal lesions typically exhibit aggressive behavior, they are classified at a minimum as stage III. For patients with resectable disease, radical surgery is indicated and often is followed by adjunctive radiation with or without systemic agents (i.e., immunotherapy, targeted therapy, chemotherapy). Patients with very advanced disease should strongly consider clinical trial participation. Some clinical trials have shown promising results with recently developed immunotherapeutic or targeted agents; however, responses to such agents usually are more limited among mucosal than cutaneous melanomas, and further studies are needed.

The prognosis for oral mucosal melanoma is extremely poor. Most authors report 5-year survival rates in the range of only about 10%–25%, and median overall survival rarely exceeds 2 years after initial diagnosis. Death usually results from distant metastasis rather than lack of local control. The poor prognosis for oral mucosal melanoma appears to be related to difficulty in achieving wide resection and a tendency for early metastasis. Younger patients exhibit better survival than older ones, and patients with amelanotic lesions appear to have a particularly poor prognosis. Nodular lesions generally have a worse prognosis than macular lesions, and

TABLE 10.12 Tumor-Node-Metastasis (TNM) Staging Classification System and Prognostic Groups for Mucosal Melanoma of the Head and Neck

Primary Tumor (T)	
T3	Tumors limited to the mucosa and immediately underlying soft tissue, regardless of thickness or greatest dimension (e.g., polypoid nasal disease; pigmented or nonpigmented lesions of the oral cavity, pharynx, or larynx)
T4	Moderately advanced or very advanced disease
T4a	Moderately advanced disease Tumor involving deep soft tissue, cartilage, bone, or overlying skin
T4b	Very advanced disease Tumor involving brain, dura, skull base, lower cranial nerves (IX, X, XI, and XII), masticator space, carotid artery, prevertebral space, or mediastinal structures
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Regional lymph node metastases present
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis present
Prognostic Groups*	
Stage III	T3 N0 M0
Stage IVA	T4a N0 M0 T3-4a N1 M0
Stage IVB	T4b any N M0
Stage IVC	Any T Any N M1

*Prognostic groups shown here are from the 7th edition of the *AJCC Cancer Staging Manual*. No prognostic groups were proposed in the 8th edition.
(From: Mucosal melanoma of the head and neck. In Edge SB, Byrd DR, Compton CC, et al, editors: *AJCC cancer staging manual*, ed 7, New York, 2010, Springer, pp. 97–100. Mucosal melanoma of the head and neck. In Amin MB, Edge SB, Greene FL, et al, editors: *AJCC Cancer Staging Manual*, ed. 8, Chicago, 2018, American College Of Surgeons, pp. 163–170.)

ulceration appears to be an adverse prognostic factor. However, depth of invasion and presence of ulceration are not so closely correlated with prognosis of mucosal melanomas compared to cutaneous melanomas.
